Hashimoto thyroiditis

Hashimoto thyroiditis (or 'chronic autoimmune thyroiditis') is characterised by destructive lymphocytic infiltration of the thyroid, ultimately leading to a varying degree of fibrosis and thyroid enlargement. It has atrophic and goitrous variants.

Hashimoto thyroiditis increases in incidence with age and affects approximately 3.5 per 1000 women and 0.8 per 1000 men each year. Many present with a small or moderately sized diffuse goitre, which is characteristically firm or rubbery in consistency. Around 25% of patients are hypothyroid at presentation. In the remainder, serum T4 is normal and TSH normal or raised, but these patients are at risk of developing overt hypothyroidism in future years. Antibodies against thyroid peroxidase (TPO) are present in the serum in more than 90% of patients with Hashimoto thyroiditis. Thyroid lymphoma is more common in patients with Hashimoto thyroiditis, although is exceedingly rare with an incidence of 2 cases per million per year.

Levothyroxine therapy is indicated as treatment for hypothyroidism and to shrink an associated goitre. In this context, the dose of levothyroxine should be sufficient to suppress serum TSH to low but detectable levels.

Transient thyroiditis

Subacute (de Quervain) thyroiditis

In its classical painful form, subacute thyroiditis is a transient inflammation of the thyroid gland occurring after viral infection. There is pain in the region of the thyroid that may radiate to the angle of the jaw and the ears, and is made worse by swallowing, coughing and movement of the neck. The thyroid is usually palpably enlarged and tender. Systemic upset is common. Affected patients are usually females aged 20–40 years. Painless transient thyroiditis can also occur after viral infection and in patients with underlying autoimmune disease. The condition can also be precipitated by drugs, including interferon-α and lithium.

Irrespective of the clinical presentation, inflammation in the thyroid gland is associated with release of colloid and stored thyroid hormones, damage to follicular cells and impaired synthesis of new thyroid hormones. As a result, T4 and T3 levels are raised for 4–6 weeks whilst the pre-formed colloid is depleted. Thereafter, there is usually a period of hypothyroidism of variable severity before the follicular cells recover and normal thyroid function is restored within 4–6 months (Fig. 20.9). In the thyrotoxic phase, the iodine uptake is low because the damaged follicular cells are unable to trap iodine and because TSH secretion is suppressed. Low-titre thyroid autoantibodies appear transiently in the serum, and the erythrocyte sedimentation rate (ESR) is usually raised. High-titre autoantibodies suggest an underlying autoimmune pathology and greater risk of recurrence and ultimate progression to hypothyroidism.

Pain and systemic symptoms usually respond to simple measures such as non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally, however, it may be necessary to prescribe prednisolone 40 mg daily for 2–4 weeks (a lower dose of 15 mg may also be effective). The thyrotoxicosis is mild and treatment with a β-blocker is usually adequate. Antithyroid drugs are of no benefit because thyroid hormone synthesis is impaired rather than enhanced. Careful monitoring of thyroid function and symptoms is required so that levothyroxine can be prescribed temporarily if needed during the hypothyroid phase. Care must be taken to identify patients presenting with hypothyroidism who are in this late stage of transient thyroiditis, since they are unlikely to require life-long levothyroxine therapy (see Fig. 20.6). In this context a normal TSH 6 weeks following reduction of the dose of levothyroxine to 50 µg/day indicates it should be possible to withdraw treatment.

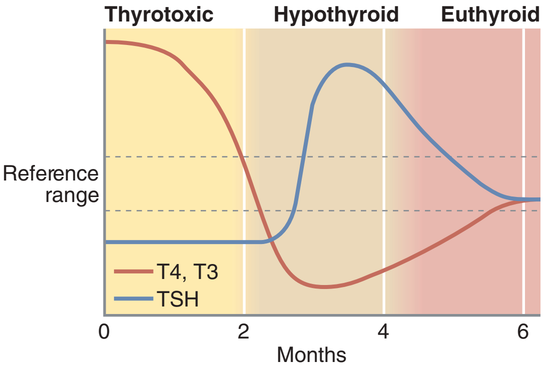

Fig. 20.9 Thyroid function tests in an episode of transient thyroiditis. This pattern might be observed in classical subacute (de Quervain) thyroiditis, painless thyroiditis or post-partum thyroiditis. The duration of each phase varies between patients. (T3 = triiodothyronine; T4 = thyroxine; TSH = thyroid-stimulating hormone)

Post-partum thyroiditis

The maternal immune response, which is attenuated during pregnancy to allow survival of the fetus, is enhanced after delivery, and may unmask previously unrecognised subclinical autoimmune thyroid disease. Surveys have shown that transient biochemical disturbances of thyroid function occur in 5%–10% of women within 6 months of delivery (see Box 20.13). Those affected are likely to have antithyroid peroxidase antibodies in the serum in early pregnancy. Symptoms of thyroid dysfunction are rare and there is no association between postnatal depression and abnormal thyroid function tests. However, symptomatic thyrotoxicosis presenting for the first time within 12 months of childbirth is likely to be due to post-partum thyroiditis and the diagnosis is confirmed by negligible ^{99m}Tc uptake (breast milk should be discarded temporarily following the scan). The clinical course and treatment are similar to those of painless subacute thyroiditis (see above). Post-partum thyroiditis tends to recur after subsequent pregnancies (see also Box 20.13).

Iodine-associated thyroid disease

Iodine deficiency

Iodine is an essential micronutrient and is a key component of thyroid hormones. The World Health Organization (WHO) recommends a daily intake of iodine of 150 µg/day for adult men and women; higher levels are recommended for pregnant women (see p. 1308) as iodine deficiency is associated with impaired fetal brain development, and severe deficiency can cause cretinism. Dietary sources of iodine include seafood, dairy products, eggs and grains. Dietary iodine deficiency is a global public health issue, with an estimated one-third of the world population living in areas of iodine insufficiency. Iodine deficiency is particularly common in Central Africa, South-east Asia and the Western Pacific. It is associated with the development of thyroid nodules and goitre (endemic goitre): the reduced substrate available for thyroid hormone production increases thyroid gland activity to maximise iodine uptake and recycling, and this acts as a potent stimulus for enlargement of the thyroid and nodule formation. Most affected patients are euthyroid with normal or raised TSH levels, although hypothyroidism can occur with severe iodine deficiency. Suspected iodine deficiency can be assessed by measuring iodine in urine (either a 24-hour collection or a spot sample). Endemic goitre can be treated by iodine supplementation, and a reduction in nodule and goitre size can be seen, particularly if it is commenced in childhood. Iodine deficiency is not associated with an increased risk of Graves disease or thyroid cancer, but the high prevalence of nodular autonomy does result in an increased risk of thyrotoxicosis and this risk may be further increased by iodine supplementation. Conversely, iodine supplementation may also increase the prevalence of subclinical hypothyroidism and autoimmune hypothyroidism. These complex effects of iodine supplementation are further discussed below.

Iodine-induced thyroid dysfunction

Iodine has complex effects on thyroid function. Very high concentrations of iodine inhibit thyroid hormone synthesis and release (known as the Wolff–Chaikoff effect) and this forms the rationale for iodine treatment in thyroid crisis and prior to thyroid surgery for thyrotoxicosis. This is an autoregulatory response thought to protect the body from the sudden release of large amounts of thyroid hormone in response to the ingestion of a substantial load of iodine. This effect only lasts for about 10 days, after which it is followed by an 'escape phenomenon': essentially, the return to normal organification of iodine and thyroid peroxidase action (see Fig. 20.3). Therefore, if iodine is given to prepare an individual with Graves disease for surgery, the operation must happen within 10–14 days; otherwise, a significant relapse of the thyrotoxicosis could occur.

Both iodine deficiency and underlying thyroid disease moderate the effects of iodine on thyroid function. In iodine-deficient parts of the world, transient thyrotoxicosis may be precipitated by prophylactic iodinisation programmes. In iodine-sufficient areas, thyrotoxicosis can be precipitated by iodine-containing radiographic contrast medium or expectorants in individuals who have underlying multinodular goitre or Graves disease in remission. Induction of thyrotoxicosis by iodine is called the Jod–Basedow effect. Chronic excess iodine administration can also result in hypothyroidism; this is, in effect, a failure to escape from the Wolff–Chaikoff effect and usually occurs in the context of prior insult to the thyroid by autoimmune disease, thyroiditis, exposure to lithium or antithyroid drugs, or surgery.

Amiodarone

The anti-arrhythmic agent amiodarone has a structure that is analogous to that of T4 (Fig. 20.10) and contains copious iodine; a 200 mg dose contains 75 mg iodine. Amiodarone has a cytotoxic effect on thyroid follicular cells and inhibits the conversion of T4 to T3 (increasing the ratio of T4:T3). Most patients receiving amiodarone have normal thyroid function, but up to 20% develop hypothyroidism or thyrotoxicosis and so thyroid function should be monitored regularly. TSH provides the best indicator of thyroid function.

The thyrotoxicosis can be classified as either:

- *type I*: iodine-induced excess thyroid hormone synthesis in patients with an underlying thyroid disorder, such as nodular goitre or latent Graves disease (an example of the Jod–Basedow effect), or
- *type II*: thyroiditis due to a direct cytotoxic effect of amiodarone administration.

These patterns can overlap and may be difficult to distinguish clinically. There is no widely accepted management algorithm, although the iodine excess renders the gland resistant to ^{131}I. Antithyroid drugs may be effective in patients with the type I form but are ineffective in type II thyrotoxicosis. Prednisolone is beneficial in the type II form. A pragmatic approach is to commence combination therapy with carbimazole and prednisolone in patients with significant thyrotoxicosis. A rapid response (within 1–2 weeks) usually indicates a type II picture and permits withdrawal of carbimazole; a slower response suggests a type I picture, in which case carbimazole may be continued and prednisolone withdrawn. If the cardiac state allows, amiodarone should be discontinued, but it has a long half-life (50–60 days) and so its effects are long-lasting. To minimise the risk of type I thyrotoxicosis, thyroid function should be measured in all patients prior to commencement of amiodarone therapy and amiodarone should be avoided if TSH is suppressed.

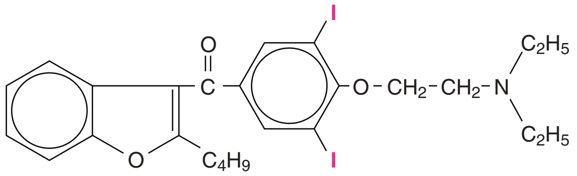

Fig. 20.10 The structure of amiodarone. Note the similarities to thyroxine (T4) (see Fig. 20.3).

Hypothyroidism should be treated with levothyroxine, which can be given with amiodarone and may need to be continued in the long term.

Simple and multinodular goitre

These terms describe diffuse or multinodular enlargement of the thyroid, which occurs sporadically and is of unknown aetiology.

Simple diffuse goitre

This form of goitre usually presents between the ages of 15 and 25 years, often during pregnancy, and tends to be noticed by friends and relatives rather than the patient. Occasionally, there is a tight sensation in the neck, particularly when swallowing. The goitre is soft and symmetrical, and the thyroid enlarged to two or three times normal. There is no tenderness, lymphadenopathy or overlying bruit. Concentrations of free T3, free T4 and TSH are normal and no thyroid autoantibodies are detected in the serum. No treatment is necessary and the goitre usually regresses. In some, however, the unknown stimulus to thyroid enlargement persists and, because of recurrent episodes of hyperplasia and involution during the following 10–20 years, the gland becomes multinodular with areas of autonomous function.

Multinodular goitre

The natural history is shown in Figure 20.11. Patients with thyroid enlargement in the absence of thyroid dysfunction or positive autoantibodies (i.e. with 'simple goitre'; see above) as young adults may progress to develop nodules. These nodules grow at varying rates and secrete thyroid hormone 'autonomously', thereby suppressing TSH-dependent growth and function in the rest of the gland. Ultimately, complete suppression of TSH occurs in about 25% of cases, with T4 and T3 levels often within the reference range (subclinical thyrotoxicosis), but sometimes elevated (toxic multinodular goitre; see Fig. 20.5).

Clinical features and investigations

Multinodular goitre is usually diagnosed in patients presenting with a large goitre with or without tracheal compression, a sudden painful swelling caused by haemorrhage into a nodule or cyst or with thyrotoxicosis. The goitre is nodular or lobulated on palpation and may extend retrosternally; however, not all multinodular goitres are easily palpable. Very large goitres can cause mediastinal compression with stridor (Fig. 20.12), dysphagia and obstruction of the superior vena cava. Hoarseness due to recurrent laryngeal nerve palsy can occur but is far more suggestive of thyroid carcinoma.

			Age (in years)	15–25	26–55	> 55
Goitre	Diffuse	Nodular	Nodular
Tracheal compression/ deviation	No	Minimal	Yes
T3, T4	Normal	Normal	Raised
TSH	Normal	Normal or undetectable	Undetectable

Fig. 20.11 Natural history of simple goitre. (T3 = triiodothyronine; T4 = thyroxine; TSH = thyroid-stimulating hormone)

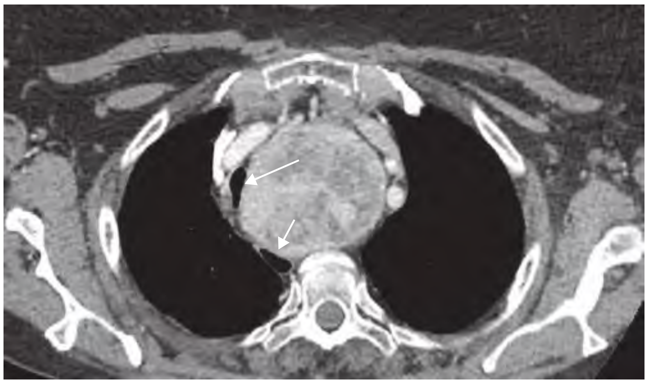

Fig. 20.12 Retrosternal goitre. CT showing retrosternal goitre compressing and displacing the trachea (long arrow) to the right with significant luminal narrowing resulting in breathlessness and stridor. The oesophagus (short arrow) is also displaced to the right.

The diagnosis can be confirmed by ultrasonography and/or thyroid scintigraphy (see Fig. 20.5). In symptomatic patients with large goitres, a flow-volume loop and barium swallow can identify significant tracheal or oesophageal compression, respectively (see Fig. 17.7). If intervention is contemplated, computed tomography (CT) or magnetic resonance imaging (MRI) of the thoracic inlet should be performed to quantify the degree of tracheal displacement or compression and the extent of retrosternal extension. Nodules should be evaluated for the possibility of thyroid neoplasia.

Management

If the goitre is small, no treatment is necessary but annual thyroid function testing should be arranged, as the natural history is progression to a toxic multinodular goitre. Thyroid surgery is indicated for large goitres that cause mediastinal compression or that are cosmetically unattractive. ^{131}I can result in some reduction in thyroid size and may be of value in older patients. Levothyroxine therapy is of no benefit in shrinking multinodular goitres in iodine-sufficient countries and may simply aggravate any associated thyrotoxicosis.

In toxic multinodular goitre, treatment is usually with ^{131}I. The iodine uptake is lower than in Graves disease, so a higher dose may be administered (up to 800 Mbq (approximately 20 mCi)); resultant hypothyroidism is less common. In thyrotoxic patients with a large goitre, thyroid surgery may be indicated. Long-term treatment with antithyroid drugs is not usually employed, as relapse is invariable after drug withdrawal; drug therapy is normally reserved for frail older patients in whom surgery or ^{131}I is not an appropriate option.

Asymptomatic patients with subclinical thyrotoxicosis may be offered ^{131}I or surgery on the grounds that a suppressed TSH is a risk factor for atrial fibrillation and, particularly in post-menopausal women, osteoporosis.

Thyroid neoplasia

Patients with thyroid neoplasms usually present with a solitary nodule. Most are benign and a few of these, called 'toxic adenomas', secrete excess thyroid hormones. Primary thyroid malignancy is rare, accounting for less than 1% of all carcinomas, and has a global age standardised incidence of 10.1 per 100,000 women and 3.1 per 100,000 men per year. As shown in Box 20.17, it can be classified according to the cell type of origin. With the exception of medullary carcinoma, thyroid cancer is more common in females. Thyroid neoplasms often have identifiable somatic mutations in genes such as *BRAF* (papillary, anaplastic), *TERT* (follicular), *RAS* (follicular), *RET* (papillary and medullary), *p53* (anaplastic). Identification of molecular abnormalities may aid in diagnosis and prognostication, and may identify targets for therapy in advanced disease.

20.17 Malignant thyroid tumours

Type of tumour	Frequency (%)	Age at presentation (years)	5-year survival (%)
Follicular cells			
Differentiated carcinoma:			
Papillary	75–85	20–40	>99
Follicular	10–20	40–60	98
Anaplastic	< 5	> 60	10
Parafollicular C cells			
Medullary carcinoma	5–8	> 40*	93
Lymphocytes			
Lymphoma	< 5	> 60	71

*Patients with medullary carcinoma as part of multiple endocrine neoplasia (MEN) types 2a and 2b (p. 742) may present in childhood.

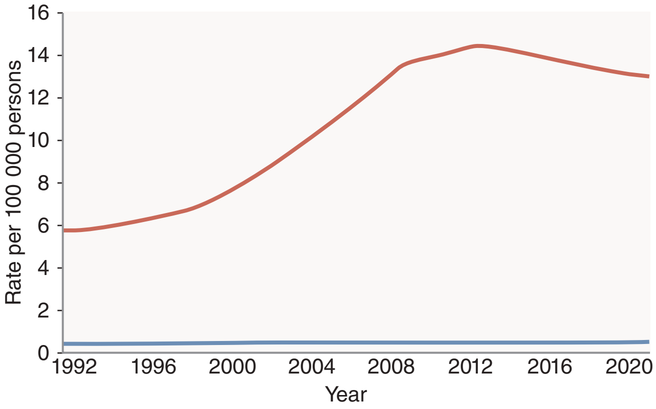

Fig. 20.13 Incidence and death rates of thyroid cancer in the USA. Although the incidence (red line) has increased from 1990 because of higher rates of discovery due to the use of more imaging, the overall death rate (blue line) remains very low with an overall 5-year survival of > 98%. *From National Cancer Institute: https://seer.cancer.gov/statfacts/html/thyro.html.*

Toxic adenoma

A solitary toxic nodule is the cause of less than 5% of all cases of thyrotoxicosis. The nodule is a follicular adenoma, which autonomously secretes excess thyroid hormones and inhibits endogenous TSH secretion, with subsequent atrophy of the rest of the thyroid gland. The adenoma is usually greater than 3 cm in diameter.

Most patients are female and over 40 years of age. Although many nodules are palpable, the diagnosis can be made with certainty only by thyroid scintigraphy (see Fig. 20.5). The thyrotoxicosis is usually mild and in almost 50% of patients the plasma T3 alone is elevated (T3 thyrotoxicosis). ^{131}I (400–800 MBq (10–20 mCi)) is highly effective and is an ideal treatment since the atrophic cells surrounding the nodule do not take up iodine and so receive little or no radiation. For this reason, permanent hypothyroidism is unusual. Hemithyroidectomy is an alternative management option.

Differentiated carcinoma

The incidence of thyroid carcinoma has increased significantly since the early 1990s, although this has not been paralleled by any significant increase in thyroid carcinoma deaths over the same period (Fig. 20.13). Increasing incidence of thyroid carcinoma is, at least in part, explained by an increased rate of incidental detection, because of greater use of neck imaging.

Papillary carcinoma

This is the most common of the malignant thyroid tumours and accounts for 90% of radiation-induced thyroid cancer. It may be multifocal and spread is initially to regional lymph nodes. Some patients present with cervical lymphadenopathy and no apparent thyroid enlargement; in such instances, the primary lesion may be less than 10 mm in diameter.

Follicular carcinoma

This is usually a single encapsulated lesion. Spread to cervical lymph nodes is rare. Metastases are blood-borne and are most often found in bone, lungs and brain.

Management

The management of thyroid cancers should be individualised and planned in multidisciplinary team meetings that may include thyroid surgeons, endocrinologists, oncologists, pathologists, radiologists and nurse specialists. Large tumours, those with adverse histological features and/or tumours with metastatic disease at presentation are usually managed by total thyroidectomy (either as a single operation or a lobectomy followed by completion thyroidectomy) followed by a large dose of ^{131}I (1100 or 3700 MBq (approximately 30 or 100 mCi)) to ablate any remaining normal or malignant thyroid tissue. Depending on risk of recurrence, levothyroxine doses sufficient to suppress TSH may be required. Smaller tumours with no adverse histological features may require only thyroid lobectomy.

Follow-up involves measurement of serum thyroglobulin, which should be undetectable in patients whose normal thyroid has been ablated by ^{131}I and who are taking a suppressive dose of levothyroxine. Thyroglobulin antibodies may interfere with the assay and, depending on the method employed, may falsely increase or decrease the result. Detectable thyroglobulin, in the absence of assay interference, is suggestive of tumour recurrence or metastasis, particularly if the thyroglobulin titre is rising across serial measurements. Locally recurrent or metastatic disease may be identified by ultrasound, CT, MRI and/or whole-body scanning with ^{131}I, and may be treated with further surgery and/or ^{131}I therapy. ^{131}I treatment in thyroid cancer and isotope scanning both require serum TSH concentrations to be elevated (> 20 mIU/L). This may be achieved by administering intramuscular recombinant human TSH or by levothyroxine withdrawal for 3–4 weeks, inducing symptomatic hypothyroidism. The former approach is more acceptable to patients, but it is more expensive. Those with locally advanced or metastatic papillary and follicular carcinoma that is refractive to ^{131}I may be considered for therapy with sorafenib, lenvatinib or vandetanib. These drugs are multi-targeted tyrosine kinase inhibitors and have been shown in trials to prolong progression-free survival by between 5 and 14 months. They have multiple toxicities, however, including poor appetite, weight loss, fatigue, diarrhoea, mucositis, rashes, hypertension and blood dyscrasias. The potential benefits of therapy should therefore be weighed carefully against side-effects that could significantly impair quality of life. Selpercatinib, a RET inhibitor, may also be used in advanced disease where a *RET* mutation has been identified on molecular analysis.

Prognosis

Most patients with papillary and follicular thyroid cancer are cured with appropriate treatment. Adverse prognostic factors include older age at presentation, the presence of distant metastases, male sex and certain histological subtypes. ^{131}I therapy can be effective in treating those with distant metastases, particularly small-volume disease in the lungs, and prolonged survival is quite common.

Anaplastic carcinoma and lymphoma

These two conditions are difficult to distinguish clinically but are cytologically and histologically distinct. Patients are usually over 60 years of age and present with rapid thyroid enlargement over 2–3 months. The goitre is hard and there may be stridor due to tracheal compression and hoarseness due to recurrent laryngeal nerve palsy. For many patients there is no effective treatment for anaplastic carcinoma, although surgery and radiotherapy may be considered in some circumstances. In older patients, median survival is only 7 months. There are reports of survival benefit using dabrafenib (a BRAF inhibitor) and trametinib (a kinase inhibitor) in tumours where a *BRAF* mutation has been identified.

The prognosis for lymphoma, which may arise from pre-existing Hashimoto thyroiditis, is better, with a median survival of 9 years. Some 98% of tumours are non-Hodgkin lymphomas, usually the diffuse large B-cell subtype. Treatment is with combination chemotherapy and external beam radiotherapy.

Medullary carcinoma

This tumour arises from the parafollicular C cells of the thyroid. In addition to calcitonin, the tumour may secrete 5-hydroxytryptamine (5-HT, serotonin) and adrenocorticotrophic hormone (ACTH). Consequently, carcinoid syndrome (see Box 20.49) and Cushing syndrome (see p. 722) may occur. Medullary carcinoma of the thyroid occurs sporadically in 70%–90% cases; in 10%–30% there is a genetic predisposition that is inherited in an autosomal dominant fashion and due to an activating mutation in the *RET* gene. This inherited tendency normally forms part of one of the MEN syndromes (MEN 2a or 2b, p. 742) but, occasionally, susceptibility to medullary carcinoma is the only inherited trait (familial medullary thyroid cancer; this depends on the specific codon of the *RET* gene that is mutated).

Patients usually present in middle age with a firm thyroid mass. Cervical lymph node involvement is common but distant metastases are rare initially. Serum calcitonin levels are raised and are useful in monitoring response to treatment. Despite the very high levels of calcitonin found in some patients, hypocalcaemia is extremely rare; however, hypercalcitoninaemia can be associated with severe, watery diarrhoea.

Treatment is by total thyroidectomy with removal of regional cervical lymph nodes. Since the C cells do not trap iodine and are not responsive to TSH, there is no role for ^{131}I therapy or TSH suppression with levothyroxine. External beam radiotherapy may be considered in some patients at high risk of local recurrence. Vandetanib and cabozantinib are tyrosine kinase inhibitors licensed for patients with progressive advanced medullary cancer. Selpercatinib is also licensed in advanced disease for those with a *RET* mutation (either germline or somatic). The prognosis is not as good as papillary and follicular carcinoma, but individuals can live for many decades with persistent disease that behaves in an indolent fashion.

Riedel thyroiditis

Although not a form of thyroid cancer, the presentation is similar and differentiation can usually be made only by thyroid biopsy. It has an estimated incidence of 1 in 100 000. Riedel thyroiditis is an autoimmune disease and, in most cases, appears to be IgG4-related (p. 1074). Fibrosing variants of Hashimoto thyroiditis and Graves disease have also been described. There may be associated systemic features, e.g. mediastinal, retroperitoneal, salivary, and/or cardiovascular fibrosis, seen in around 30% of patients. Presentation is with a slow-growing goitre that is irregular and stony-hard. Tracheal and oesophageal compression occur often necessitating partial thyroidectomy. Other recognised local complications include recurrent laryngeal nerve palsy, hypoparathyroidism and eventually hypothyroidism. Immunosuppressive therapy may be indicated for symptomatic disease.

Congenital thyroid disease

Early treatment with levothyroxine is essential to prevent irreversible brain damage in children (cretinism) with congenital hypothyroidism. Routine screening of TSH levels in heel-prick blood samples obtained 5–7 days after birth (as part of the Guthrie test) shows congenital hypothyroidism has an incidence of approximately 1 in 3000. Causes include thyroid agenesis, ectopic or hypoplastic glands, and dyshormonogenesis. Levothyroxine replacement therapy should be initiated within 2 weeks of birth. Developmental assessment of infants treated at this early stage suggests an excellent response to treatment.

Dyshormonogenesis

Several genetic defects in thyroid hormone synthesis have been described; the most common results from deficiency of the intrathyroidal peroxidase enzyme. Homozygous individuals present with congenital hypothyroidism; heterozygotes present in the first two decades of life with goitre, normal thyroid hormone levels and a raised TSH. The combination of dyshormonogenetic goitre and nerve deafness is known as Pendred syndrome. Most cases of Pendred syndrome are caused by pathogenic variants in the *SLC26A4* gene, which encodes pendrin, the protein that transports iodide to the luminal surface of the follicular cell (see Fig. 20.3).

Thyroid hormone resistance

This is a rare disorder in which the pituitary and hypothalamus are resistant to feedback suppression of TSH by T3, sometimes due to pathogenic variants in the thyroid hormone receptor β gene or because of defects in deiodinase activity. TSH, T4 and T3, are all increased and patients may also have a goitre in adulthood. Thyroid hormone signalling is highly complex and involves different isozymes of both deiodinases and thyroid hormone receptors in different tissues. For this reason, some tissues do not share the resistance to thyroid hormone and there may be features of thyrotoxicosis (e.g. tachycardia). This condition can be difficult to distinguish from an equally rare TSH-producing pituitary tumour (TSHoma; see Box 20.5); administration of TRH tends to result in elevation of TSH in thyroid hormone resistance and not in TSHoma, but an MRI scan of the pituitary may be necessary to exclude an adenoma.

The reproductive system

Clinical practice in reproductive medicine is shared between several specialties, including gynaecology, urology, paediatric endocrinology, psychiatry and endocrinology. The following section is focused on disorders managed by adult endocrinologists.

Functional anatomy, physiology and investigations

The physiology of male and female reproductive function is illustrated in Figures 20.14 and 20.15, respectively. Pathways for synthesis of sex steroids are shown in Figure 20.20.

The male

In the male, the testis serves two principal functions: synthesis of testosterone by the interstitial Leydig cells under the control of luteinising hormone (LH), and spermatogenesis by Sertoli cells under the control of follicle-stimulating hormone (FSH) (but also requiring adequate testosterone). Negative feedback suppression of LH is mediated principally by testosterone, while secretion of another hormone produced by the testis, inhibin, suppresses FSH. The axis is optimally assessed by fasted, early morning measurement of testosterone, LH and FSH (as testosterone levels reach their peak in the morning and can be mildly suppressed post-prandially). Testosterone is largely bound in plasma to sex hormone-binding globulin and this can also be measure1d to determine the 'calculated free testosterone' or the 'bioavailable' testosterone. Testicular function can also be tested by semen analysis.

There is no equivalent of the menopause in men, although testosterone concentrations decline slowly from the fourth decade onwards.

Fig. 20.14 Male reproductive physiology. (FSH = follicle-stimulating hormone; LH = luteinising hormone)

The female

In the female, physiology varies during the normal menstrual cycle. FSH stimulates growth and development of ovarian follicles during the first 14 days after the menses. This leads to a gradual increase in oestradiol production from granulosa cells, which initially suppresses FSH secretion (negative feedback) but, once a threshold is reached, stimulates an increase in both the frequency and amplitude of gonadotrophin-releasing hormone (GnRH) pulses, resulting in a marked increase in LH secretion (positive feedback). The mid-cycle 'surge' of LH induces ovulation. After release of the ovum, the follicle differentiates into a corpus luteum, which secretes progesterone. Unless pregnancy occurs during the cycle, the corpus luteum regresses and the fall in progesterone levels results in menstrual bleeding. Circulating levels of oestrogen and progesterone in pre-menopausal women are, therefore, critically dependent on the time of the cycle. The most useful 'test' of ovarian function is a careful menstrual history: if menses are regular, measurement of gonadotrophins and oestrogen is not necessary. Ovulation can be confirmed by measuring plasma progesterone levels during the luteal phase ('day 21 progesterone').

Cessation of menstruation (the menopause) occurs at an average age of approximately 50 years in high-income countries. In the 5 years before, there is a gradual increase in the number of anovulatory cycles and this is referred to as the climacteric. Oestrogen and inhibin secretion falls and negative feedback results in increased pituitary secretion of LH and FSH (both typically to levels above 30 IU/L (3.3 µg/L)).

The pathophysiology of male and female reproductive dysfunction is summarised in Box 20.18.

Presenting problems in reproductive disease

Delayed puberty

Normal pubertal development is discussed in Chapter 31. Puberty is considered to be delayed if the onset of the physical features of sexual maturation has not occurred by a chronological age that is 2.5 standard

20.18 Classification of diseases of the reproductive system

	Primary	Secondary
Hormone excess	Polycystic ovary syndrome Granulosa cell tumour Leydig cell tumour Teratoma	Pituitary gonadotrophinoma
Hormone deficiency	Hypogonadism (see Box 20.19) Turner syndrome Klinefelter syndrome	Hypopituitarism Isolated GnRH deficiency (Kallmann syndrome) Severe systemic illness, including anorexia nervosa
Hormone hypersensitivity	Idiopathic hirsutism	
Hormone resistance	Androgen resistance syndromes Complete ('testicular feminisation') Partial (Reifenstein syndrome) 5α-reductase type 2 deficiency	
Non-functioning tumours	Ovarian cysts Carcinoma Teratoma Seminoma	

(GnRH = gonadotrophin-releasing hormone)

20.19 Causes of delayed puberty and hypogonadism

Constitutional delay

Hypogonadotrophic hypogonadism

- Structural hypothalamic/pituitary disease (see Box 20.53)
- Functional gonadotrophin deficiency:
  - Chronic systemic illness (e.g. asthma, malabsorption, coeliac disease, cystic fibrosis, renal failure)
  - Opioid analgesia
  - Psychological stress
  - Anorexia nervosa
  - Excessive physical exercise
  - Hyperprolactinaemia
  - Other endocrine disease (e.g. Cushing syndrome, primary hypothyroidism)
- Isolated gonadotrophin deficiency (Kallmann syndrome)

Hypergonadotrophic hypogonadism

- Acquired gonadal damage:
  - Chemotherapy/radiotherapy to gonads
  - Trauma/surgery to gonads
  - Autoimmune gonadal failure
  - Mumps orchitis
  - Tuberculosis
  - Haemochromatosis
- Developmental/congenital gonadal disorders:
  - Steroid biosynthetic defects
  - Anorchidism/cryptorchidism in males
  - Klinefelter syndrome (47,XXY, male phenotype)
  - Turner syndrome (45,X, female phenotype)

deviations (SD) above the national average. In the UK, this is by the age of 14 in boys and 13 in girls. Genetic factors have a major influence in determining the timing of the onset of puberty, such that the age of menarche (the onset of menstruation) is often comparable within sibling and mother–daughter pairs and within ethnic groups. However, because there is also a threshold for body weight that acts as a trigger for normal puberty, the onset of puberty can be influenced by other factors, including nutritional status and chronic illness.

Clinical assessment

The differential diagnosis is shown in Box 20.19. The key issue is to determine whether the delay in puberty is simply because the 'clock

20.20 Delayed puberty

- **Aetiology**: in boys the most common cause is constitutional delay, whereas in girls there is inevitably a structural hypothalamic/pituitary abnormality or a factor that affects their function.
- **Psychological effects**: whatever the underlying cause, delayed puberty is often associated with substantial psychological distress.
- **Investigations**: a karyotype should be performed in all adolescents with hypergonadotrophic hypogonadism, to exclude Turner and Klinefelter syndromes, unless there is an obvious precipitating cause.
- **Medical induction of puberty**: if this is being considered, it needs to be managed carefully and carried out in a controlled fashion, to avoid premature fusion of the epiphyses.

is running slow' (constitutional delay of puberty) or because there is pathology in the hypothalamus/pituitary (hypogonadotrophic hypogonadism) or the gonads (hypergonadotrophic hypogonadism). A general history and physical examination should be performed with particular reference to previous or current medical disorders, social circumstances and family history. Body proportions, sense of smell and pubertal stage should be carefully documented and, in boys, the presence or absence of testes in the scrotum noted. Current weight and height may be plotted on centile charts, along with parental heights. Previous growth measurements in childhood, which can usually be obtained from health records, are extremely useful. Healthy growth usually follows a centile. Usually, children with constitutional delay have always been small but have maintained a normal growth velocity that is appropriate for bone age. Poor linear growth, with 'crossing of the height centiles', is more likely to be associated with acquired disease. Issues that are commonly encountered in the management of adolescents with delayed puberty are summarised in Box 20.20.

Constitutional delay of puberty

This is the most common cause of delayed puberty, but is a much more frequent explanation for lack of pubertal development in boys than in girls. Affected children are healthy and have usually been more than 2 SD below the mean height for their age throughout childhood. There is often a history of delayed puberty in siblings or parents. Since sex steroids are essential for fusion of the epiphyses, 'bone age' can be estimated by X-rays of epiphyses, usually in the wrist and hand (see Fig 31.6; p. 1325); in constitutional delay, bone age is lower than chronological age. Constitutional delay of puberty should be considered as a normal variant, as puberty will commence spontaneously. However, affected children can experience significant psychological distress because of their lack of physical development, particularly when compared with their peers.

Hypogonadotrophic hypogonadism

This may be due to structural, inflammatory or infiltrative disorders of the pituitary and/or hypothalamus (see Box 20.53). In such circumstances, other pituitary hormones, such as growth hormone, are also likely to be deficient.

'Functional' gonadotrophin deficiency is caused by a variety of factors, including low body weight, chronic systemic illness (as a consequence of the disease itself or secondary malnutrition), endocrine disorders and profound psychosocial stress.

Isolated gonadotrophin deficiency is usually due to a genetic abnormality that affects the synthesis of either GnRH or gonadotrophins. The most common form is Kallmann syndrome, in which there is primary GnRH deficiency and, in most affected individuals, agenesis or hypoplasia of the olfactory bulbs, resulting in anosmia or hyposmia. If isolated gonadotrophin deficiency is left untreated, the epiphyses fail to fuse, resulting in tall stature with disproportionately long arms and legs relative to trunk height (eunuchoid habitus).

Cryptorchidism (undescended testes) and gynaecomastia are commonly observed in all forms of hypogonadotrophic hypogonadism.

Hypergonadotrophic hypogonadism

Hypergonadotrophic hypogonadism associated with delayed puberty is usually due to Klinefelter syndrome in boys and Turner syndrome in girls. Other causes of primary gonadal failure are shown in Box 20.19.

Investigations

Key measurements are LH and FSH, testosterone (in boys) and oestradiol (in girls). Chromosome analysis should be performed if gonadotrophin concentrations are elevated. If gonadotrophin concentrations are low, then the differential diagnosis lies between constitutional delay and hypogonadotrophic hypogonadism. A plain X-ray of the wrist and hand may be compared with a set of standard films to obtain a bone age. Full blood count, renal function, liver function, thyroid function and coeliac disease autoantibodies (see p. 837) should be measured, but further tests may be unnecessary if the blood tests are normal and the child has all the clinical features of constitutional delay. If hypogonadotrophic hypogonadism is suspected, neuroimaging and further investigations are required (see Box 20.51).

Management

Puberty can be induced using low doses of oral oestrogen in girls (e.g. ethinylestradiol 2 μg daily) or testosterone in boys (low doses of testosterone gel or depot testosterone esters). Higher doses carry a risk of early fusion of epiphyses. This therapy should be given in a specialist clinic where the progress of puberty and growth can be carefully monitored. In children with constitutional delay, this 'priming' therapy can be discontinued when endogenous puberty is established, usually in less than a year. In children with hypogonadism, the underlying cause should be treated and reversed if possible. If hypogonadism is permanent, sex hormone doses are gradually increased during puberty and full adult replacement doses given when development is complete.

Amenorrhoea

Primary amenorrhoea may be diagnosed in a female who has never menstruated; this usually occurs as a manifestation of delayed puberty but may also be a consequence of anatomical defects of the female reproductive system, such as endometrial hypoplasia or vaginal agenesis. Secondary amenorrhoea describes the cessation of menstruation in a female who has previously had periods. The causes of this common presentation are shown in Box 20.21. In non-pregnant women, secondary amenorrhoea is almost invariably a consequence of either ovarian or hypothalamic/pituitary dysfunction. Premature ovarian failure (premature menopause) is defined, arbitrarily, as occurring before 40 years of age. Rarely, endometrial adhesions (Asherman syndrome) can form after uterine curettage, surgery or infection with tuberculosis or schistosomiasis, preventing endometrial proliferation and shedding.

Clinical assessment

The underlying cause can often be suspected from associated clinical features and the patient's age. Hypothalamic/pituitary disease and premature ovarian failure result in oestrogen deficiency, which causes a variety of symptoms usually associated with the menopause (Box 20.22). A history of galactorrhoea should be sought. Significant weight loss of

20.21 Causes of secondary amenorrhoea

Vasomotor effects

- Hot flushes
- Sweating

Psychological

- Anxiety
- Irritability
- Emotional lability

Genitourinary

- Dyspareunia
- Urgency of micturition
- Vaginal infections

any cause can cause amenorrhoea by suppression of gonadotrophins. Weight gain may suggest hypothyroidism, Cushing syndrome (if other discriminatory features are present), or very rarely, a hypothalamic lesion. Hirsutism, obesity and long-standing irregular periods suggest polycystic ovary syndrome (PCOS). The presence of other autoimmune disease raises the possibility of autoimmune premature ovarian failure.

Investigations

Pregnancy should be excluded in women of reproductive age by measuring urine or serum human chorionic gonadotrophin (hCG). Serum LH, FSH, oestradiol, prolactin, testosterone, T4 and TSH should be measured and, in the absence of a menstrual cycle, can be taken at any time. Investigation of hyperprolactinaemia is described on page 738. High concentrations of LH and FSH with low or low-normal oestradiol suggest primary ovarian failure. Ovarian autoantibodies may be positive when there is an underlying autoimmune aetiology, and a karyotype should be performed in younger women to exclude mosaic Turner syndrome. Elevated LH, prolactin and testosterone levels, with normal oestradiol, are common in PCOS. Low levels of LH, FSH and oestradiol suggest hypothalamic or pituitary disease and a pituitary MRI is indicated.

There is some overlap in gonadotrophin and oestrogen concentrations between women with hypogonadotrophic hypogonadism and PCOS. If there is doubt as to the underlying cause of secondary amenorrhoea, then the response to 5–10 days of treatment with an oral progestogen (e.g. medroxyprogesterone acetate 5–10 mg daily) can be assessed. In women with PCOS, the progestogen will cause maturation of the (usually thickened) endometrium and menstruation will occur a few days after the progestogen is stopped. In women with hypogonadotrophic hypogonadism, menstruation does not occur following progestogen withdrawal because the endometrium is atrophic as a result of oestrogen deficiency. Transvaginal ultrasound can also be used to assess endometrial thickness and to examine the ovaries for evidence of polycystic change.

Assessment of bone mineral density by dual X-ray absorptiometry (DXA, see Ch. 25) may be appropriate in patients with low oestrogen levels.

Management

Where possible, the underlying cause should be treated. For example, women with functional amenorrhoea due to excessive exercise and low weight should be encouraged to reduce their exercise and regain some weight. The management of structural pituitary and hypothalamic disease is described on page 734 and that of PCOS on page 714.

In oestrogen-deficient women, replacement therapy may be necessary to treat symptoms and/or to prevent osteoporosis. Women who have had a hysterectomy can be treated with oestrogen alone but those with a uterus should be treated with combined oestrogen/progestogen therapy, since unopposed oestrogen increases the risk of endometrial cancer. Cyclical hormone replacement therapy (HRT) regimens typically involve giving oestrogen on days 1–21 and progestogen on days 14–21 of the cycle, and this can be conveniently administered as the oral contraceptive pill. If oestrogenic side-effects (fluid retention, hypertension and thrombosis) are a concern, then lower-dose oral or transdermal HRT may be more appropriate. Preparations that administer oestrogen and a progesterone continuously are available for women who do not wish to have a withdrawal bleed. A hormonal intrauterine device (a coil that slowly releases progestogen into the uterus and thus keeps the endometrium atrophic) is an alternative means of delivering the progestogen and may be used in combination with an oral or transdermal oestrogen (cyclical or continuous). There are some data to suggest that transdermal preparations (compared with oral) are associated with a lower risk of certain side-effects, such as venous thromboembolism.

The timing of the discontinuation of oestrogen replacement therapy is still a matter of debate. In post-menopausal women, HRT has been shown to relieve menopausal symptoms and to prevent osteoporotic fractures but is associated with adverse effects (such as an increased risk of breast cancer and venous thromboembolism), which are related to the duration of therapy and to the patient's age. In patients with premature menopause, HRT should be continued up to the age of around 50 years, but continued beyond this age only if there are continued symptoms of oestrogen deficiency on discontinuation.

Management of infertility in oestrogen-deficient women is described below.

Male hypogonadism

The clinical features of both hypo- and hypergonadotrophic hypogonadism include loss of libido, erectile dysfunction, lethargy with muscle weakness and decreased frequency of shaving. Patients may also present with gynaecomastia, infertility, delayed puberty, osteoporosis or anaemia. The causes of hypogonadism are listed in Box 20.19. Mild hypogonadism may also occur in older men, particularly in the context of central adiposity. Postulated mechanisms are complex and include reduction in GnRH and gonadotrophin secretion by cytokines or oestrogen released by adipose tissue. Testosterone levels also fall gradually with age in men (see Box 20.24) and this is associated with gonadotrophin levels that are low or inappropriately within the 'normal' range. There is an increasing trend to measure testosterone in older men, typically as part of an assessment of erectile dysfunction and reduced libido.

Investigations

Male hypogonadism is confirmed by demonstrating a low fasting 9 am serum testosterone level. The distinction between hypo- and hypergonadotrophic hypogonadism is by measurement of random LH and FSH. Patients with hypogonadotrophic hypogonadism should be investigated as described for pituitary disease on page 733. Pituitary imaging is not always necessary in biochemically mild testosterone deficiency (> 5 nmol/L), with otherwise normal pituitary function, in the context of obesity. Patients with hypergonadotrophic hypogonadism should have the testes examined for cryptorchidism or atrophy, and a karyotype should be performed (to identify Klinefelter syndrome).

Management

Testosterone replacement is clearly indicated in younger men with significant hypogonadism to prevent osteoporosis and to restore muscle power and libido. Debate exists as to whether replacement therapy is of benefit in mild hypogonadism associated with ageing and central adiposity, particularly in the absence of structural pituitary/hypothalamic disease or other pituitary hormone deficiency. In such instances, a therapeutic trial of testosterone therapy may be considered if symptoms are present (e.g. low libido and erectile dysfunction) and the serum testosterone is consistently low, but the benefits of therapy must be carefully weighed against the potential for harm (see below). Recent randomised controlled trial evidence has partially allayed concerns that testosterone replacement may increase cardiovascular risk in older men.

Routes of testosterone administration are shown in Box 20.23. First-pass hepatic metabolism of testosterone is highly efficient, so bioavailability of ingested preparations is poor. Doses of systemic testosterone can be titrated against symptoms; circulating testosterone levels may provide only a rough guide to dosage because they may be highly variable (see Box 20.23). Testosterone therapy can worsen prostatic hypertrophy and

20.23 Options for androgen replacement therapy

Route of administration	Preparation	Dose	Frequency	Comments
Intramuscular	Testosterone undecanoate	1000 mg	Every 3 months	Smoother profile than testosterone enantate, with less frequent injections
	Testosterone enanthate	50–250 mg	Every 3–4 weeks	Produces peaks and troughs of testosterone levels that are outside the physiological range and may be symptomatic
Transdermal	Testosterone gel	Preparation dependent	Daily	Stable testosterone levels; transfer of gel can occur following skin-to-skin contact with another person

20.24 Gonadal function in old age

- **Post-menopausal osteoporosis**: a major public health issue due to the high incidence of associated fragility fractures, especially of hip.
- **Hormone replacement therapy**: should be prescribed only above the age of 50 for the short-term relief of symptoms of oestrogen deficiency.
- **Sexual activity**: many older people are sexually active.
- **'Male menopause'**: does not occur, although testosterone concentrations do fall with age. Testosterone therapy in mildly hypogonadal men may be of benefit for body composition, muscle and bone. A recent large randomised trial of testosterone replacement indicated no significant effect upon cardiovascular or prostatic disease.
- **Androgens in older women**: hirsutism and balding occur. In those rare patients with significantly elevated androgen levels, this may be pathological, e.g. from an ovarian tumour.

20.25 Causes of infertility

Female factors (35%–40%)

- Ovulatory dysfunction:
    Polycystic ovary syndrome
    Hypogonadotrophic hypogonadism (see Box 20.19)
    Hypergonadotrophic hypogonadism (see Box 20.19)
- Tubular dysfunction:
    Pelvic inflammatory disease (chlamydia, gonorrhoea)
    Endometriosis
    Previous sterilisation
    Previous pelvic or abdominal surgery
- Cervical and/or uterine dysfunction:
    Congenital abnormalities
    Fibroids
    Treatment for cervical carcinoma
    Asherman syndrome

Male factors (35%–40%)

- Reduced sperm quality or production:
    Y chromosome microdeletions
    Varicocele
    Hypergonadotrophic hypogonadism (see Box 20.19)
    Hypogonadotrophic hypogonadism (see Box 20.19)
- Tubular dysfunction:
    Varicocele
    Congenital abnormality of vas deferens/epididymis
    Previous sexually transmitted infection (chlamydia, gonorrhoea)
    Previous vasectomy

Unexplained or mixed factors (20%–35%)

aggravate prostate carcinoma; prostate-specific antigen (PSA) should be measured before commencing testosterone therapy in men older than 50 years and monitored annually thereafter. Haemoglobin concentration should also be monitored, as androgen replacement can cause polycythaemia. Testosterone replacement inhibits spermatogenesis; treatment for fertility is described below.

Some important aspects of gonadal function in older women and men are summarised in Box 20.24.

Infertility

Infertility affects around 1 in 7 couples of reproductive age, often causing psychological distress. The main causes are listed in Box 20.25. In women, it may result from anovulation or abnormalities of the reproductive tract that prevent fertilisation or embryonic implantation, often damaged fallopian tubes from previous infection. In men, infertility may result from impaired sperm quality (e.g. reduced motility) or reduced sperm number. Azoospermia or oligospermia is usually idiopathic but may be a consequence of hypogonadism (see Box 20.19). Microdeletions of the Y chromosome are recognised as a cause of severely abnormal spermatogenesis. In many couples more than one factor causing subfertility is present, and in a large proportion no cause can be identified.

Clinical assessment

A history of previous pregnancies, relevant infections and surgery is important in both men and women. A sexual history must be explored sensitively, as some couples have intercourse infrequently or only when they consider the woman to be ovulating, and psychosexual difficulties are common. Irregular and/or infrequent menstrual periods are an indicator of anovulatory cycles in the woman, in which case causes such as PCOS should be considered. In men, the testes should be examined to confirm that both are in the scrotum and to identify any structural abnormality, such as small size, absent vas deferens or the presence of a varicocele.

Investigations

Investigations should generally be performed after a couple has failed to conceive despite unprotected intercourse for 12 months, unless there is an obvious abnormality like amenorrhoea. Both partners need to be investigated. The male partner needs a semen analysis to assess sperm count and quality. In women with regular periods, ovulation can be confirmed by an elevated serum progesterone concentration on day 21 of the menstrual cycle. Transvaginal ultrasound can be used to assess uterine and ovarian anatomy. Tubal patency may be examined at laparoscopy or by hysterosalpingography (HSG; a radio-opaque medium is injected into the uterus and should normally outline the fallopian tubes).

Management

Couples should be advised to have regular sexual intercourse, ideally every 2–3 days throughout the menstrual cycle. It is not uncommon for 'spontaneous' pregnancies to occur in couples undergoing investigations for infertility or with identified causes of male or female subfertility.

In women with anovulatory cycles secondary to PCOS, clomifene, which has partial anti-oestrogen action, blocks negative feedback of oestrogen on the hypothalamus/pituitary, causing gonadotrophin secretion and thus ovulation. In women with gonadotrophin deficiency or in whom anti-oestrogen therapy is unsuccessful, ovulation may be induced by direct stimulation of the ovary by daily injection of FSH and an injection of hCG or LH to induce follicular rupture at the appropriate time. In hypothalamic disease, pulsatile GnRH therapy with a portable infusion pump can be used to stimulate pituitary gonadotrophin secretion (note that non-pulsatile administration of GnRH or its analogues paradoxically suppresses LH and FSH secretion). Whatever method of ovulation induction is employed, monitoring of response is essential to avoid multiple ovulation. For clomifene, ultrasound monitoring is recommended for at least the first cycle. During gonadotrophin therapy, closer monitoring of follicular growth by transvaginal ultrasonography and blood oestradiol levels is mandatory. 'Ovarian hyperstimulation syndrome' is characterised by grossly enlarged ovaries and capillary leak with circulatory shock, pleural effusions and ascites. Anovulatory women who fail to respond to ovulation induction or who have primary ovarian failure may wish to consider using donated eggs or embryos, surrogacy and adoption.

Surgery to restore fallopian tube patency can be effective but in vitro fertilisation (IVF) is normally recommended. IVF is widely used for many causes of infertility and in unexplained cases of prolonged (>3 years) infertility. The success of IVF depends on age, with low success rates in women over 40 years.

Men with hypogonadotrophic hypogonadism who wish fertility are usually given injections of hCG several times a week (recombinant FSH may also be required in men with hypogonadism of pre-pubertal origin); it may take up to 2 years to achieve satisfactory sperm counts. Surgery is rarely an option in primary testicular disease but removal of a varicocele can improve semen quality. Extraction of sperm from the epididymis for IVF, and intracytoplasmic sperm injection (ICSI, when single spermatozoa are injected into each oocyte) are used in men with oligospermia or poor sperm quality who have primary testicular disease. Azoospermic men may opt to use donated sperm.

Gynaecomastia

Gynaecomastia is the presence of glandular breast tissue in males. Normal breast development in women is oestrogen-dependent, while androgens oppose this effect. Gynaecomastia results from an imbalance between androgen and oestrogen activity, which may reflect androgen deficiency or oestrogen excess. Causes are listed in Box 20.26. The most common are physiological: for example, in the newborn baby (due to maternal and placental oestrogens), in pubertal boys (in whom oestradiol concentrations reach adult levels before testosterone) and in older men (due to decreasing testosterone concentrations). Prolactin excess alone does not cause gynaecomastia.

Clinical assessment

A drug history is important. Gynaecomastia is often asymmetrical and palpation may allow breast tissue to be distinguished from the prominent adipose tissue (lipomastia) around the nipple that is often observed in obesity. Features of hypogonadism should be sought (see above) and the testes examined for evidence of cryptorchidism, atrophy or a tumour.

20.26 Causes of gynaecomastia

Idiopathic

Physiological

Drug-induced

- Cimetidine
- Digoxin
- Anti-androgens (cyproterone acetate, spironolactone)
- Some exogenous anabolic steroids (diethylstilbestrol)
- Cannabis

Hypogonadism (see Box 20.19)

Androgen resistance syndromes

Oestrogen excess

- Liver failure (impaired steroid metabolism)
- Oestrogen-secreting tumour (e.g. of testis)
- Human chorionic gonadotrophin-secreting tumour (e.g. of testis or lung)

Investigations

If a clinical distinction between gynaecomastia and adipose tissue cannot be made, then ultrasonography or mammography is required. A random blood sample should be taken for testosterone, LH, FSH, oestradiol, prolactin and hCG. Elevated oestrogen concentrations are found in testicular tumours and hCG-producing neoplasms.

Management

An adolescent with gynaecomastia who is progressing normally through puberty may be reassured that the gynaecomastia will usually resolve once development is complete. If puberty does not proceed normally, then there may be an underlying abnormality that requires investigation. Gynaecomastia may cause significant psychological distress, especially in adolescent boys, and surgical excision may be justified for cosmetic reasons. There is little evidence to suggest testosterone replacement therapy ameliorates gynaecomastia in hypogonadal men and any other identifiable underlying cause should be addressed if possible. The anti-oestrogen tamoxifen may be effective in reducing the size of the breast tissue.

Hirsutism

Hirsutism refers to the excessive growth of terminal hair (the thick, pigmented hair usually associated with the adult male chest) in an androgen-dependent distribution in women (upper lip, chin, chest, back, lower abdomen, thigh, forearm) and is one of the most common presentations of endocrine disease. It should be distinguished from hypertrichosis, which is generalised excessive growth of vellus hair (the thin, non-pigmented hair that is typically found all over the body from childhood onwards). The aetiology of androgen excess is shown in Box 20.27.

Clinical assessment

The severity of hirsutism is subjective. Some women suffer profound embarrassment from a degree of hair growth that others would not consider remarkable. Important observations are a drug and menstrual history, calculation of body mass index, measurement of blood pressure and examination for virilisation (clitoromegaly, deep voice, male-pattern balding, breast atrophy) and associated features, including acne vulgaris or Cushing syndrome. Hirsutism of recent onset associated with virilisation is suggestive of an androgen-secreting tumour or ovarian hyperthecosis.

Investigations

A random blood sample should be taken for testosterone, prolactin, LH and FSH. If there are clinical features of Cushing syndrome, further investigations should be performed as detailed on page 722.

If testosterone levels are more than twice the upper limit of normal for females, idiopathic hirsutism and PCOS are less likely, especially if LH and FSH levels are low. Under these circumstances, other causes of androgen excess should be sought. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency is diagnosed by an ACTH stimulation test with measurement of 17-OH-progesterone. In post-menopausal women with significant hyperandrogenism, administration of GnRH analogue can be helpful in differentiating between an ovarian ($>50\%$ suppression of testosterone) or adrenal source ($\leq 50\%$ suppression) of androgen excess. The tumour should then be sought by CT or MRI of the adrenals and ovaries, as indicated by biochemical testing.

Management

This depends on the cause (Box 20.27). Options for the treatment of PCOS and idiopathic hirsutism are similar and are described below.

Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) affects up to 10% of women of reproductive age. It is a heterogeneous disorder (Box 20.28), often associated with obesity, for which the primary cause remains uncertain.

20.27 Causes of hirsutism

Cause	Clinical features	Investigation findings	Treatment
Idiopathic	Often familial Mediterranean or Asian background	Normal	Cosmetic measures Anti-androgens
Polycystic ovary syndrome	Obesity Oligomenorrhoea or secondary amenorrhoea Infertility	LH:FSH ratio > 2.5:1 Minor elevation of androgens* Mild hyperprolactinaemia	Weight loss Cosmetic measures Anti-androgens (Metformin, glitazones may be useful)
Congenital adrenal hyperplasia (95% 21-hydroxylase deficiency)	Pigmentation History of salt-wasting in childhood, ambiguous genitalia, or adrenal crisis when stressed	Elevated androgens* that suppress with dexamethasone Abnormal rise in 17-OH-progesterone with ACTH	Glucocorticoid replacement administered in reverse rhythm to suppress early morning ACTH
Exogenous androgen administration	Athletes Virilisation	Low LH and FSH Analysis of urinary androgens may detect drug of misuse	Stop steroid misuse
Androgen-secreting tumour of ovary or adrenal cortex	Rapid onset Virilisation: clitoromegaly, deep voice, balding, breast atrophy	High androgens* that do not suppress with GnRH analogues Low LH and FSH CT or MRI usually demonstrates a tumour	Surgical excision
Cushing syndrome	Clinical features of Cushing syndrome	Normal or mild elevation of adrenal androgens* See investigations (p. 721)	Treat the cause

*e.g. Serum testosterone levels in women: < 2 nmol/L (< 58 ng/dL) is normal; 2–5 nmol/L (58–144 ng/dL) is minor elevation; > 5 nmol/L (> 144 ng/dL) is high and requires further investigation.
(ACTH = adrenocorticotrophic hormone; CT = computed tomography; FH = follicle-stimulating hormone; GnRH = gonadotrophin releasing hormone; LH = luteinising hormone; MRI = magnetic resonance imaging)

20.28 Features of polycystic ovary syndrome

Mechanisms*	Manifestations
Pituitary dysfunction	High serum LH High serum prolactin
Anovulatory menstrual cycles	Oligomenorrhoea Secondary amenorrhoea Cystic ovaries Infertility
Androgen excess	Hirsutism Acne
Obesity	Hyperglycaemia Elevated oestrogens
Insulin resistance	Dyslipidaemia Hypertension

*These mechanisms are interrelated; it is not known which, if any, is primary. PCOS probably represents the common endpoint of several different pathologies.
(LH = luteinising hormone)

Genetic factors probably play a role, since PCOS often affects several family members. The severity and clinical features of PCOS vary markedly between individual patients but diagnosis is usually made during the investigation of hirsutism or amenorrhoea/oligomenorrhoea. Infertility may also be present. There is no universally accepted definition but it has been recommended that a diagnosis of PCOS requires the presence of two of the following three features:

- menstrual irregularity
- clinical or biochemical androgen excess
- multiple cysts in the ovaries (most readily detected by transvaginal ultrasound; Fig. 20.16).

Women with PCOS are at increased risk of glucose intolerance and some authorities recommend screening for type 2 diabetes and other cardiovascular risk factors associated with the metabolic syndrome.

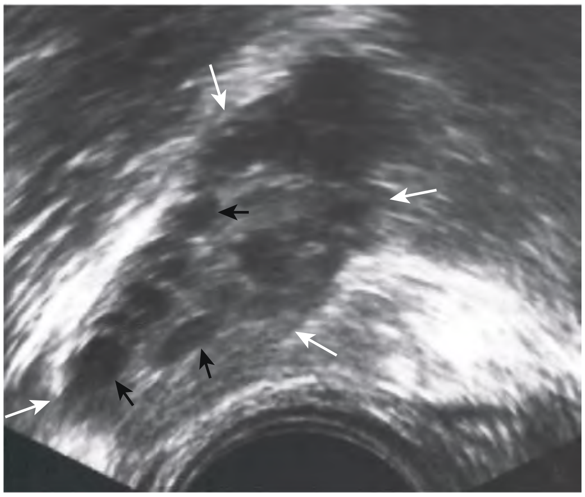

Fig. 20.16 Polycystic ovary. A transvaginal ultrasound scan showing multiple cysts (some indicated by black arrows) in the ovary (highlighted by white arrows) of a woman with polycystic ovary syndrome.

Management

This should be directed at the presenting complaint but all women with PCOS who are overweight should be encouraged to lose weight, as this can improve several symptoms, including menstrual irregularity, and reduces the risk of type 2 diabetes.

Menstrual irregularity and infertility

Most women with PCOS have oligomenorrhoea, with irregular, heavy menstrual periods. This may not require treatment unless fertility is desired. Metformin may restore regular ovulatory cycles in overweight women by reducing insulin resistance, although it is less effective than clomifene at restoring fertility as measured by successful pregnancy.

In women who have very few periods each year or are amenorrhoeic, the high oestrogen concentrations associated with PCOS can cause endometrial hyperplasia. Progestogens can be administered on a cyclical basis to induce regular shedding of the endometrium and a withdrawal bleed, or a progestogen-impregnated intrauterine coil can be fitted.

Hirsutism

For hirsutism, most patients will have used cosmetic measures, such as shaving, bleaching and waxing, before consulting a doctor. Electrolysis and laser treatment are effective for small areas like the upper lip and for chest hair but are expensive. Eflornithine cream inhibits ornithine decarboxylase in hair follicles and may reduce hair growth when applied daily to affected areas of the face.

If conservative measures are unsuccessful, anti-androgen therapy is given (Box 20.29). The life cycle of a hair follicle is at least 3 months and no improvement is likely before this time, when follicles have shed their hair and replacement hair growth has been suppressed. Metformin is less effective at treating hirsutism than at restoring menstrual regularity. Unless weight is lost, hirsutism will return if therapy is discontinued. The patient should know that prolonged exposure to some agents may not be desirable and they should be stopped before pregnancy.

Turner syndrome

Turner syndrome affects around 1 in 2500 females. It is classically associated with a 45,X karyotype but other cytogenetic abnormalities may be responsible, including mosaic forms (e.g. 45,X/46,XX or 45,X/46,XY) and partial deletions of an X chromosome.

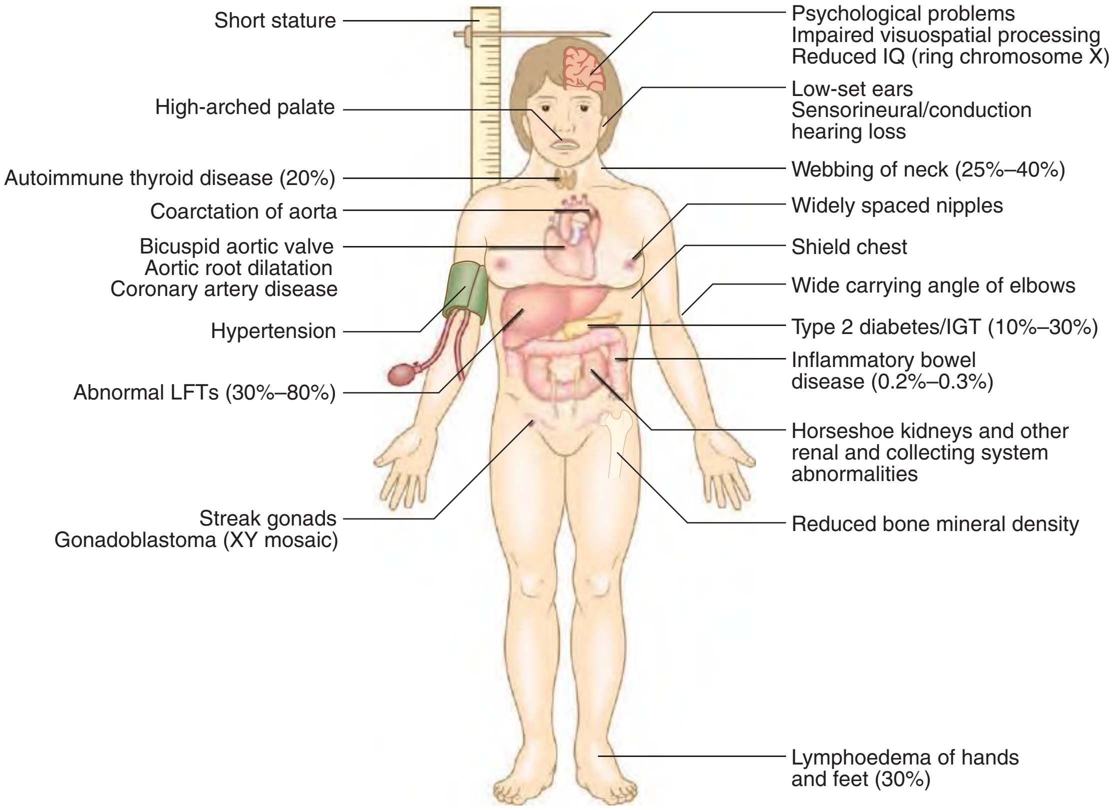
Clinical features

These are shown in Figure 20.17.

Individuals with Turner syndrome invariably have short stature from an early age and this is often the initial presenting symptom; it is probably due to haploinsufficiency of the *SHOX* gene, one copy of which is found

i 20.29 Anti-androgen therapy

Mechanism of action	Drug	Dose	Hazards
Androgen receptor antagonism	Spironolactone	25–200 mg daily	Electrolyte disturbance
5α-reductase inhibition (prevent conversion of testosterone to active dihydrotestosterone)	Finasteride	5 mg daily	Limited clinical experience; possibly less efficacious than other treatments
Suppression of ovarian steroid production and elevation of sex hormone-binding globulin	Oestrogen	As co-cyprindiol, a combination with low-dose cyproterone acetate (androgen receptor antagonist) *or* Conventional oestrogen-containing contraceptive	Venous thromboembolism Hypertension Hepatic dysfunction Hepatic neoplasms (rare) Weight gain Dyslipidaemia Increased breast and endometrial carcinoma



Short stature
High-arched palate
Autoimmune thyroid disease (20%)
Coarctation of aorta
Bicuspid aortic valve
Aortic root dilatation
Coronary artery disease
Hypertension
Abnormal LFTs (30%–80%)
Streak gonads
Gonadoblastoma (XY mosaic)
Psychological problems
Impaired visuospatial processing
Reduced IQ (ring chromosome X)
Low-set ears
Sensorineural/conduction hearing loss
Webbing of neck (25%–40%)
Widely spaced nipples
Shield chest
Wide carrying angle of elbows
Type 2 diabetes/IGT (10%–30%)
Inflammatory bowel disease (0.2%–0.3%)
Horseshoe kidneys and other renal and collecting system abnormalities
Reduced bone mineral density
Lymphoedema of hands and feet (30%)

Fig. 20.17 Clinical features of Turner syndrome (45,X). (IGT = impaired glucose tolerance; LFTs = liver function tests)

on both the X and Y chromosomes, which encodes a protein that is predominantly found in bone fibroblasts.

The genital tract and external genitalia in Turner syndrome are female in character, since this is the default developmental outcome in the absence of testes. Ovarian tissue develops normally until the third month of gestation, but thereafter there is gonadal dysgenesis with accelerated degeneration of oöcytes and increased ovarian stromal fibrosis, resulting in 'streak ovaries'. The inability of ovarian tissue to produce oestrogen results in loss of negative feedback and elevation of FSH and LH concentrations.

There is a wide variation in the spectrum of associated somatic abnormalities. The severity of the phenotype is, in part, related to the underlying cytogenetic abnormality. Mosaic individuals may have only mild short stature and may enter puberty spontaneously before developing gonadal failure.

Diagnosis and management

The diagnosis of Turner syndrome can be confirmed by karyotype analysis. Short stature, although not directly due to growth hormone deficiency, responds to high doses of growth hormone. Prophylactic gonadectomy is recommended for individuals with 45,X/46,XY mosaicism because there is an increased risk of gonadoblastoma. Pubertal development can be induced with oestrogen therapy but causes fusion of the epiphyses and cessation of growth. The timing of pubertal induction therefore needs to be carefully planned. Adults with Turner syndrome require long-term oestrogen replacement therapy and should be monitored periodically for the development of aortic root dilatation, hearing loss and other somatic complications.

Klinefelter syndrome

Klinefelter syndrome affects approximately 1 in 1000 males and is usually associated with a 47,XXY karyotype. However, other cytogenetic variants may be responsible, especially 46,XY/47,XXY mosaicism. The principal pathological abnormality is dysgenesis of the seminiferous tubules. This is evident from infancy (and possibly even in utero) and progresses with age. By adolescence, hyalinisation and fibrosis are present within the seminiferous tubules and Leydig cell function is impaired, resulting in hypogonadism.

Clinical features

The diagnosis is typically made in adolescents who have presented with gynaecomastia and failure to progress normally through puberty. Affected individuals usually have small, firm testes. Tall stature is apparent from early childhood, reflecting characteristically long leg length associated with 47,XXY, and may be exacerbated by androgen deficiency with lack of epiphyseal closure in puberty. Other clinical features may include learning difficulties and behavioural disorders, as well as an increased risk of breast cancer and type 2 diabetes in later life. The spectrum of clinical features is wide and some individuals, especially those with 46,XY/47,XXY mosaicism, may pass through puberty normally and be identified only during investigation for infertility.

Diagnosis and management

Klinefelter syndrome is suggested by the typical phenotype in a patient with hypergonadotrophic hypogonadism and can be confirmed by karyotype analysis. Individuals with clinical and biochemical evidence of androgen deficiency require androgen replacement (see Box 20.23). Although success rates are variable, pregnancy can occur following ICSI therapy where sperm has been surgically retrieved from the gonads of men with Klinefelter syndrome.

The parathyroid glands

Parathyroid hormone (PTH) plays a key role in the regulation of calcium and phosphate homeostasis and vitamin D metabolism, as shown in Figure 25.60. The consequences of altered function of this axis in gut and renal disease are covered in Chapters 22 and 18, respectively. Other metabolic bone diseases are explored in Chapter 25. Here, the investigation of hypercalcaemia and hypocalcaemia and disorders of the parathyroid glands are discussed.

Functional anatomy, physiology and investigations

The four parathyroid glands lie behind the lobes of the thyroid. The parathyroid chief cells respond directly to changes in calcium concentrations via a G protein-coupled cell surface receptor (the calcium-sensing receptor) located on the cell surface (see Fig. 25.60). When serum ionised calcium levels fall, PTH secretion rises. PTH is a single-chain polypeptide of 84 amino acids. It acts on the renal tubules to promote reabsorption of calcium and reduce reabsorption of phosphate, and on the skeleton to increase osteoclastic bone resorption and bone formation. PTH also promotes the conversion of 25-hydroxyvitamin D to the active metabolite, 1,25-dihydroxyvitamin D; the 1,25-dihydroxyvitamin D, in turn, enhances calcium absorption from the gut.

More than 99% of total body calcium is in bone. Prolonged exposure of bone to high levels of PTH is associated with increased osteoclastic activity and new bone formation, but the net effect is to cause bone loss with mobilisation of calcium into the extracellular fluid. In contrast, pulsatile release of PTH causes net bone gain. This effect is exploited therapeutically in the treatment of osteoporosis, as discussed in Chapter 25.

The differential diagnosis of disorders of calcium metabolism requires measurement of calcium phosphate, alkaline phosphatase, renal function, PTH and 25-hydroxyvitamin D. Although the parathyroid glands detect and respond to ionised calcium levels, most clinical laboratories measure only total serum calcium levels. About 50% of total calcium is bound to organic ions, such as citrate or phosphate, and to proteins, especially albumin. Accordingly, if the serum albumin level is reduced, total calcium concentrations should be 'corrected' by adjusting the value for calcium upwards by 0.02 mmol/L (0.08 mg/dL) for each 1 g/L reduction in albumin below 40 g/L. If albumin concentrations are significantly low, as in severe acute illness and other chronic illness such as liver cirrhosis, this correction is less accurate and measurement of ionised calcium is recommended.

Calcitonin is secreted from the parafollicular C cells of the thyroid gland. Although it is a useful tumour marker in medullary carcinoma of thyroid, its release from the thyroid is of no clinical relevance to calcium homeostasis in humans.

Disorders of the parathyroid glands are summarised in Box 20.30. Some specific features of parathyroid disease in older people are summarised in Box 20.31.

Presenting problems in parathyroid disease

Hypercalcaemia

Hypercalcaemia is one of the most common biochemical abnormalities and is often detected during routine biochemical analysis in asymptomatic patients. However, it can present with chronic symptoms, as described below, and occasionally as an acute emergency with severe hypercalcaemia and dehydration.

Causes of hypercalcaemia are listed in Box 20.32. Of these, primary hyperparathyroidism and malignant hypercalcaemia are by far the most common. Familial hypocalciuric hypercalcaemia (FHH) is a rare but important cause that needs differentiation from primary hyperparathyroidism (HPT). Lithium may cause hyperparathyroidism by reducing the sensitivity of the calcium-sensing receptor.

Clinical assessment

Symptoms and signs of hypercalcaemia include polyuria and polydipsia, renal colic, lethargy, anorexia, nausea, dyspepsia and peptic ulceration, constipation, depression, drowsiness and impaired cognition. Patients

20.30 Classification of diseases of the parathyroid glands

	Primary	Secondary
Hormone excess	Primary hyperparathyroidism Parathyroid adenoma Parathyroid carcinoma[1] Parathyroid hyperplasia[2] Tertiary hyperparathyroidism (following prolonged secondary hyperparathyroidism)	Secondary hyperparathyroidism Chronic kidney disease Malabsorption Vitamin D deficiency
Hormone deficiency	Hypoparathyroidism Post-surgical Autoimmune Inherited	
Hormone hypersensitivity	Autosomal dominant hypercalciuric hypocalcaemic (CASR-activating mutation)	
Hormone resistance	Pseudohypoparathyroidism Familial hypocalciuric hypercalcaemia	
Non-functioning tumours	Parathyroid carcinoma[1]	

[1] Parathyroid carcinomas may or may not produce parathyroid hormone.
[2] In multiple endocrine neoplasia (MEN) syndromes (p. 742).
(CASR = calcium-sensing receptor)

20.31 The parathyroid glands in old age

- **Osteoporosis**: always exclude osteomalacia and hyperparathyroidism by checking vitamin D and calcium concentrations.
- **Primary hyperparathyroidism**: more common with ageing. Older people can often be observed without surgical intervention.
- **Hypercalcaemia**: may cause delirium.
- **Vitamin D deficiency**: common because of limited exposure to the sun and reduced ability of older skin to synthesise cholecalciferol.

20.32 Causes of hypercalcaemia

With normal or elevated parathyroid hormone (PTH) levels

- Primary or tertiary hyperparathyroidism
- Lithium-induced hyperparathyroidism
- Familial hypocalciuric hypercalcaemia

With low PTH levels

- Malignancy (lung, breast, myeloma, renal, lymphoma, thyroid)
- Elevated 1,25-dihydroxyvitamin D (vitamin D intoxication, sarcoidosis, human immunodeficiency virus, other granulomatous disease)
- Thyrotoxicosis
- Paget disease with immobilisation
- Milk-alkali syndrome
- Thiazide diuretics
- Glucocorticoid deficiency

with malignant hypercalcaemia can have a rapid onset of symptoms and may have clinical features that help to localise the tumour.

The classic symptoms of primary hyperparathyroidism are described by the adage ‘bones, stones and abdominal groans’, but few patients present in this way nowadays and the disorder is most often picked up as an incidental finding on biochemical testing. About 50% of patients with primary hyperparathyroidism are asymptomatic while others have non-specific symptoms such as polyuria, thirst, fatigue, depression and generalised aches and pains. Some present with renal calculi and it has been estimated that 5% of first stone formers and 15% of recurrent stone formers have primary hyperparathyroidism. Hypertension is a common association with hyperparathyroidism. Parathyroid tumours are almost never palpable.

A family history of hypercalcaemia raises the possibility of FHH or MEN.

Investigations

The most discriminatory investigation is measurement of PTH. If PTH levels are elevated (or less commonly ‘inappropriately’ in the upper half of the normal range) in the presence of hypercalcaemia, then primary hyperparathyroidism is the most likely diagnosis. High plasma phosphate and alkaline phosphatase accompanied by renal impairment suggest tertiary hyperparathyroidism. Hypercalcaemia may cause nephrocalcinosis and renal tubular impairment, resulting in hyperuricaemia and hyperchloraemia.

Patients with FHH can present with a similar biochemical picture to primary hyperparathyroidism but typically have low urinary calcium excretion (a ratio of urinary calcium clearance to creatinine clearance of <0.01). The diagnosis of FHH can be confirmed by screening family members for hypercalcaemia and/or identifying a genetic cause (most commonly an inactivating variant in *CASR*, the gene encoding the calcium-sensing receptor). FHH is much less common than primary hyperparathyroidism.

If PTH is low and no other cause is apparent, then malignancy with or without bony metastases is likely. PTH-related peptide, which is often responsible for the hypercalcaemia associated with malignancy, is not detected by PTH assays, but can be measured by a specific assay (although this is not usually necessary). Unless the source is obvious, the patient should be screened for malignancy with a chest X-ray, myeloma screen (see p. 1000) and CT as appropriate.

Management

Treatment of severe hypercalcaemia and primary hyperparathyroidism is described below and on page 171. FHH does not require any specific intervention.

Hypocalcaemia

Aetiology

Hypocalcaemia is much less common than hypercalcaemia. The differential diagnosis is shown in Box 20.33. The most common cause of a low total serum calcium is a low serum albumin with normal ionised calcium concentration. Conversely, ionised calcium may be low in the face of normal total serum calcium in patients with alkalosis: for example, as a result of hyperventilation.

Hypocalcaemia may also develop as a result of magnesium depletion and should be considered in patients with malabsorption, those on diuretic or proton pump inhibitor therapy, and/or those with a history of alcohol excess. Magnesium deficiency causes hypocalcaemia by impairing the ability of the parathyroid glands to secrete PTH (resulting in PTH

20.33 Differential diagnosis of hypocalcaemia

(↑ = levels increased; ↓ = levels reduced; ↔ = levels normal)

concentrations that are low or inappropriately in the reference range) and may also impair the actions of PTH on bone and kidney.

Clinical assessment

Mild hypocalcaemia is often asymptomatic but, with more profound reductions in serum calcium, tetany can occur. This is characterised by muscle spasms due to increased excitability of peripheral nerves.

Children are more liable to develop tetany than adults and present with a characteristic triad of carpopedal spasm, stridor and convulsions, although one or more of these may be found independently of the others. In carpopedal spasm, the hands adopt a characteristic position with flexion of the metacarpophalangeal joints of the fingers and adduction of the thumb ('main d'accoucheur'). Pedal spasm can also occur but is less frequent. Stridor is caused by spasm of the glottis. Adults can also develop carpopedal spasm in association with tingling of the hands and feet and around the mouth, but stridor and fits are rare.

Latent tetany may be detected by eliciting the Trousseau sign: inflation of a sphygmomanometer cuff on the upper arm to more than the systolic blood pressure is followed by carpal spasm within 3 minutes. Less specific is the Chvostek sign, in which tapping over the branches of the facial nerve as they emerge from the parotid gland produces twitching of the facial muscles.

Hypocalcaemia can cause papilloedema and prolongation of the ECG QT interval, which may predispose to ventricular arrhythmias. Prolonged hypocalcaemia and hyperphosphataemia (as in hypoparathyroidism) may cause calcification of the basal ganglia, grand mal epilepsy, psychosis and cataracts. Hypocalcaemia associated with hypophosphataemia, as in vitamin D deficiency, causes rickets in children and osteomalacia in adults.

Management

Emergency management of hypocalcaemia associated with tetany is given in Box 20.34. Treatment of chronic hypocalcaemia is described on page 1081.

Primary hyperparathyroidism

Primary hyperparathyroidism is caused by autonomous secretion of PTH, usually by a single parathyroid adenoma. It should be distinguished from secondary hyperparathyroidism, in which there is a physiological increase in PTH secretion to compensate for prolonged hypocalcaemia (plasma calcium levels are not elevated in secondary hyperparathyroidism); and from tertiary hyperparathyroidism, in which continuous stimulation of the parathyroids over a prolonged period of time results in adenoma formation and autonomous PTH secretion (Box 20.35). This is most commonly seen in individuals with advanced chronic kidney disease.

20.34 Management of severe hypocalcaemia

Immediate management

- 10–20 mL 10% calcium gluconate IV over 10–20 mins
- Continuous IV infusion may be required for several hours (equivalent of 10 mL 10% calcium gluconate/hr)
- Cardiac monitoring is recommended

If associated with hypomagnesaemia

- 24 mmol (6 g) magnesium sulphate in 500 mL 0.9% sodium chloride or 5% dextrose IV over 24 hours
- Most parenteral magnesium will be excreted in the urine, so further doses may be required to replenish body stores

(IV = intravenous)

20.35 Hyperparathyroidism

Type	Serum calcium	PTH
Primary Single adenoma (90%) Multiple adenomas (4%) Nodular hyperplasia (5%) Carcinoma (1%)	Raised	Not suppressed
Secondary Chronic renal failure Malabsorption Osteomalacia and rickets	Low	Raised
Tertiary	Raised	Not suppressed

The prevalence of primary hyperparathyroidism is about 1 in 500 and it is 2–3 times more common in women than men; 90% of patients are over 50 years of age. It also occurs in the familial MEN syndromes, in which case hyperplasia or multiple adenomas of all four parathyroid glands are more likely than a solitary adenoma. Primary hyperparathyroidism can also be caused by parathyroid carcinoma, although this accounts for less than 1% of cases. The presence of parathyroid carcinoma should prompt assessment for pathogenic variants of *CDC73*, which are associated with hyperparathyroidism–jaw tumour syndrome (primary hyperparathyroidism and ossifying fibromas of the jaw).

Clinical and radiological features

The clinical presentation of primary hyperparathyroidism is described on page 717. Parathyroid bone disease is now extremely rare due to earlier diagnosis and treatment, and plain X-ray assessment is not routinely recommended. Osteitis fibrosa results from increased bone resorption by osteoclasts with fibrous replacement in the lacunae. This may present as bone pain and tenderness, fracture and deformity. Chondrocalcinosis can occur due to deposition of calcium pyrophosphate crystals within articular cartilage. It typically affects the menisci at the knees and can result in secondary degenerative arthritis or predispose to attacks of acute pseudogout (p. 1047). Skeletal X-rays are usually normal in mild primary hyperparathyroidism but DXA (including assessment of forearm bone mineral density) should be obtained as a matter of routine in people with primary hyperparathyroidism to exclude osteoporosis (a potential indication for surgical intervention). Renal imaging (ultrasound, plain X-ray or CT of kidneys, ureters and bladder (CT KUB)) is recommended to screen for asymptomatic nephrocalcinosis or nephrolithiasis.

Investigations

The diagnosis can be confirmed by finding a raised (or inappropriately normal) PTH level in the presence of hypercalcaemia, provided that FHH is excluded. Parathyroid scanning by ultrasound examination is often sufficient to localise an adenoma prior to surgery, although it is highly dependent on an experienced operator. Where ultrasound is equivocal, or does not identify an adenoma, a range of additional imaging modalities are available. These include ^{99m}Tc sestamibi scintigraphy (MIBI; Fig. 20.18), ^{99m}Tc single-photon emission computed tomography (SPECT)/CT and, most recently, fluorine-18 (^{18}F)-fluorocholine PET-CT. Negative imaging does not exclude the diagnosis, however, and four-gland exploration may be needed. Genetic testing should be considered when primary hyperparathyroidism is diagnosed before the age of 40, as the likelihood of underlying MEN syndromes is greater in this context.

Management

The treatment of choice for primary hyperparathyroidism is surgery, with excision of a solitary parathyroid adenoma or hyperplastic glands. Patients with parathyroid bone disease run a significant risk of developing hypocalcaemia post-operatively, but the risk of this can be reduced by correcting vitamin D deficiency pre-operatively.

Surgery is usually indicated for individuals with clear-cut symptoms or documented complications (such as renal stones, renal impairment or osteoporosis), and (in asymptomatic patients) significant hypercalcaemia (corrected serum calcium >2.85 mmol/L (>11.4 mg/dL)). Patients who are treated conservatively without surgery should have calcium biochemistry and renal function checked annually and bone density monitored periodically. They should be encouraged to maintain a high oral fluid intake to avoid renal stones.

Occasionally, primary hyperparathyroidism presents with severe life-threatening hypercalcaemia. This is often due to dehydration and should be managed medically with intravenous fluids and bisphosphonates, as described on page 171. If this is not effective, then urgent parathyroidectomy should be considered.

Cinacalcet is a calcimimetic that enhances the sensitivity of the calcium-sensing receptor, and thus reduces PTH levels. It is licensed for tertiary hyperparathyroidism (p. 633) and as a treatment for patients with primary hyperparathyroidism who are unwilling to have surgery or are medically unfit. However, unlike parathyroid surgery, there is no evidence that cinacalcet reduces the risk of primary hyperparathyroidism–related end-organ damage.

Familial hypocalciuric hypercalcaemia

This autosomal dominant disorder is most commonly caused by an inactivating variant in one of the alleles of the *CASR* gene, which reduces the sensitivity of the parathyroid gland to ionised calcium concentrations. As a result, higher than normal calcium levels are required to suppress PTH secretion. The typical presentation is with mild hypercalcaemia with PTH concentrations that are ‘inappropriately’ at the upper end of the reference range or are slightly elevated. Calcium-sensing receptors in the renal tubules are also affected and this leads to increased renal tubular reabsorption of calcium and hypocalciuria (as measured in the vitamin D-replete individual by a fractional calcium excretion or 24-hour calcium excretion). The hypercalcaemia of FHH is asymptomatic and complications generally do not occur. The main risk of FHH is that of the patient being subjected to an unnecessary (and ineffective) parathyroidectomy if misdiagnosed as having primary hyperparathyroidism. Testing of family members for hypercalcaemia is helpful in confirming the diagnosis and it is also possible to perform genetic testing. No treatment is necessary.

Hypoparathyroidism

The most common cause of hypoparathyroidism is damage to the parathyroid glands (or their blood supply) during thyroid surgery. Rarely, hypoparathyroidism can occur as a result of infiltration of the glands with iron in haemochromatosis or copper in Wilson disease.

There are a number of rare congenital or inherited forms of hypoparathyroidism. One form is associated with autoimmune polyendocrine syndrome type 1 (p. 742) and another with DiGeorge syndrome. Autosomal dominant hypoparathyroidism is the mirror image of FHH (see above), in that an activating variant in the *CASR* gene reduces PTH levels, resulting in hypocalcaemia and hypercalciuria.

Pseudohypoparathyroidism

In this disorder, the individual is functionally hypoparathyroid but, instead of PTH deficiency, there is tissue resistance to the effects of PTH, such that PTH concentrations are markedly elevated. The PTH receptor itself is normal but the downstream signalling pathways are defective due to mutations that affect *GNAS1*, which encodes the Gsα protein, a molecule involved in signal transduction downstream of the PTH receptor and other G protein–coupled receptors. There are several subtypes but the most common (pseudohypoparathyroidism type 1a) is characterised by hypocalcaemia and hyperphosphataemia, in association with short stature, short fourth metacarpals and metatarsals, rounded face, obesity and subcutaneous calcification; these features are collectively referred to as Albright hereditary osteodystrophy (AHO). Type 1a pseudohypoparathyroidism occurs only when the *GNAS1* pathogenic variant is inherited on the maternal chromosome.

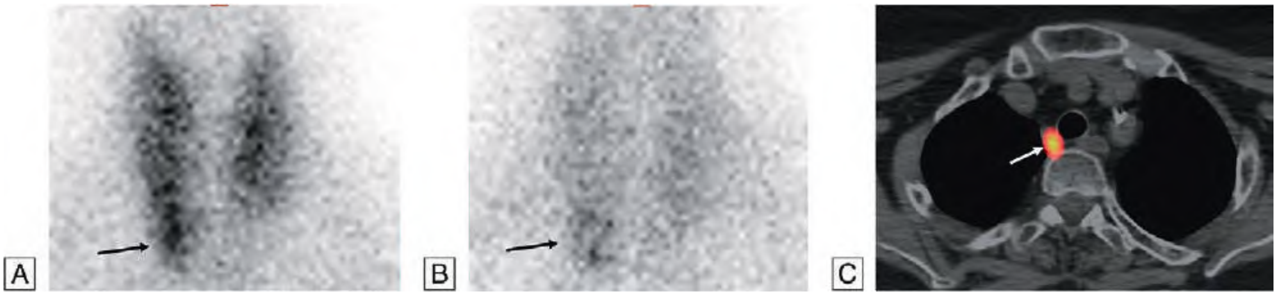

Fig. 20.18 **A** Early and **B** late planar ^{99m}Tc sestamibi scans demonstrating uptake of isotope within the thyroid gland and a right inferior parathyroid adenoma (arrow) on the early phase scan with retention of isotope within the parathyroid adenoma and washout of isotope from the thyroid gland on the late phase scan. **C** SPECT/CT allows precise anatomical location of the adenoma adjacent to the right posterior wall of the trachea (arrow) facilitating targeted surgical resection.

The term pseudopseudohypoparathyroidism is used to describe patients who have clinical features of AHO but normal serum calcium and PTH concentrations; it occurs when the *GNAS1* pathogenic variant is inherited on the paternal chromosome. The inheritance of these disorders is an example of genetic imprinting (see Ch. 3). The difference in clinical features occurs as a result of the fact that renal cells exclusively express the maternal *GNAS1* allele, whereas both maternal and paternal alleles are expressed in other cell types.

Management of hypoparathyroidism

Persistent hypoparathyroidism and pseudohypoparathyroidism are treated with oral calcium salts and vitamin D analogues, either 1α-hydroxycholecalciferol (alfacalcidol) or 1,25-dihydroxycholecalciferol (calcitriol). This therapy needs careful monitoring because of the risks of iatrogenic hypercalcaemia, hypercalciuria and nephrocalcinosis. Recombinant PTH is available as a subcutaneous injection and has been used in hypoparathyroidism (but not in pseudohypoparathyroidism as it would not be effective). It is much more expensive than calcium and vitamin D analogues and remains a second-line therapy but has the advantage that it is less likely to cause hypercalciuria. There is no specific treatment for pseudohypoparathyroidism other than to try to maintain calcium levels within the reference range using active vitamin D metabolites.

The adrenal glands

The adrenals comprise several separate endocrine glands within a single anatomical structure. The adrenal medulla is an extension of the sympathetic nervous system that secretes catecholamines into capillaries rather than synapses. Most of the adrenal cortex is made up of cells that secrete cortisol and adrenal androgens, and form part of the hypothalamic–pituitary–adrenal (HPA) axis. The small outer glomerulosa of the cortex secretes aldosterone under the control of the renin–angiotensin system. These functions are important in the integrated control of cardiovascular, metabolic and immune responses to stress.

There is increasing evidence that subtle alterations in adrenal function contribute to the pathogenesis of common diseases such as hypertension, obesity and type 2 diabetes mellitus. However, classical syndromes of adrenal hormone deficiency and excess are relatively rare.

Functional anatomy and physiology

Adrenal anatomy and function are shown in Figure 20.19. Histologically, the cortex is divided into three zones, but these function as two units (zona glomerulosa and zonae fasciculata/reticularis) that produce

corticosteroids in response to humoral stimuli. Pathways for the biosynthesis of corticosteroids are shown in Figure 20.20. Investigation of adrenal function is described under specific diseases below. The different types of adrenal disease are shown in Box 20.36.

Glucocorticoids

Cortisol is the major glucocorticoid in humans. Levels are highest in the morning on waking and lowest in the middle of the night. Cortisol rises dramatically during stress, including any illness. This elevation protects key metabolic functions (such as the maintenance of cerebral glucose supply during starvation) and inhibits potentially damaging inflammatory responses to infection and injury. The clinical importance of cortisol deficiency is, therefore, most obvious at times of stress.

More than 95% of circulating cortisol is bound to protein, principally cortisol-binding globulin, which is increased by oestrogens. It is the free fraction that is biologically active. Cortisol regulates cell function by binding to glucocorticoid receptors, which regulate the transcription of many genes. Cortisol can also activate mineralocorticoid receptors, but it does not normally do so because most cells containing mineralocorticoid receptors also express an enzyme called 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which inactivates cortisol by converting it to cortisone. Inhibitors of 11β-HSD2 (such as some liquorice) or pathogenic variants in the gene that encodes 11β-HSD2 cause cortisol to act as a mineralocorticoid, resulting in sodium retention and hypertension (see Box 20.45).

Mineralocorticoids

Aldosterone is the most important mineralocorticoid. It binds to mineralocorticoid receptors in the kidney and causes sodium retention and increased excretion of potassium and hydrogen ions (see Fig. 19.2). The principal stimulus to aldosterone secretion is angiotensin II, a peptide produced by activation of the renin–angiotensin system (see Fig. 20.19). Renin activity in the juxtaglomerular apparatus of the kidney is stimulated by low perfusion pressure in the afferent arteriole, low sodium filtration leading to low sodium concentrations at the macula densa, or increased sympathetic nerve activity. As a result, renin activity is increased in hypovolaemia and renal artery stenosis, and is approximately doubled when standing up from a recumbent position.

Catecholamines

In humans, only a small proportion of circulating noradrenaline (norepinephrine) is derived from the adrenal medulla; much more is released from sympathetic nerve endings. Conversion of noradrenaline to adrenaline (epinephrine) is catalysed by phenylethanolamine N-methyltransferase (PNMT), which is induced by glucocorticoids. Blood flow in the adrenal is centripetal, so that the medulla is bathed in high concentrations of cortisol and is the major source of circulating adrenaline. However, after surgical removal of the adrenal medullae, there appear to be no clinical consequences attributable to deficiency of circulating catecholamines.

Adrenal androgens

Adrenal androgens are secreted in response to ACTH and are the most abundant steroids in the blood stream. They are probably important in the initiation of puberty (adrenarche). The adrenals are also the major source of androgens in adult females and may be important in female libido.

Presenting problems in adrenal disease

Cushing syndrome

Cushing syndrome is caused by excessive activation of glucocorticoid receptors. It is most commonly iatrogenic, due to prolonged administration of synthetic glucocorticoids such as prednisolone. Endogenous

Cushing syndrome is uncommon but is caused by chronic over-production of cortisol by the adrenal glands, either as the result of an adrenal tumour or because of excessive production of ACTH by a pituitary tumour or ectopic ACTH production by other tumours.

Aetiology

The causes are shown in Box 20.37. Amongst endogenous causes, pituitary-dependent cortisol excess (by convention, called Cushing disease) accounts for approximately 80% of cases. Both Cushing disease and cortisol-secreting adrenal tumours are four times more common in women than men. In contrast, ectopic ACTH syndrome (often due to a small-cell carcinoma of the bronchus) is more common in men.

i **20.37 Classification of endogenous Cushing syndrome**

ACTH-dependent – 80%

- Pituitary adenoma secreting ACTH (Cushing disease) – 70%
- Ectopic ACTH syndrome (bronchial carcinoid, small-cell lung carcinoma, other neuroendocrine tumour) – 10%

Non-ACTH-dependent – 20%

- Adrenal adenoma – 15%
- Adrenal carcinoma – 5%
- ACTH-independent macronodular hyperplasia; primary pigmented nodular adrenal disease; McCune–Albright syndrome (together < 1%)

Hypercortisolism due to other causes (also referred to as pseudo-Cushing syndrome)

- Alcohol excess (biochemical and clinical features)
- Major depressive illness (biochemical features only, some clinical overlap)
- Primary obesity (mild biochemical features, some clinical overlap)

(ACTH = adrenocorticotrophic hormone)

Clinical assessment

The diverse manifestations of glucocorticoid excess are shown in Figure 20.21. Many of these are not specific to Cushing syndrome and, because spontaneous Cushing syndrome is rare, the positive predictive value of any single clinical feature alone is low. Moreover, some common disorders can be confused with Cushing syndrome because they are associated with alterations in cortisol secretion, e.g. obesity and depression (see Box 20.37). Features that favour Cushing syndrome in an obese patient are those of protein-wasting, including bruising, proximal myopathy and thin skin. Any clinical suspicion of cortisol excess is best resolved by further investigation.

It is vital to exclude iatrogenic causes in all patients with Cushing syndrome since even inhaled or topical glucocorticoids can induce the syndrome in susceptible individuals. A careful drug history must therefore be taken before embarking on complex investigations. An 0800–0900 hrs serum cortisol of < 100 nmol/L (3.6 μg/dL) in a patient with a normal sleep–wake pattern and Cushingoid appearance is consistent with exogenous synthetic glucocorticoid use (common); however, morning cortisol measurement cannot be used as a diagnostic test to confirm the presence of endogenous glucocorticoid excess.

Some clinical features are more common in ectopic ACTH syndrome. While ACTH-secreting pituitary tumours retain some negative feedback sensitivity to cortisol, this is absent in tumours that produce ectopic ACTH, typically resulting in higher levels of both ACTH and cortisol than are observed in pituitary-driven disease. The high ACTH levels are associated with marked pigmentation because of binding to melanocortin 1 receptors on melanocytes in the skin. The high cortisol

levels also overcome the capacity of 11β-HSD2 to inactivate cortisol in the kidney, causing hypokalaemic alkalosis, which aggravates myopathy and hyperglycaemia (by inhibiting insulin secretion). When the tumour that is secreting ACTH is malignant, the onset is usually rapid and may be associated with cachexia. For these reasons, the classical features of Cushing syndrome are less common in ectopic ACTH syndrome; if present, they suggest that a less aggressive tumour, such as a bronchial carcinoid, is responsible.

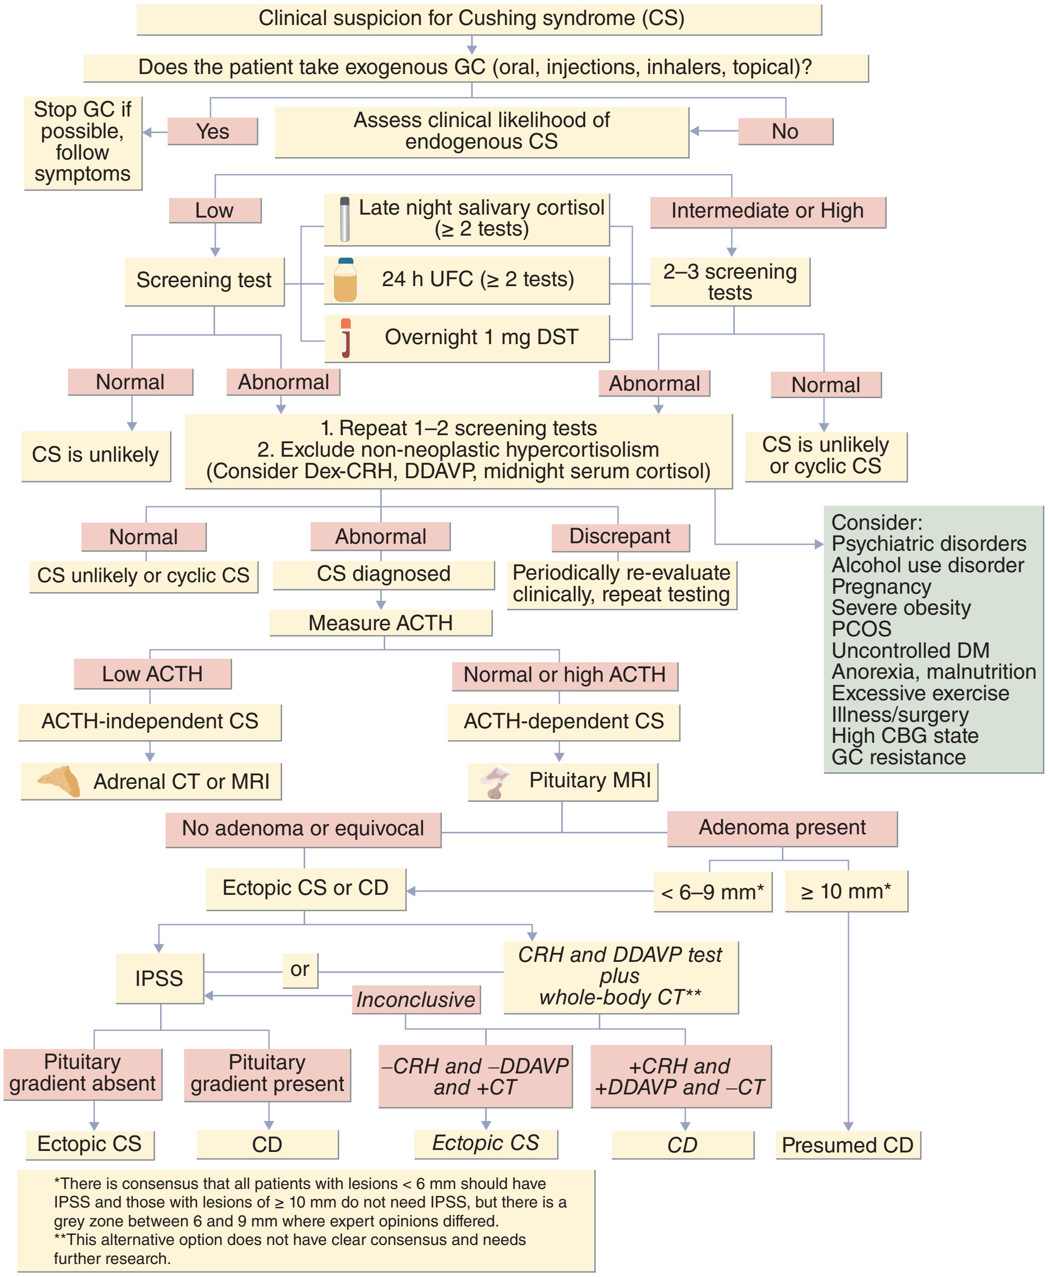
In Cushing disease, the pituitary tumour is usually a microadenoma (≤10 mm in diameter); hence other features of a pituitary macroadenoma (visual failure or disconnection hyperprolactinaemia, p. 737) are rare, but there may be secondary hypogonadism due to the inhibitory effects of excess glucocorticoids on gonadotrophin secretion. If a diagnosis of Cushing disease is suspected, early discussion/referral to a specialist is recommended.

Investigations

The large number of tests available for Cushing syndrome reflects the fact that each one has limited specificity and sensitivity in isolation. Accordingly, several tests are usually combined to establish the diagnosis. Testing for Cushing syndrome should be avoided under conditions of stress, such as an acute illness, because this activates the HPA axis, causing potentially spurious results. The diagnosis of Cushing syndrome is a two-step process (Fig. 20.22):

1. to establish whether the patient has Cushing syndrome, and
2. to define its cause.

Some additional tests are useful in all cases of Cushing syndrome, including plasma electrolytes, glucose, glycosylated haemoglobin and bone mineral density measurement.



Clinical suspicion for Cushing syndrome (CS)
Does the patient take exogenous GC (oral, injections, inhalers, topical)?
Stop GC if possible, follow symptoms
Yes
Assess clinical likelihood of endogenous CS
No
Low
Late night salivary cortisol (≥ 2 tests)
Intermediate or High
Screening test
24 h UFC (≥ 2 tests)
2–3 screening tests
Overnight 1 mg DST
Normal
Abnormal
Abnormal
Normal
CS is unlikely
1. Repeat 1–2 screening tests
2. Exclude non-neoplastic hypercortisolism
(Consider Dex-CRH, DDAVP, midnight serum cortisol)
CS is unlikely or cyclic CS
Consider:
Psychiatric disorders
Alcohol use disorder
Pregnancy
Severe obesity
PCOS
Uncontrolled DM
Anorexia, malnutrition
Excessive exercise
Illness/surgery
High CBG state
GC resistance
Normal

Presumed CD

*There is consensus that all patients with lesions < 6 mm should have IPSS and those with lesions of ≥ 10 mm do not need IPSS, but there is a grey zone between 6 and 9 mm where expert opinions differed.
**This alternative option does not have clear consensus and needs further research.

Fig. 20.22 Sequence of investigations in suspected Cushing syndrome. (ACTH = adrenocorticotrophic hormone; CBG = corticosteroid-binding globulin; CD = Cushing disease; CRH = corticotrophin-releasing hormone; CS = Cushing syndrome; CT = computed tomography scan; DDAVP = 1-deamino-8-D-arginine vasopressin; Dex = dexamethasone; DM = diabetes mellitus; DST = dexamethasone suppression test; GC = glucocorticoid; IPSS = inferior petrosal sinus sampling; MRI = magnetic resonance imaging; PCOS, polycystic ovary syndrome; UFC = urinary free cortisol)

Establishing the presence of Cushing syndrome

In patients where there is appropriate clinical suspicion, Cushing syndrome is confirmed by using two of three main tests:

1. Failure to suppress serum cortisol with low doses of oral dexamethasone
2. Loss of the normal circadian rhythm of cortisol, with inappropriately elevated late-night serum or salivary cortisol
3. Increased 24-hour urine free cortisol (lower sensitivity than the above tests) (see Fig. 20.22).

Dexamethasone is used for suppression testing because it does not cross-react in immunoassays for cortisol. An overnight dexamethasone suppression test (ONDST) involves administration of 1 mg dexamethasone at 2300 hrs and measurement of serum cortisol at 0900 hrs the following day; a normal response is a serum cortisol of < 50 nmol/L (1.8 µg/dL). It is important for any oestrogens to be stopped for 6 weeks prior to investigation to allow corticosteroid-binding globulin (CBG) levels to return to normal and to avoid false-positive responses, as most cortisol assays measure total cortisol, including that bound to CBG. Cyclicity of cortisol secretion is a feature of all types of Cushing syndrome and, if very variable, can confuse diagnosis. Use of multiple salivary cortisol samples over weeks or months can be helpful in diagnosis, but an elevated salivary cortisol alone should not be taken as proof of diagnosis. In iatrogenic Cushing syndrome, cortisol levels are low unless the patient is taking a glucocorticoid (such as prednisolone) that cross-reacts in immunoassays with cortisol.

Determining the underlying cause

Once the presence of Cushing syndrome is confirmed, measurement of plasma ACTH is the key to establishing the differential diagnosis; it is best measured in the morning around 0900 hrs. Low ACTH is indicative of a primary adrenal source. CT or MRI detects most adrenal tumours; adrenal carcinomas are usually large (> 5 cm) and have other features of malignancy. Where ACTH is normal or high, a pituitary MRI scan should be performed to determine whether a pituitary adenoma can be identified. Where pituitary MRI identifies a macroadenoma (≥ 10 mm), this is typically regarded as sufficient to confirm a pituitary source of ACTH excess (Cushing disease). More commonly, a smaller adenoma or no adenoma is identified and, in this eventuality, further tests are recommended to distinguish between a pituitary source or ectopic ACTH secretion (this is because small, non-functioning pituitary 'incidentalomas' are common and so a pituitary microadenoma cannot be presumed to be the source of ACTH). If available, inferior petrosal sinus sampling (IPSS) with measurement of plasma ACTH and a comparison of the results to peripheral levels is the best means of confirming Cushing disease (increased central:peripheral gradient). An alternative approach, where IPSS is unavailable, is corticotrophin-releasing hormone (CRH) and 1-deamino-8-D-arginine vasopressin (DDAVP) testing, plus whole-body CT (although global supply issues are likely to compromise CRH availability for the foreseeable future) (see Fig. 20.22).

Management

Untreated severe Cushing syndrome has a 50% 5-year mortality. Most patients are treated surgically, but medical therapy may be given in severe cases for a few weeks prior to operation to optimise perioperative health, or where there is recurrent or incurable disease. Drugs that inhibit glucocorticoid biosynthesis (metyrapone, ketoconazole and osilodrostat) form the mainstay of management. The dose of these agents is best titrated against serum cortisol levels or 24-hour urine free cortisol.

Cushing disease

Trans-sphenoidal surgery carried out by an experienced surgeon with selective removal of the adenoma is the treatment of choice, with approximately 70% of patients going into immediate remission. Around 20% of patients suffer a recurrence, often years later, emphasising the need for life-long follow-up.

Laparoscopic bilateral adrenalectomy performed by an expert surgeon effectively cures any type of ACTH-dependent Cushing syndrome, but in patients with Cushing disease (pituitary) this can result in Nelson syndrome – an invasive pituitary macroadenoma (which causes local mass effects) and very high ACTH levels (which cause pigmentation). The risk of Nelson syndrome is reported to be reduced by pituitary irradiation in some series, but not all.

The somatostatin analogue pasireotide is also licensed for the treatment of Cushing disease and works by suppressing ACTH secretion by the tumour.

Adrenal tumours

Laparoscopic adrenal surgery is the treatment of choice for adrenal adenomas. Surgery offers the only prospect of cure for adrenocortical carcinomas but, in general, prognosis is poor with high rates of recurrence, even in patients with localised disease at presentation. Radiotherapy to the tumour bed reduces the risk of local recurrence; systemic therapy consists of the adrenolytic drug mitotane and chemotherapy, but responses are often poor.

Ectopic ACTH syndrome

Localised tumours, such as bronchial carcinoids, should be removed surgically. In patients with incurable malignancy, it is important to reduce the severity of the Cushing syndrome using medical therapy (see above) or, if appropriate, bilateral adrenalectomy.

Therapeutic use of glucocorticoids

The remarkable anti-inflammatory properties of glucocorticoids have led to their use in a wide variety of clinical conditions but the hazards are significant. Equivalent doses of commonly used glucocorticoids are listed in Box 20.38. Topical preparations (dermal, rectal and inhaled) can also be absorbed into the systemic circulation, and although this rarely occurs to a sufficient degree to produce clinical features of Cushing syndrome, it can result in significant suppression of endogenous ACTH and cortisol secretion. Severe Cushing syndrome can result if there is concomitant administration of inhaled glucocorticoids and strong inhibitors of the liver enzyme CYP450 3A4, such as the antiretroviral drug ritonavir.

Adverse effects of glucocorticoids

The clinical features of glucocorticoid excess are illustrated in Figure 20.21. Adverse effects are related to dose, duration of therapy, and pre-existing conditions that might be worsened by glucocorticoid therapy, such as diabetes mellitus or osteoporosis. Osteoporosis is a particularly important problem because, for a given bone mineral density, the fracture risk is greater in glucocorticoid-treated patients than in post-menopausal osteoporosis. Therefore, when systemic glucocorticoids are prescribed and the anticipated duration of therapy is more than 3 months, bone-protective therapy should be considered. Rapid changes in glucocorticoid levels can also lead to marked mood disturbances, including depression, mania and insomnia. Glucocorticoid use also increases the white blood cell count (predominantly neutrophils), which must be taken into account when assessing patients with possible infection.

The anti-inflammatory effect of glucocorticoids may mask signs of disease. For example, perforation of a viscus may be masked and the patient may show no febrile response to an infection. Although there is debate about whether or not glucocorticoids increase the risk of peptic ulcer when used alone, they act synergistically with NSAIDs, including aspirin, to increase the risk of serious gastrointestinal adverse effects.

i 20.38 Approximate equivalent doses of glucocorticoids

- Hydrocortisone: 20 mg
- Cortisone acetate: 25 mg
- Prednisolone: 5 mg
- Dexamethasone: 0.5 mg

Latent tuberculosis may be reactivated and patients on glucocorticoids are at risk of severe varicella zoster virus infection, so should avoid contact with chickenpox or shingles if they are non-immune.

Management of glucocorticoid withdrawal

All glucocorticoid therapy, even if inhaled or applied topically, can suppress the HPA axis. In practice, this is likely to result in a crisis due to adrenal insufficiency on withdrawal of treatment only if glucocorticoids have been administered orally or systemically for longer than 4 weeks, if repeated courses have been prescribed within the previous year, or if the dose is higher than the equivalent of 5 mg prednisolone per day. In these circumstances, the drug, when it is no longer required for the underlying condition, must be withdrawn slowly at a rate dictated by the duration of treatment. If glucocorticoid therapy has been prolonged, then it may take many months for the HPA axis to recover. All patients must be advised to avoid sudden drug withdrawal. They should be issued with a steroid emergency card and/or wear an engraved bracelet (Box 20.39).

Recovery of the HPA axis is aided if there is no exogenous glucocorticoid present during the nocturnal surge in ACTH secretion. This can be achieved by giving glucocorticoid in the morning. Giving ACTH to stimulate adrenal recovery is of no value, as the pituitary remains suppressed.

Patients who have received supraphysiological glucocorticoids (5 mg of prednisolone or equivalent or more) for longer than four weeks, in whom the dose has dropped below a physiological equivalent, should be monitored for signs and symptoms of adrenal insufficiency and provided advice to cover 'sick days' with 10 mg prednisolone or equivalent as per the steroid emergency card (see Box 20.39). Adrenal function can be assessed biochemically (once the dose of glucocorticoid is below 5 mg prednisolone or equivalent) by measuring serum cortisol at 0800–0900 hrs prior to taking glucocorticoid medication. A morning cortisol over 300 nmol/L is reassuring in this context as > 99% of these patients would pass a stimulation test. In patients with a morning cortisol < 300 nmol/L, ACTH stimulation testing may help to determine adequacy of adrenal function. Glucocorticoid treatment can stop if adequate adrenal function has been demonstrated; however, if adrenal function is inadequate then encouraging recovery with a period of sub-physiological replacement (< 4 mg prednisolone or equivalent with sick day advice) may be necessary with repeat testing after 3–6 months. The thresholds cited above are for guidance only and may vary depending on the cortisol assay used. Even when glucocorticoids have been successfully withdrawn, short-term replacement therapy is often advised during significant intercurrent illness occurring in subsequent months, as the HPA axis may not be able to respond fully to severe stress.

20.39 Advice to patients on glucocorticoid replacement therapy

Intercurrent stress

- Febrile illness: double dose of hydrocortisone

Surgery

- Minor operation: hydrocortisone 100 mg IV with pre-medication
- Major operation: hydrocortisone 100 mg IV 4 times daily for 24 hrs, then 50 mg IV 4 times daily until ready to take tablets

Vomiting

- Patients must have parenteral hydrocortisone if unable to take it by mouth

Steroid card

- Patient should carry this at all times; it should give information regarding diagnosis, steroid, dose and doctor

Bracelet and emergency pack

- Patients should be encouraged to buy a bracelet and have it engraved with the diagnosis, current treatment and a reference number for a central database
- Patients should be given a hydrocortisone emergency pack and trained in the self-administration of hydrocortisone 100 mg IM; they should be advised to take the pack on holidays/trips abroad

(IM = intramuscular; IV = intravenous)

Adrenal insufficiency

Adrenal insufficiency (AI) results from inadequate secretion of cortisol and/or aldosterone. It is potentially fatal and notoriously variable in its presentation. A high index of suspicion is therefore required in patients with unexplained fatigue, hyponatraemia or hypotension. Causes are shown in Box 20.40. The most common is ACTH deficiency (secondary AI), usually because of inappropriate withdrawal of chronic glucocorticoid therapy or a large pituitary tumour. Addison disease is often used as a collective term for primary AI, but strictly speaking refers to destructive processes involving the adrenal cortex, such as autoimmune disease and tuberculosis.

Clinical assessment

The clinical features of adrenal insufficiency are shown in Box 20.41. In primary AI, either glucocorticoid or mineralocorticoid deficiency may come first, but eventually all patients fail to secrete both classes of corticosteroid (and adrenal androgens).

Patients may present with chronic features and/or in acute circulatory shock. With a chronic presentation, initial symptoms are often misdiagnosed as chronic fatigue syndrome or depression. In primary AI, weight loss is a uniform presenting feature. AI should also be considered in patients with hyponatraemia, even in the absence of symptoms.

Features of an acute adrenal crisis include circulatory shock with severe hypotension, hyponatraemia, hyperkalaemia and, in some instances, hypoglycaemia and hypercalcaemia. Muscle cramps, nausea, vomiting, diarrhoea and unexplained fever may be present. The crisis is often precipitated by intercurrent disease, surgery or infection.

Vitiligo occurs in 10%–20% of patients with autoimmune Addison disease.

Investigations

Treatment should not be delayed in patients with suspected acute adrenal crisis. A random blood sample should be taken for measurement of serum cortisol and, if possible, plasma ACTH; if the patient's clinical condition permits, it may be appropriate to spend 30 minutes performing an ACTH stimulation test (Box 20.42) before administering

20.40 Causes of adrenal insufficiency

Secondary (↓ACTH)

- Withdrawal of suppressive glucocorticoid therapy
- Hypothalamic or pituitary disease

Primary (↑ACTH)

Common destructive causes

- Autoimmune:
  - Sporadic
  - Polyendocrine syndromes (APS types 1 and 2)
- Tuberculosis
- HIV
- CMV
- Metastatic carcinoma
- Bilateral adrenalectomy

Rare destructive causes

- Lymphoma
- Intra-adrenal haemorrhage (Waterhouse–Friderichsen syndrome following meningococcal sepsis)
- Amyloidosis

Haemochromatosis

Corticosteroid biosynthetic enzyme defects

- Congenital adrenal hyperplasias
- Drugs: metyrapone, ketoconazole, etomidate

(ACTH = adrenocorticotrophic hormone; APS = autoendocrine polyendocrine syndromes; CMV = cytomegalovirus; HIV = human immunodeficiency virus)

20.41 Clinical and biochemical features of adrenal insufficiency

	Glucocorticoid insufficiency	Mineralocorticoid insufficiency	ACTH excess	Adrenal androgen insufficiency
Withdrawal of exogenous glucocorticoid	+	–	–	+
Hypopituitarism	+	–	–	+
Addison disease	+	+	+	+
Congenital adrenal hyperplasia (21-hydroxylase deficiency)	+	+	+	–
Clinical features	Weight loss, anorexia Malaise, weakness Nausea, vomiting Diarrhoea or constipation Postural hypotension Shock Hypoglycaemia Hyponatraemia (dilutional) Hypercalcaemia	Hypotension Shock Hyponatraemia (depletional) Hyperkalaemia	Pigmentation of: Sun-exposed areas Pressure areas (e.g. elbows, knees) Palmar creases, knuckles Mucous membranes Conjunctivae Recent scars	Decreased body hair and loss of libido, especially in females

(ACTH = adrenocorticotrophic hormone)

20.42 How and when to do an ACTH stimulation test*

Use

- Diagnosis of primary or secondary adrenal insufficiency
- Assessment of HPA axis in patients taking suppressive glucocorticoid therapy
- Relies on ACTH-dependent adrenal atrophy in secondary adrenal insufficiency, so may not detect acute ACTH deficiency (e.g. in pituitary apoplexy)

Dose

- 250 μg ACTH$_{1–24}$ (Synacthen) by IM injection at any time of day

Blood samples

- 0 and 30 mins for plasma cortisol
- 0 mins also for ACTH (on ice) if Addison disease is being considered (patient not known to have pituitary disease or to be taking exogenous glucocorticoids)

Results

- Normal subjects: plasma cortisol > 430 nmol/L (approximately 15.6 μg/dL) either at baseline or at 30 mins
- Incremental change in cortisol is not a criterion

*May also be referred to as 'short Synacthen', cosyntropin, corticotropin or tetracosactide test
(ACTH = adrenocorticotrophic hormone; HPA = hypothalamic–pituitary–adrenal; IM = intramuscular)

hydrocortisone, but delays must be avoided if there is circulatory compromise. Investigations should be performed before treatment is given in patients who present with features suggestive of chronic adrenal insufficiency.

Assessment of glucocorticoids

Random serum cortisol is usually low in patients with AI but it may be within the reference range, yet inappropriately low, for a seriously ill patient. Random measurement of serum cortisol cannot therefore be used to confirm or refute the diagnosis, unless the value is above 430 nmol/L (> 15.6 μg/dL), which effectively excludes AI. However, random cortisol > 300 nmol/L is almost never associated with AI and may be sufficiently reassuring where the clinical index of suspicion (pre-test probability) is low. It is important to note that thresholds cited here are indicative and will vary between different cortisol assays. More useful is the ACTH stimulation test described in Box 20.42. Cortisol levels fail to increase in response to exogenous ACTH in patients with primary or secondary AI. These can be distinguished by measurement of ACTH (which is low in secondary AI and high in primary AI).

Assessment of mineralocorticoids

Mineralocorticoid secretion in patients with suspected primary AI cannot be adequately assessed by electrolyte measurements since hyponatraemia occurs in both aldosterone and cortisol deficiency (see Box 20.41). Hyperkalaemia is common, but not universal, in aldosterone deficiency. Plasma renin and aldosterone should be measured in the supine position. In mineralocorticoid deficiency, plasma renin activity is high, with plasma aldosterone being either low or in the lower part of the reference range.

Assessment of adrenal androgens

This is not necessary in men because testosterone from the testes is the principal androgen. In women, dehydroepiandrosterone sulphate (DHEAS) and androstenedione may be measured in a random specimen of blood, though levels are highest in the morning.

Other tests to establish the cause

Patients with unexplained secondary AI should be investigated as described in Box 20.51. In patients with elevated ACTH, further tests are required to establish the cause of primary AI. Adrenal autoantibodies to 21-hydroxylase are frequently positive in autoimmune adrenal failure. If antibody tests are negative, imaging of the adrenal glands with CT or MRI is indicated. Tuberculosis causes adrenal calcification, visible on plain X-ray or ultrasound scan. A human immunodeficiency virus (HIV) test should be performed if relevant risk factors are present. Adrenal metastases are a rare cause of primary AI. Patients with evidence of autoimmune adrenal failure should be screened for other organ-specific autoimmune diseases, such as thyroid disease, pernicious anaemia and coeliac disease.

Management

Patients with AI always need glucocorticoid replacement therapy and usually, but not always, mineralocorticoid therapy. There is some evidence that adrenal androgen replacement may also be beneficial in some women. Other treatments depend on the underlying cause. The emergency management of adrenal crisis is described in Box 20.43.

Glucocorticoid replacement

Adrenal replacement therapy consists of oral hydrocortisone (cortisol) 15–20 mg daily in divided doses, typically 10 mg on waking and 5 mg at

20.43 Management of adrenal crisis

Correct volume depletion

- IV saline as required to normalise blood pressure and pulse
- In severe hyponatraemia (<125 mmol/L) avoid increases of plasma Na >10 mmol/L/day to prevent pontine demyelination
- Fludrocortisone is not required during the acute phase of treatment

Replace glucocorticoids

- IV hydrocortisone succinate 100 mg stat, and 50 mg 4 times daily for first 12–24 hrs
- Continue parenteral hydrocortisone (50 mg IM 4 times daily) until patient is well enough for reliable oral therapy

Correct other metabolic abnormalities

- Acute hypoglycaemia: IV 10% glucose
- Hyperkalaemia: should respond to volume replacement but occasionally requires specific therapy (see Box 19.17)

Identify and treat underlying cause

- Consider acute precipitant, such as infection
- Consider adrenal or pituitary pathology (see Box 20.40)

(IM = intramuscular; IV = intravenous)

20.44 Glucocorticoids in old age

- **Adrenal insufficiency**: often insidious and may present with tiredness, drowsiness, delirium, falls, immobility and orthostatic hypotension.
- **Glucocorticoid therapy**: especially hazardous in older people, who are already relatively immunocompromised and susceptible to osteoporosis, diabetes, hypertension and other complications.
- **‘Physiological’ glucocorticoid replacement therapy**: increased risk of adrenal crisis because adherence may be poor and there is a greater incidence of intercurrent illness. Patient and carer education, with regular reinforcement of the principles described in Box 20.39, is crucial.

around 1500 hrs. These are physiological replacement doses that should not cause Cushingoid side-effects. The dose may need to be adjusted for the individual patient but this is subjective. Excess weight gain usually indicates over-replacement, while persistent lethargy or hyperpigmentation may be due to an inadequate dose or lack of absorption. Measurement of serum cortisol levels is not usually helpful. Advice to patients dependent on glucocorticoid replacement is given in Box 20.39 and considerations in respect of glucocorticoids in old age are given in Box 20.44.

Mineralocorticoid replacement

Fludrocortisone (9α-fluoro-hydrocortisone) is administered at the usual dose of 0.05–0.15 mg daily, and adequacy of replacement may be assessed by measurement of blood pressure, plasma electrolytes and plasma renin. It is indicated for virtually every patient with primary AI, but is not needed in secondary AI.

Androgen replacement

Androgen replacement with DHEAS (25–50 mg/day) is occasionally given to women with primary AI who have symptoms of reduced libido and fatigue, but the evidence in support of this is not robust and treatment may be associated with side-effects such as acne and hirsutism.

Incidental adrenal mass

Enlarged or hyperplastic adrenal glands are commonly found on CT or MRI scans of the abdomen that have been performed for other indications. Such lesions are known as adrenal ‘incidentalomas’. The prevalence increases with age and they are present in up to 10% of adults aged 70 years and older.

Sixty per cent of adrenal incidentalomas are non-functioning adrenal adenomas. The remainder includes functional tumours of the adrenal cortex (secreting cortisol, aldosterone or androgens), phaeochromocytomas, primary and secondary carcinomas, hamartomas and other rare disorders, including granulomatous infiltrations. Bilateral masses are frequently identified and may be simple adrenal adenomas, but the diagnostic possibilities also include phaeochromocytomas, tuberculosis, primary adrenal lymphoma, metastatic disease and bilateral nodular hyperplasia.

Clinical assessment and investigations

There are two key questions to be resolved: is the lesion secreting hormones, and is it benign or malignant? These are best assessed by a dedicated adrenal multidisciplinary team (MDT).

Patients with an adrenal incidentaloma are usually asymptomatic. However, clinical signs and symptoms of excess glucocorticoids, mineralocorticoids, catecholamines and, in women, androgens should be sought, as discussed elsewhere in this chapter. Investigations should include a dexamethasone suppression test, urine or plasma metanephrines and, in virilised women, measurement of serum testosterone, DHEAS and androstenedione. Patients with hypertension should be investigated for mineralocorticoid excess, as described below.

CT and MRI are equally effective in assessing the malignant potential of an adrenal mass, using the following parameters:

- *Size*. The larger the lesion, the greater the malignant potential. Around 90% of adrenocortical carcinomas are over 4 cm in diameter, but specificity is poor since only approximately 25% of such lesions are malignant.
- *Configuration*. Homogeneous and smooth lesions are more likely to be benign. The presence of metastatic lesions elsewhere increases the risk of malignancy, but as many as two-thirds of adrenal incidentalomas in patients with cancer are benign.
- *Presence of lipid*. Adenomas are usually lipid-rich, resulting in an attenuation of ≤ 10 Hounsfield units (HU) on an unenhanced CT, and in signal dropout on chemical shift MRI.
- *Enhancement*. Benign lesions demonstrate rapid washout of contrast, whereas malignant lesions tend to retain contrast.

Histology in a sample obtained by CT-guided biopsy is rarely indicated, and is not useful in distinguishing an adrenal adenoma from an adrenocortical carcinoma. Biopsy is occasionally helpful in confirming adrenal metastases from other cancers, but should be avoided if either phaeochromocytoma or primary adrenal cancer is suspected in order to avoid precipitation of a hypertensive crisis or seeding of tumour cells, respectively. An endocrine opinion must be sought before any biopsy.

Management

Homogeneous lesions with attenuation ≤ 10 HU do not require intervention or follow-up, irrespective of size. Functional lesions and tumours of ≥ 4 cm that are inhomogeneous or have attenuation ≥ 20 HU should be considered for surgery. Intermediate lesions should be considered for radiological follow-up. Optimal management of patients with low-grade cortisol secretion (termed mild autonomous cortisol secretion), as demonstrated by the dexamethasone suppression test, remains to be established.

Primary hyperaldosteronism

Estimates of the prevalence of primary hyperaldosteronism vary according to the screening tests employed, but it may occur in as many as 10% of people with hypertension. Indications to test for mineralocorticoid excess in hypertensive patients include hypokalaemia (including hypokalaemia induced by thiazide diuretics), poor control of blood pressure with conventional therapy, a family history of early-onset hypertension, or presentation at a young age.

i 20.45 Causes of mineralocorticoid excess

With renin high and aldosterone high (secondary hyperaldosteronism)

- Inadequate renal perfusion (diuretic therapy, cardiac failure, liver failure, nephrotic syndrome, renal artery stenosis)
- Renin-secreting renal tumour (very rare)

With renin low and aldosterone high (primary hyperaldosteronism)

- Adrenal adenoma secreting aldosterone (Conn syndrome)
- Idiopathic bilateral adrenal hyperplasia
- Glucocorticoid-suppressible hyperaldosteronism (rare)

With renin low and aldosterone low (non-aldosterone-dependent activation of mineralocorticoid pathway)

- Ectopic ACTH syndrome
- Liquorice misuse (inhibition of 11β-HSD2)
- Liddle syndrome
- 11-deoxycorticosterone-secreting adrenal tumour
- Rare forms of congenital adrenal hyperplasia and 11β-HSD2 deficiency

(11β-HSD2 = 11β-hydroxysteroid dehydrogenase type 2; ACTH = adrenocorticotrophic hormone)

Causes of excessive activation of mineralocorticoid receptors are shown in Box 20.45. It is important to differentiate primary hyperaldosteronism, caused by an intrinsic abnormality of the adrenal glands resulting in aldosterone excess, from secondary hyperaldosteronism, which is usually a consequence of enhanced activity of renin in response to inadequate renal perfusion and hypotension. Most individuals with primary hyperaldosteronism have bilateral adrenal hyperplasia (idiopathic hyperaldosteronism), while only a minority have an aldosterone-producing adenoma (APA; Conn syndrome). Glucocorticoid-suppressible hyperaldosteronism is a rare autosomal dominant condition in which aldosterone is secreted 'ectopically' from the adrenal zonae fasciculata/reticularis in response to ACTH. Rarely, the mineralocorticoid receptor pathway in the distal nephron is activated, even though aldosterone concentrations are low.

Clinical features

Individuals with primary hyperaldosteronism are usually asymptomatic, but may have features of sodium retention or potassium loss. Sodium retention may cause oedema, while hypokalaemia may cause muscle weakness (or even paralysis, especially in South-east Asian populations), polyuria (secondary to renal tubular damage, which produces arginine vasopressin resistance) and occasionally tetany (because of associated metabolic alkalosis and low ionised calcium). Blood pressure is elevated, but accelerated phase hypertension is rare.

Investigations

Biochemical

Routine blood tests may show a hypokalaemic alkalosis. Sodium is usually at the upper end of the reference range in primary hyperaldosteronism, but is characteristically low in secondary hyperaldosteronism (because low plasma volume stimulates arginine vasopressin (antidiuretic hormone, ADH) release and high angiotensin II levels stimulate thirst). The key measurements are plasma renin and aldosterone (see Box 20.45), and in many centres the aldosterone:renin ratio (ARR) is employed as a screening test for primary hyperaldosteronism in hypertensive patients. Almost all antihypertensive drugs interfere with this ratio (β-blockers inhibit, while diuretics stimulate renin secretion). Thus, individuals with an elevated ARR require further testing after stopping many antihypertensive drugs for at least 4 weeks (although if the ratio is still high despite a patient taking ACE inhibitors or angiotensin receptor–blocking drugs then this need not be done as these agents would normally cause a lowering of the ratio). If necessary, antihypertensive agents that have minimal effects on the renin–angiotensin system, such as calcium antagonists and α-blockers, may be substituted. Oral potassium supplementation may also be required, as hypokalaemia itself suppresses renin activity. If, on repeat testing, plasma renin is low and aldosterone concentrations are elevated, then further investigation under specialist supervision may include saline or fludrocortisone suppression tests.

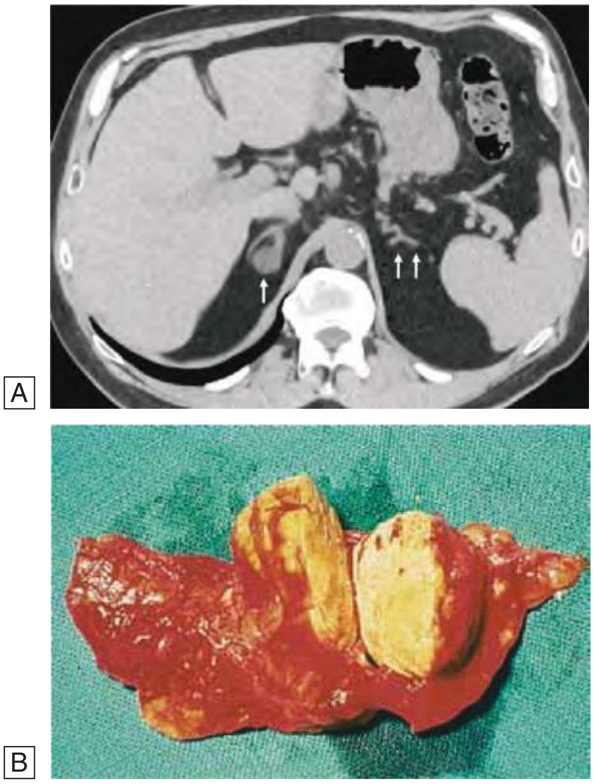

Fig. 20.23 Aldosterone-producing adenoma causing Conn syndrome. **A** CT scan demonstrating a low attenuation nodule in relation to the medial limb of the right adrenal gland (single arrow) consistent with a lipid-rich adenoma. The left adrenal gland is normal (double arrow). **B** The tumour is 'canary yellow' because of intracellular lipid accumulation.

Imaging and localisation

Imaging with CT or MRI will identify most APAs (Fig. 20.23A), but it is important to recognise the risk of false positives (non-functioning adrenal adenomas are common) and false negatives (imaging may have insufficient resolution to identify adenomas with a diameter of less than 0.5 cm). If the imaging is inconclusive and there is an intention to proceed with surgery on the basis of strong biochemical evidence of an APA, then adrenal vein catheterisation with measurement of aldosterone (and cortisol to confirm positioning of the catheters) is usually required. In some centres, this is performed even in the presence of a unilateral 'adenoma' in patients aged > 30 years, to avoid inadvertent removal of an incidental non-functioning adenoma contralateral to a radiologically inapparent cause of aldosterone excess.

Management

Mineralocorticoid receptor antagonists (spironolactone and eplerenone) are valuable in treating both hypokalaemia and hypertension in all forms of mineralocorticoid excess. Up to 20% of males develop gynaecomastia on spironolactone. Amiloride (10–40 mg/day), which blocks the epithelial sodium channel regulated by aldosterone, is an alternative.

In patients with an APA, medical therapy is usually given for a few weeks to normalise whole-body electrolyte balance before unilateral adrenalectomy. Laparoscopic surgery cures the biochemical abnormality but, depending on the pre-operative duration, hypertension remains in as many as 70% of cases, probably because of irreversible damage to the systemic microcirculation.

Phaeochromocytoma and paraganglioma

These are rare neuroendocrine tumours that may secrete catecholamines (adrenaline/epinephrine, noradrenaline/norepinephrine). Approximately 80% of these tumours occur in the adrenal medulla (phaeochromocytomas), while 20% arise elsewhere in the body in sympathetic ganglia (paragangliomas). Most are benign, but approximately 15% show malignant features (local invasion or metastases) at presentation or at a later date. Around 40% are associated with inherited disorders, including neurofibromatosis, von Hippel–Lindau syndrome, MEN 2a and MEN 2b. Paragangliomas are particularly associated with pathogenic variants in the succinate dehydrogenase (SDH) A, B, C and D genes. Other genetic causes include pathogenic variants in *SDHAF2*, *TMEN127* and *MAX*.

Clinical features

These depend on the pattern of catecholamine secretion and are listed in Box 20.46.

Some patients present with hypertension, although it has been estimated that phaeochromocytoma accounts for less than 0.1% of cases of hypertension. The presentation may be with a complication of hypertension, such as stroke, myocardial infarction, left ventricular failure, hypertensive retinopathy or accelerated phase hypertension. The apparent paradox of postural hypotension between episodes is explained by 'pressure natriuresis' during hypertensive episodes so that intravascular volume is reduced. There may also be features of the familial syndromes associated with phaeochromocytoma. Paragangliomas are often non-functioning.

Investigations

Excessive secretion of catecholamines can be confirmed by measuring metabolites in plasma and/or urine (metanephrine and normetanephrine). There is a high 'false-positive' rate, as elevated metanephrine concentrations may be seen in stressed patients (during acute illness, following vigorous exercise or severe pain) and following ingestion of some drugs such as tricyclic antidepressants. For this reason, a repeat sample should usually be requested if elevated levels are found, although, as a rule, the higher the concentration of metanephrines, the more likely the diagnosis of phaeochromocytoma/paraganglioma. Serum chromogranin A may be a useful tumour marker in patients with non-secretory tumours and/or metastatic disease. 3-methoxytyramine (3-MT) is a dopamine metabolite, which may be elevated in head and neck paragangliomas and in paragangliomas with a greater propensity to metastasise, especially those associated with SDH B paraganglioma syndrome. Genetic testing should be considered in all individuals with phaeochromocytoma/paraganglioma.

i 20.46 Clinical features of phaeochromocytoma/functional paraganglioma

- Hypertension (usually paroxysmal; often postural drop of blood pressure)
- Paroxysms of:
  - Pallor (occasionally flushing)
  - Palpitations, sweating
  - Headache
  - Anxiety (angor animi)
- Abdominal pain, vomiting
- Constipation
- Weight loss
- Glucose intolerance

Localisation

Phaeochromocytomas are usually identified by abdominal CT or MRI (Fig. 20.24). Localisation of paragangliomas may be more difficult. Scintigraphy using meta-iodobenzyl guanidine (MIBG) can be useful, particularly if combined with CT, for adrenal phaeochromocytoma, but is often negative in paraganglioma. ^{18}F-deoxyglucose PET or gallium-68 (^{68}Ga)-DOTANOC or DOTATATE PET-CT are especially useful for detection of malignant disease and for confirming an imaging abnormality as a paraganglioma in an individual with underlying risk due to a genetic syndrome.

Management

In functioning tumours, medical therapy is required to prepare the patient for surgery, preferably for a minimum of 6 weeks, to allow restoration of normal plasma volume. Traditionally the non-competitive α-blocker phenoxybenzamine (10–20 mg orally 3–4 times daily) is used, but competitive α-blockers, such as doxazosin, provide equally effective preparation with fewer side-effects. If α-blockade produces a marked tachycardia, then a β-blocker such as propranolol can be added. On no account should a β-blocker be given before an α-blocker, as this may cause a paradoxical rise in blood pressure due to unopposed α-mediated vasoconstriction.

During surgery, intravenous sodium nitroprusside, magnesium and the short-acting α-antagonist phentolamine are useful in controlling hypertensive episodes, which may result from anaesthetic induction or tumour mobilisation. Post-operative hypotension may occur and require volume expansion and, very occasionally, noradrenaline (norepinephrine) infusion, but is uncommon if the patient has been adequately prepared.

Metastatic tumours may behave in an aggressive or a very indolent fashion. Management options include debulking surgery, radionuclide therapy with ^{131}I MIBG or lutetium-177 (^{177}Lu)-DOTATATE, chemotherapy and (chemo)embolisation of hepatic metastases; some may respond to tyrosine kinase and angiogenesis inhibitors.

Congenital adrenal hyperplasia

Pathophysiology and clinical features

Inherited defects in enzymes of the cortisol biosynthetic pathway (see Fig. 20.20) result in insufficiency of hormones downstream of the block, with impaired negative feedback and increased ACTH secretion. ACTH

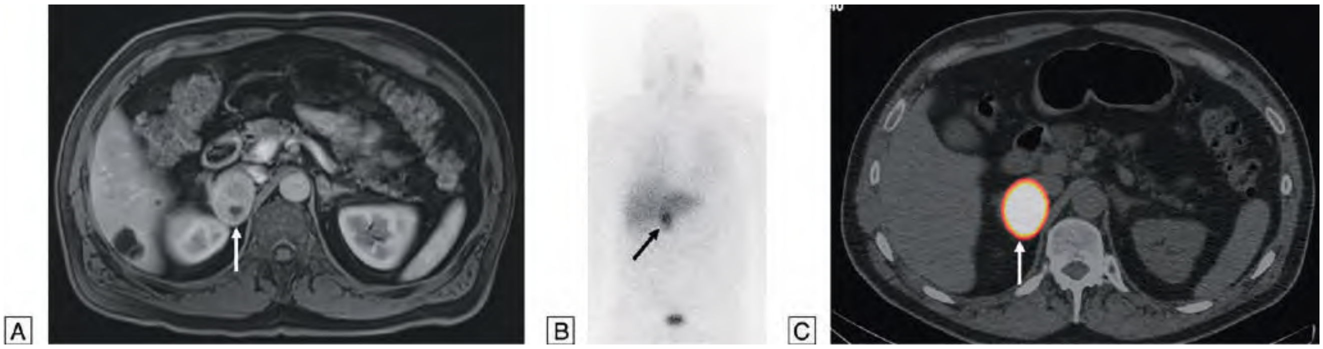

Fig. 20.24 A Contrast-enhanced MRI demonstrating a 5 cm right adrenal mass (arrow) consistent with a phaeochromocytoma. B Planar ^{123}I MIBG scan shows a solitary focus of abnormal MIBG uptake projected over the right upper abdomen (arrow). C SPECT/CT localising the uptake to the right adrenal mass (arrow).

then stimulates the production of steroids upstream of the enzyme block. This produces adrenal hyperplasia and a combination of clinical features that depend on the severity and site of the defect in biosynthesis. All of these enzyme abnormalities are inherited as autosomal recessive traits.

The most common enzyme defect is 21-hydroxylase deficiency. This results in impaired synthesis of cortisol and aldosterone, and accumulation of 17-OH-progesterone, which is then diverted to form adrenal androgens. In about one-third of cases, this defect is severe and presents in infancy with features of glucocorticoid and mineralocorticoid deficiency (see Box 20.41) and androgen excess, such as ambiguous genitalia in girls. In the other two-thirds, mineralocorticoid secretion is adequate but there may be features of AI and/or ACTH and androgen excess, including precocious pseudo-puberty, which is distinguished from 'true' precocious puberty by low gonadotrophins. Sometimes the mildest enzyme defects are not apparent until adult life, when females may present with amenorrhoea and/or hirsutism. This is called 'non-classical' or 'late-onset' congenital adrenal hyperplasia.

Defects of all the other enzymes in Figure 20.20 are rare. Both 17-hydroxylase and 11β-hydroxylase deficiency may produce hypertension due to excess production of 11-deoxycorticosterone, which has mineralocorticoid activity.

Investigations

Circulating 17-OH-progesterone levels are raised in 21-hydroxylase deficiency, but this may be demonstrated only after ACTH administration (ACTH stimulation test) in late-onset cases. To avoid salt-wasting crises in infancy, 17-OH-progesterone can be routinely measured in heel-prick blood spot samples taken from all infants in the first week of life. Assessment is otherwise as described earlier for AI.

Management

The aim is to replace deficient corticosteroids and to suppress ACTH-driven adrenal androgen production. A careful balance is required between adequate suppression of adrenal androgen excess and excessive glucocorticoid replacement resulting in features of Cushing syndrome. In children, growth velocity is an important measurement, since either under- or over-replacement with glucocorticoids suppresses growth. In adults, there is no uniformly agreed adrenal replacement regimen, and clinical features (menstrual cycle, hirsutism, weight gain, blood pressure) and biochemical profiles (plasma renin, 17-OH-progesterone and testosterone levels) provide a guide.

Women with late-onset 21-hydroxylase deficiency may not require corticosteroid replacement. If hirsutism is the main problem, anti-androgen therapy may be just as effective.

The endocrine pancreas and gastrointestinal tract

A series of hormones are secreted from cells distributed throughout the gastrointestinal tract and pancreas. Functional anatomy and physiology are described in Chapters 22 and 23. Diseases associated with abnormalities of these hormones are listed in Box 20.47. Most are rare, with the exception of diabetes mellitus (Ch. 21).

Presenting problems in endocrine pancreas disease

Hypoglycaemic disorders

Hypoglycaemia most commonly occurs as a side-effect of treatment with insulin or sulphonylurea drugs in people with diabetes mellitus. In non-diabetic individuals, symptomatic hypoglycaemia is rare, but it is not uncommon to detect venous blood glucose concentrations below 3.0 mmol/L (54 mg/dL) in asymptomatic patients. Similarly, the increasingly common use of continuous glucose monitoring systems in non-diabetic individuals identifies apparent 'hypoglycaemia' in a significant proportion of healthy people. For these reasons, and because the symptoms of hypoglycaemia are non-specific, investigation of a potential hypoglycaemic disorder should be pursued only if all three conditions of the Whipple triad are met (Fig. 20.25). There is no specific blood glucose concentration at which hypoglycaemia can be said to occur, although the lower the blood glucose concentration, the more likely it is to have pathological significance. Investigations are unlikely to be needed unless glucose concentrations below 3.0 mmol/L are observed; many patients with true hypoglycaemia demonstrate glucose levels below 2.2 mmol/L (40 mg/dL).

Other drugs
Hyperinsulinism of infancy
Insulin antibody syndrome
Post-bariatric/gastric surgery

Fig. 20.25 Differential diagnosis of hypoglycaemic disorders. Measurement of insulin and C-peptide concentrations during an episode is helpful in determining the underlying cause.

Hypoglycaemia is often precipitated and/or exacerbated by fasting and physical exercise. With the increasing use of bariatric surgery, and more specifically gastric bypass surgery, more patients are presenting with post-prandial hypoglycaemia due to excess stimulated insulin secretion due to the rapid carbohydrate loads being delivered directly to the small intestine.

Clinical assessment

The clinical features of hypoglycaemia are described in the section on insulin-induced hypoglycaemia in Chapter 21. Individuals with chronic hypoglycaemic disorders often have attenuated autonomic responses and 'impaired awareness of hypoglycaemia', and may present with a wide variety of features of neuroglycopenia, including odd behaviour and convulsions. The symptoms are usually episodic and relieved by consumption of carbohydrate. Hypoglycaemia should be considered in all comatose patients, even if there is an apparently obvious cause, such as hemiplegic stroke or alcohol intoxication.

Investigations

Does the patient have a hypoglycaemic disorder?

Patients who present acutely with delirium, coma, convulsions or stroke should be tested for hypoglycaemia at the bedside with a capillary blood glucose sample. While this is sufficient to exclude hypoglycaemia, blood glucose meters are relatively inaccurate in the hypoglycaemic range and the diagnosis should always be confirmed by a laboratory-based glucose measurement. At the same time, a sample should be taken for later measurement of alcohol, insulin, C-peptide, cortisol and sulphonylurea levels, if hypoglycaemia is confirmed. Taking these samples during an acute presentation prevents subsequent unnecessary dynamic tests and is of medico-legal importance in cases where poisoning is suspected.

Patients who attend the outpatient clinic with episodic symptoms suggestive of hypoglycaemia present a more challenging problem. The gold standard diagnostic test is the prolonged (72-hour) fast. If symptoms of hypoglycaemia develop during the fast, then blood samples should be taken to confirm hypoglycaemia and for measurement of insulin and C-peptide. Hypoglycaemia is then corrected with oral or intravenous glucose and the Whipple triad completed by confirmation of the resolution of symptoms. A mixed meal tolerance test may be undertaken in suspected post-prandial hypoglycaemia.

What is the cause of the hypoglycaemia?

In the acute setting, the underlying diagnosis is often obvious. In non-diabetic individuals, alcohol excess is the most common cause of hypoglycaemia in the UK, but other drugs – e.g. salicylates, quinine and pentamidine – may also be implicated. Hypoglycaemia is one of many metabolic derangements that occur in patients with hepatic failure, renal failure, adrenal insufficiency, sepsis or malaria.

Hypoglycaemia in the absence of insulin, or any insulin-like factor, in the blood indicates impaired gluconeogenesis and/or availability of glucose from glycogen in the liver. Hypoglycaemia associated with high insulin and low C-peptide concentrations is indicative of administration of exogenous insulin, either factitiously or feloniously. Adults with high insulin and C-peptide concentrations during an episode of hypoglycaemia are most likely to have an insulinoma, but insulin antibody syndrome and sulphonylurea ingestion should also be considered (the latter particularly in individuals with access to such medication, such as health-care professionals or family members of someone with type 2 diabetes). Individuals with post-prandial hypoglycaemia following bariatric/gastric surgery will also have elevated insulin and C-peptide concentrations, but the diagnosis is usually obvious from the history. Suppressed plasma β-hydroxybutyrate helps confirm inappropriate insulin secretion during fasting. Usually, insulinomas in the pancreas are small (< 10 mm diameter) but can be identified by CT, MRI or ultrasound (endoscopic or laparoscopic). Imaging should include the liver since around 10% of insulinomas are malignant and may metastasise to the liver. Rarely, large non-pancreatic tumours, such as sarcomas, may cause recurrent hypoglycaemia because of their ability to produce excess pro-insulin-like growth factor-2 (pro-IGF-2), which has considerable structural homology to insulin.

Management

Treatment of acute hypoglycaemia should be initiated as soon as laboratory blood samples have been taken and should *not* be deferred until formal laboratory confirmation has been obtained. Intravenous dextrose (5% or 10%) is effective in the short term in the obtunded patient and should be followed on recovery with oral unrefined carbohydrate (starch). Continuous dextrose infusion may be necessary, especially in sulphonylurea poisoning. Intramuscular glucagon (1 mg) stimulates hepatic glucose release but is ineffective in patients with depleted glycogen reserves, such as in alcohol excess or liver disease.

Chronic recurrent hypoglycaemia in insulin-secreting tumours can be treated by regular consumption of oral carbohydrate combined with agents that inhibit insulin secretion (diazoxide or somatostatin analogues). Insulinomas are resected when benign, providing the individual is fit enough to undergo surgery. Metastatic malignant insulinomas may be incurable and are managed along the same lines as other metastatic neuroendocrine tumours (see below). Insulin antibody syndrome may settle spontaneously after a few months, but immunosuppressive therapy with glucocorticoids and biologics (such as rituximab) may be required.

Gastroenteropancreatic neuroendocrine tumours

Neuroendocrine tumours (NETs) are a heterogeneous group derived from neuroendocrine cells in many organs, including the gastrointestinal tract, lung, adrenals (phaeochromocytoma) and thyroid (medullary carcinoma). Most NETs occur sporadically but a proportion are associated with genetic cancer syndromes, such as MEN 1, 2a and 2b, and neurofibromatosis type 1. NETs may secrete hormones into the circulation.

Gastroenteropancreatic NETs arise in organs that are derived embryologically from the gastrointestinal tract. Most commonly, they occur in the small bowel but they can also arise elsewhere in the bowel, pancreas, thymus and bronchi. The term 'carcinoid' is often used when referring to non-pancreatic gastrointestinal NETs because, when initially described, they were thought to behave in an indolent fashion compared with conventional cancers. It is now recognised that there is a wide spectrum of malignant potential for all NETs; some are more usually benign (most insulinomas and appendiceal carcinoid tumours), while others have an aggressive clinical course with widespread metastases (small-cell carcinoma of the lung). The majority of gastroenteropancreatic NETs behave in an intermediate manner, with relatively slow growth but a propensity to invade and metastasise to remote organs, especially the liver.

Clinical features

Patients with gastroenteropancreatic NETs often have a history of abdominal pain over many years prior to diagnosis and usually present with local mass effects, such as small-bowel obstruction, appendicitis and pain from hepatic metastases. Thymic and bronchial carcinoids occasionally present with ectopic ACTH syndrome. Pancreatic NETs can also cause hormone excess (Box 20.48) but most are non-functional. The classic 'carcinoid syndrome' (Box 20.49) occurs when vasoactive hormones reach the

20.48 Pancreatic neuroendocrine tumours

Tumour	Hormone	Effects
Gastrinoma	Gastrin	Peptic ulcer and steatorrhoea (Zollinger–Ellison syndrome)
Insulinoma	Insulin	Recurrent hypoglycaemia (see above)
VIPoma	Vasoactive intestinal peptide (VIP)	Watery diarrhoea and hypokalaemia
Glucagonoma	Glucagon	Diabetes mellitus, necrolytic migratory erythema
Somatostatinoma	Somatostatin	Diabetes mellitus and steatorrhoea

20.49 Clinical features of the carcinoid syndrome

- Episodic flushing, wheezing and diarrhoea
- Facial telangiectasia
- Cardiac involvement (tricuspid regurgitation, pulmonary stenosis, right ventricular endocardial plaques) leading to heart failure

systemic circulation. In the case of gastrointestinal carcinoids, this invariably means that the tumour has metastasised to the liver or there are peritoneal deposits, which allow secreted hormones to gain access to the systemic circulation; hormones secreted by the primary tumour into the portal vein are metabolised and inactivated in the liver. The features of Zollinger–Ellison syndrome are described on page 834.

Investigations

A combination of ultrasound, CT, MRI and/or functional imaging (Fig. 20.26) will usually identify the primary tumour and allow staging, which is crucial for determining prognosis. Biopsy of the primary tumour or a metastatic deposit is required to confirm the histological type. NETs demonstrate immunohistochemical staining for the proteins chromogranin A and synaptophysin, and the histological grade provides important prognostic information: the higher the Ki67 proliferation index, the worse the prognosis.

Carcinoid syndrome is confirmed by measuring elevated concentrations of 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, in a 24-hour urine collection. False positives can occur, particularly if the individual has been eating serotonin-rich foods, such as avocado and pineapple. Plasma chromogranin A can be measured in a fasting blood sample, along with the hormones listed in Box 20.48. All of these can be useful as tumour markers.

Management

Treatment of solitary tumours is by surgical resection. If metastatic or multifocal primary disease is present, then surgery is usually not indicated, unless there is a complication such as gastrointestinal obstruction. Diazoxide can reduce insulin secretion in insulinomas, and high doses of proton pump inhibitors suppress acid production in gastrinomas. Somatostatin analogues are effective in reducing the symptoms of carcinoid syndrome and of excess glucagon and vasoactive intestinal peptide (VIP) production. The slow-growing nature of NETs means that conventional cancer therapies, such as chemotherapy and radiotherapy, have limited efficacy, but use of somatostatin analogues is associated with improved progression-free survival, and ^{177}Lu-DOTATATE is indicated for many patients with further disease progression. Other treatments, such as resection/embolisation/ablation of hepatic metastases, may have a role in the palliation of symptoms, but debate exists as to whether this prolongs life. The tyrosine kinase inhibitor sunitinib and the mammalian target of rapamycin (mTOR) inhibitor everolimus have shown significant improvements in progression-free survival in patients with advanced and progressive pancreatic and lung NETs that are not poorly differentiated.

The hypothalamus and the pituitary gland

Diseases of the hypothalamus and pituitary have an annual incidence of approximately 3:100 000 and a prevalence of 30–70 per 100 000. The pituitary plays a central role in several major endocrine axes, so that investigation and treatment invariably involve several other endocrine glands.

Functional anatomy, physiology and investigations

The anatomical relationships of the pituitary are shown in Figure 20.27 and its numerous functions are shown in Figure 20.2. The pituitary gland is enclosed in the sella turcica and bridged over by a fold of dura mater called the diaphragma sellae, with the sphenoidal air sinuses below and the optic chiasm above. The cavernous sinuses are lateral

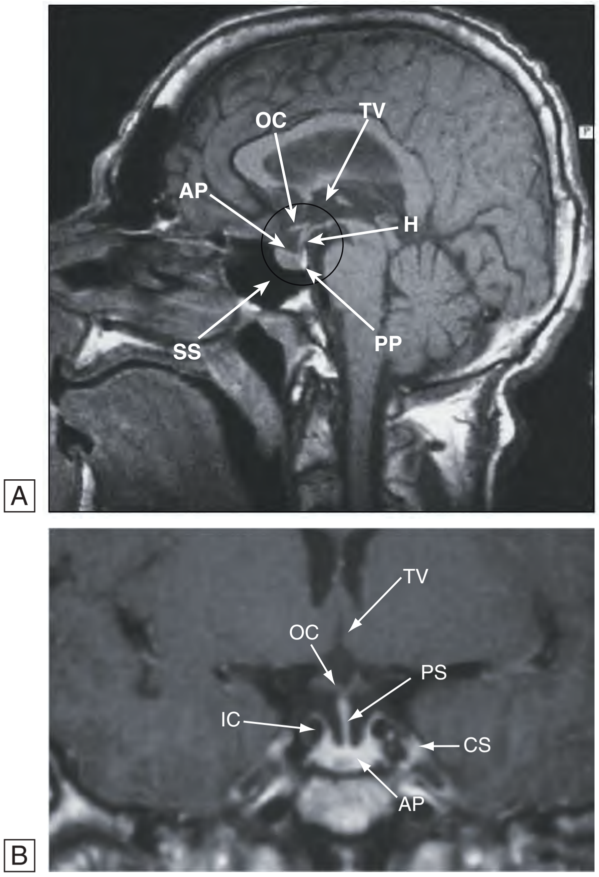

Fig. 20.27 Anatomical relationships of the normal pituitary gland and hypothalamus. See also Fig. 20.2. **A** Sagittal MRI. **B** Coronal MRI. (AP = anterior pituitary; CS = cavernous sinus; H = hypothalamus; IC = internal carotid artery; OC = optic chiasm; PP = posterior pituitary; PS = pituitary stalk; SS = sphenoid sinus; TV = third ventricle)

20.50 Classification of diseases of the pituitary and hypothalamus

	Primary	Secondary
Non-functioning tumours	Pituitary adenoma Craniopharyngioma Metastatic tumours	
Hormone excess	Prolactinoma Acromegaly Cushing disease Rare TSH-, LH- and FSH-secreting adenomas Syndrome of inappropriate antidiuretic hormone (SIADH, p. 666)	Disconnection hyperprolactinaemia
Hormone deficiency	Hypopituitarism AVP deficiency (cranial diabetes insipidus)	GnRH deficiency (Kallmann syndrome)
Hormone resistance	Growth hormone resistance (Laron dwarfism) AVP resistance (nephrogenic diabetes insipidus)	

(FSH = follicle-stimulating hormone; GnRH = gonadotrophin-releasing hormone; LH = luteinising hormone; TSH = thyroid-stimulating hormone)

to the pituitary fossa and contain the 3rd, 4th and 6th cranial nerves and the internal carotid arteries. The gland is composed of two lobes, anterior and posterior, and is connected to the hypothalamus by the infundibular stalk, which has portal vessels carrying blood from the median eminence of the hypothalamus to the anterior lobe and nerve fibres to the posterior lobe.

Diseases of the hypothalamus and pituitary are classified in Box 20.50. By far the most common disorder is an adenoma of the anterior pituitary gland.

Investigation of patients with pituitary disease

Although pituitary disease presents with diverse clinical manifestations (see below), the approach to investigation is similar in all cases (Box 20.51).

The approach to testing for hormone deficiency is outlined in Box 20.51. Details are given in the sections on individual glands elsewhere in this chapter. Tests for hormone excess vary according to the hormone in question. For example, although prolactin secretion rises in response to stress and slightly during sleep, levels are generally steady across the day. Thus, assuming that the patient was not distressed by venepuncture, a random measurement of serum prolactin is usually sufficient to diagnose hyperprolactinaemia. In contrast, growth hormone is secreted in a pulsatile fashion. A high random level does not confirm acromegaly; the diagnosis is confirmed only by failure of growth hormone to be suppressed during an oral glucose tolerance test, with usually a high serum IGF-1. Similarly, in suspected ACTH-dependent Cushing disease, random measurement of plasma cortisol is unreliable and the diagnosis is usually made by a dexamethasone suppression and other tests.

The most common local complication of a large pituitary tumour is compression of the optic pathway. The resulting visual field defect can be documented using a Goldmann perimetry chart or with an automated perimetry method.

MRI reveals 'abnormalities' of the pituitary gland in as many as 10% of 'healthy' middle-aged people. It should therefore be performed only if there is a clear biochemical abnormality or if a patient presents with clinical features of pituitary tumour (see below). A pituitary tumour may be classified as either a macroadenoma (> 10 mm diameter) or a microadenoma (≤10 mm diameter).

20.51 How to investigate patients with suspected pituitary or hypothalamic disease

Identify pituitary hormone deficiency

ACTH deficiency
- ACTH stimulation test (see Box 20.42)
- Insulin tolerance test (see Box 20.55): only if there is uncertainty in interpretation of ACTH stimulation test (e.g. acute presentation)

LH/FSH deficiency
- In the male, measure random serum testosterone, LH and FSH
- In the pre-menopausal female, ask if the menses are regular
- In the post-menopausal female, measure random serum LH and FSH (FSH normally > 30 IU/L and LH > 20 IU/L)

TSH deficiency
- Measure random serum T4
- Note that TSH is often detectable in secondary hypothyroidism

Growth hormone deficiency

Only investigate if growth hormone replacement therapy is being contemplated
- Measure immediately after exercise
- Consider other stimulatory tests (see Box 20.54)

AVP deficiency (cranial diabetes insipidus)

Only investigate if patient complains of polyuria/polydipsia, which may be masked by ACTH or TSH deficiency
- Exclude other causes of polyuria with blood glucose, potassium and calcium measurements
- 3% saline infusion test or water deprivation test

Identify hormone excess
- Measure random serum prolactin
- Investigate for acromegaly (glucose tolerance test) or Cushing syndrome if there are clinical features

Establish the anatomy and diagnosis
- Consider visual field testing
- Image the pituitary and hypothalamus by MRI or CT

(ACTH = adrenocorticotrophic hormone; CT = computed tomography; FSH = follicle-stimulating hormone; LH = luteinising hormone; MRI = magnetic resonance imaging; TSH = thyroid-stimulating hormone)

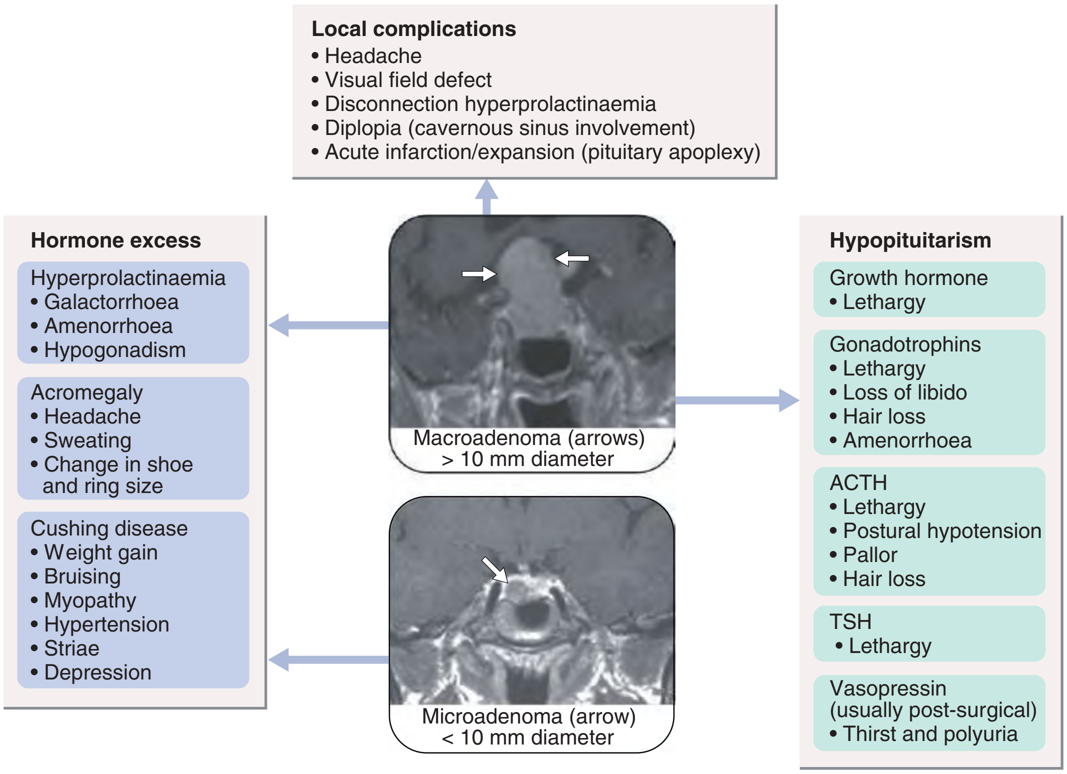
Surgical biopsy is usually only performed as part of a therapeutic operation. Conventional histology identifies tumours as chromophobe (usually non-functioning), acidophil (typically prolactin- or growth hormone–secreting) or basophil (typically ACTH-secreting); immunohistochemistry may confirm their secretory capacity but is poorly predictive of growth potential of the tumour.

Presenting problems in hypothalamic and pituitary disease

The clinical features of pituitary disease are shown in Figure 20.28. Younger women with pituitary disease most commonly present with secondary amenorrhoea or galactorrhoea (in hyperprolactinaemia). Post-menopausal women and men of any age are less likely to report symptoms of hypogonadism and so are more likely to present late with larger tumours causing visual field defects. The presentation and management of pituitary and hypothalamic disease may be affected by old age (Box 20.52). Nowadays, many patients present with an incidental finding of a pituitary tumour on a CT or MRI scan.

Hypopituitarism

Hypopituitarism describes combined deficiency of any of the anterior pituitary hormones. The clinical presentation is variable and depends on the underlying lesion and the pattern of resulting hormone deficiency. The most common cause is a pituitary macroadenoma but other causes are listed in Box 20.53.



Local complications
• Headache
• Visual field defect
• Disconnection hyperprolactinaemia
• Diplopia (cavernous sinus involvement)
• Acute infarction/expansion (pituitary apoplexy)
Hormone excess
Hyperprolactinaemia
• Galactorrhoea
• Amenorrhoea
• Hypogonadism
Acromegaly
• Headache
• Sweating
• Change in shoe and ring size
Cushing disease
• Weight gain
• Bruising
• Myopathy
• Hypertension
• Striae
• Depression
Macroadenoma (arrows)
> 10 mm diameter
Microadenoma (arrow)
< 10 mm diameter
Hypopituitarism
Growth hormone
• Lethargy
Gonadotrophins
• Lethargy
• Loss of libido
• Hair loss
• Amenorrhoea
ACTH
• Lethargy
• Postural hypotension
• Pallor
• Hair loss
TSH
• Lethargy
Vasopressin (usually post-surgical)
• Thirst and polyuria

Fig. 20.28 **Common symptoms and signs to consider in a patient with suspected pituitary disease.** (ACTH = adrenocorticotrophic hormone; TSH = thyroid-stimulating hormone)

20.52 The pituitary and hypothalamus in old age

- **Late presentation**: often with large tumours causing visual disturbance, because early symptoms such as amenorrhoea and sexual dysfunction do not occur or are not recognised.
- **Coincidentally discovered pituitary tumours**: may not require surgical intervention if the visual apparatus is not involved, because of slow growth.
- **Hyperprolactinaemia**: less impact in post-menopausal women who are already 'physiologically' hypogonadal. Macroprolactinomas, however, require treatment because of their potential to cause mass effects.

20.53 Causes of anterior pituitary hormone deficiency

Structural

- Primary pituitary tumour
  - Adenoma*
  - Carcinoma (exceptionally rare)
- Craniopharyngioma*
- Meningioma*
- Secondary tumour (including leukaemia and lymphoma)
- Chordoma
- Germinoma (pinealoma)
- Arachnoid cyst
- Rathke cleft cyst
- Haemorrhage (apoplexy)

Inflammatory/infiltrative

- Sarcoidosis
- Infections, e.g. pituitary abscess, tuberculosis, syphilis, encephalitis
- Lymphocytic hypophysitis
- Haemochromatosis
- Langerhans cell histiocytosis

Congenital deficiencies

- GnRH (Kallmann syndrome)*
- GHRH*
- TRH
- CRH

Functional*

- Chronic systemic illness
- Anorexia nervosa
- Excessive exercise

Other

- Head injury*
- (Para)sellar surgery*
- (Para)sellar radiotherapy*
- Post-partum necrosis (Sheehan syndrome)
- Opioid analgesia

*The most common causes of pituitary hormone deficiency.
(CRH = corticotrophin-releasing hormone; GHRH = growth hormone–releasing hormone; GnRH = gonadotrophin-releasing hormone; TRH = thyrotrophin-releasing hormone)

Clinical assessment

The presentation is highly variable. For example, following radiotherapy to the pituitary region, there is a characteristic sequence of loss of pituitary hormone secretion. Growth hormone secretion is often the earliest to be lost. In adults, this produces lethargy, muscle weakness and increased fat mass, but these features are not obvious in isolation. Next, gonadotrophin (LH and FSH) secretion becomes impaired with loss of libido in the male and oligomenorrhoea or amenorrhoea in the female. Later, in the male there may be gynaecomastia and decreased frequency of shaving. In both sexes, axillary and pubic hair eventually become sparse or even absent and the skin becomes characteristically finer and wrinkled. Chronic anaemia may also occur. The next hormone to be lost is usually ACTH, resulting in symptoms of cortisol insufficiency (including postural hypotension and a *dilutional* hyponatraemia). In contrast to primary adrenal insufficiency (AI), angiotensin II–dependent zona glomerulosa function is not lost and hence aldosterone secretion maintains normal plasma potassium. In contrast to the pigmentation of primary AI due to high levels of circulating ACTH acting on the skin melanocytes, a striking degree of pallor is usually present. Finally, TSH secretion is lost with consequent secondary hypothyroidism. This contributes further to apathy and cold intolerance. In contrast to primary hypothyroidism, frank myxoedema is rare, presumably because the thyroid retains some autonomous function. The onset of all the above symptoms is notoriously insidious.

However, patients sometimes present acutely unwell with glucocorticoid deficiency. This may be precipitated by a mild infection or injury, or may occur secondary to pituitary apoplexy.

Other features of pituitary disease may be present (see Fig. 20.28).

Investigations

The strategy for investigation of pituitary disease is described in Box 20.51. In acutely unwell patients, the priority is to diagnose and treat cortisol deficiency. Other tests can be undertaken later. Specific dynamic tests for diagnosing hormone deficiency are described in Box 20.42 and Box 20.54. More specialised biochemical tests, such as insulin tolerance tests (Box 20.55), GnRH and TRH tests, are rarely required. All patients with biochemical evidence of pituitary hormone deficiency should have an MRI or CT scan to identify pituitary or hypothalamic tumours. If a tumour is not identified, then further investigations are indicated to exclude infectious or infiltrative causes.

Management

Treatment of acutely ill patients is similar to that described for AI, except that sodium depletion is less likely to be present as there is still mineralocorticoid activity due to the renin–angiotensin–aldosterone system (which is lost in primary adrenal insufficiency). Chronic hormone replacement therapies are described below. Once the cause of hypopituitarism is established, specific treatment – of a pituitary macroadenoma, for example (see below) – may be required.

Cortisol replacement

Hydrocortisone should be given if there is ACTH deficiency. Suitable doses are described in the section on adrenal disease on page 722. Mineralocorticoid replacement is not required.

Thyroid hormone replacement

Levothyroxine 50–150 µg once daily should be given as described on page 700. Unlike in primary hypothyroidism, measuring TSH is not helpful in adjusting the replacement dose because patients with hypopituitarism often secrete glycoproteins that are measured in the TSH assays but are not bioactive. The aim is to maintain serum T4 in the upper part of the reference range. It is dangerous to give thyroid replacement in AI without first giving glucocorticoid therapy, since this may precipitate adrenal crisis.

Sex hormone replacement

This is indicated if there is gonadotrophin deficiency in women under the age of 50 and in men to restore normal sexual function and to prevent osteoporosis.

Growth hormone replacement

Growth hormone (GH) is administered by daily subcutaneous self-injection to children and adolescents with GH deficiency and, until recently, was discontinued once the epiphyses had fused. However, although hypopituitary adults receiving 'full' replacement with hydrocortisone, levothyroxine and sex steroids are usually much improved by these therapies, some individuals remain lethargic and unwell compared with a healthy population. Some of these patients feel better, and have objective improvements in their fat:muscle mass ratio and other metabolic parameters, if they are also given GH replacement. Treatment with GH may also help young adults to achieve a higher peak bone mineral density. The principal side-effect is sodium retention, manifest as peripheral oedema or carpal tunnel syndrome if given in excess. For this reason, GH replacement should be started at a low dose, with monitoring of the response by measurement of serum IGF-1.

Pituitary tumour

Pituitary tumours produce a variety of mass effects, depending on their size and location, but also present as incidental findings on CT or MRI, or with hypopituitarism, as described above. A wide variety of disorders can present as mass lesions in or around the pituitary gland (see Box 20.53). Most intrasellar tumours are pituitary macroadenomas (most commonly non-functioning adenomas; see Fig. 20.28), whereas suprasellar masses may be craniopharyngiomas (see Fig. 20.31). The most common cause of a parasellar mass is a meningioma.

Clinical assessment

Clinical features are shown in Figure 20.28. A common but non-specific presentation is with headache, which may be the consequence of stretching of the diaphragma sellae. Although the classical abnormalities associated with compression of the optic chiasm are bitemporal hemianopia (see Fig. 20.29) or upper quadrantanopia, any type of visual field defect can result from suprasellar extension of a tumour because it may compress the optic nerve (unilateral loss of acuity or scotoma) or the optic tract (homonymous hemianopia). Optic atrophy may be apparent on ophthalmoscopy. Lateral extension of a sellar mass into the cavernous sinus with subsequent compression of the 3rd, 4th or 6th cranial nerve may cause diplopia and strabismus, but in anterior pituitary tumours this is an unusual presentation.

Occasionally, pituitary tumours infarct or there is bleeding into cystic lesions. This is termed 'pituitary apoplexy' and may result in sudden expansion with local compression symptoms and acute-onset hypopituitarism. Non-haemorrhagic infarction can also occur in a normal pituitary gland; predisposing factors include catastrophic obstetric haemorrhage (Sheehan syndrome), diabetes mellitus and raised intracranial pressure.

Investigations

Patients suspected of having a pituitary tumour should undergo MRI. If MRI is not available, CT may be used but is inferior for assessment of pituitary disease and will not show the majority of small pituitary tumours. For patients intolerant of MRI, this investigation may be performed under general anaesthaesia if needed, or imaging performed by CT. While some lesions have distinctive neuro-radiological features, the definitive diagnosis is made on histology after surgery. All patients with (para)sellar

20.54 Tests of growth hormone secretion

GH levels are commonly undetectable, so a choice from the range of 'stimulation' tests is required:

- Insulin-induced hypoglycaemia
- Macimorelin
- Arginine (may be combined with GHRH)
- Glucagon
- Clonidine (in children)

20.55 How and when to do an insulin tolerance test

Use

- Assessment of the HPA axis
- Assessment of GH deficiency
- Indicated when there is doubt after the other tests in Box 20.51
- Usually performed in specialist centres, especially in children
- IV glucose and hydrocortisone must be available for resuscitation

Contraindications

- Ischaemic heart disease
- Epilepsy
- Severe hypopituitarism (0800 hrs plasma cortisol < 180 nmol/L (6.6 µg/dL))

Dose

- 0.15 U/kg body weight soluble insulin IV

Aim

- To produce adequate hypoglycaemia (tachycardia and sweating with blood glucose < 2.2 mmol/L (40 mg/dL))

Blood samples

- 0, 30, 45, 60, 90, 120 mins for blood glucose, plasma cortisol and growth hormone

Results

- Normal subjects: GH > 6.7 µg/L (20 mIU/L)*
- Normal subjects: cortisol > 500 nmol/L (approximately 20.2 µg/dL)*

*The precise cut-off figure for a satisfactory cortisol and GH response depends on the assay used and so varies between centres.
(GH = growth hormone; HPA = hypothalamic–pituitary–adrenal; IV = intravenous)

space-occupying lesions should have pituitary function assessed as described in Box 20.51.

Management

Modalities of treatment of common pituitary and hypothalamic tumours are shown in Box 20.56. Associated hypopituitarism should be treated as described above.

Urgent treatment is required if there is evidence of pressure on visual pathways. The chances of recovery of a visual field defect are proportional to the duration of symptoms, with full recovery unlikely if the defect has been present for longer than 4 months. In the presence of a sellar mass lesion, it is crucial that serum prolactin is measured before emergency surgery is performed. If the prolactin is over 5000 mIU/L (236 ng/mL), then the lesion is likely to be a macroprolactinoma and should respond to a dopamine agonist with shrinkage of the lesion, typically making surgery unnecessary (see Fig. 20.29).

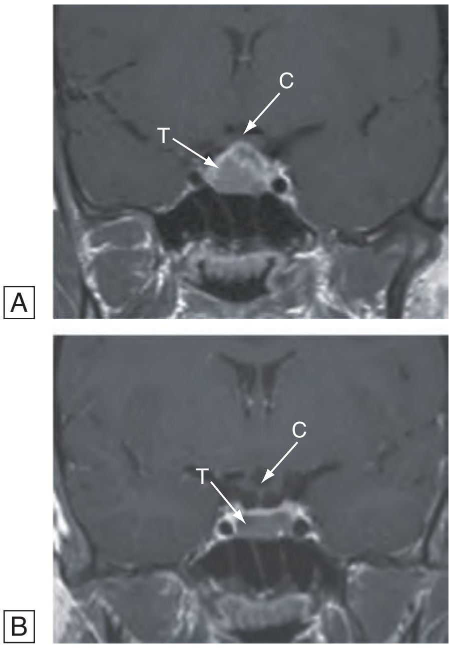


Fig. 20.29 Shrinkage of a macroprolactinoma following treatment with a dopamine agonist. **A** MRI scan showing a pituitary macroadenoma (T) compressing the optic chiasm (C). **B** MRI scan of the same tumour following treatment with a dopamine agonist. The macroadenoma, which was a prolactinoma, has decreased in size substantially and is no longer compressing the optic chiasm.

Most operations on the pituitary are performed using the trans-sphenoidal approach via the nostrils, while transfrontal surgery via a craniotomy is occasionally needed for suprasellar tumours. It is uncommon to be able to resect lateral extensions into the cavernous sinuses, although with modern endoscopic techniques this is more feasible. All operations on the pituitary carry a risk of damaging normal endocrine function; this risk increases with the size of the primary lesion.

Pituitary function (see Box 20.51) should be retested 4–6 weeks following surgery, primarily to detect the development of any new hormone deficits. Rarely, the surgical treatment of a sellar lesion can result in recovery of hormone secretion that was deficient pre-operatively.

Following surgery, usually after 3–6 months, imaging should be repeated. If there is a significant residual mass and the histology confirms an anterior pituitary tumour, external beam radiotherapy may be given to reduce the risk of recurrence but the risk:benefit ratio needs careful individualised discussion. Radiotherapy is not useful in patients requiring urgent therapy because it takes many months or years to be effective and there is a risk of acute swelling of the mass. Fractionated radiotherapy carries a life-long risk of hypopituitarism (50%–100% in the first 10 years) and annual pituitary function tests are obligatory. There is also concern that radiotherapy might impair cognitive function, cause vascular changes and even induce primary brain tumours, but these side-effects have not been quantified reliably and are likely to be rare. Stereotactic radiosurgery allows specific targeting of residual disease in a more focused fashion.

Non-functioning tumours should be followed up by repeated imaging at intervals that depend on the size of the lesion and on whether or not radiotherapy has been administered. For smaller lesions that are not causing mass effects, therapeutic surgery may not be indicated and the lesion may simply be monitored by serial neuroimaging without a clear-cut diagnosis having been established.

Hyperprolactinaemia/galactorrhoea

Hyperprolactinaemia is a common abnormality that usually presents with hypogonadism and/or galactorrhoea (lactation in the absence of breastfeeding). Since prolactin stimulates milk secretion but not breast development, galactorrhoea rarely occurs in men and only does so if gynaecomastia has been induced by hypogonadism. The differential diagnosis of hyperprolactinaemia is shown in Box 20.57. Many drugs, especially dopamine antagonists, elevate prolactin concentrations. Pituitary tumours can cause hyperprolactinaemia by directly secreting prolactin (prolactinomas, see below), or by compressing the infundibular stalk and thus interrupting the tonic inhibitory effect of hypothalamic dopamine on prolactin secretion ('disconnection' hyperprolactinaemia).

i 20.56 Therapeutic modalities for functioning and non-functioning hypothalamic and pituitary tumours

	Surgery	Radiotherapy	Medical	Comment
Non-functioning pituitary macroadenoma	1st line	2nd line	–	
Prolactinoma	2nd line	2nd line	1st line Dopamine agonists	Dopamine agonists usually cause macroadenomas to shrink
Acromegaly	1st line	2nd line	2nd line Somatostatin analogues Dopamine agonists GH receptor antagonists	Medical therapy does not reliably cause macroadenomas to shrink Radiotherapy and medical therapy are used in combination for inoperable tumours
Cushing disease	1st line	2nd line	2nd line Steroidogenesis inhibitors Pasireotide	Radiotherapy may take many years to reduce ACTH excess and medical therapies may be used as a bridge. Bilateral adrenalectomy may also be considered if the pituitary tumour is not completely resectable
Craniopharyngioma	1st line	2nd line	–	

(ACTH = adrenocorticotrophic hormone; GH = growth hormone)

i 20.57 Causes of hyperprolactinaemia

Physiological

- Stress (e.g. post-seizure, venepuncture)
- Pregnancy
- Lactation
- Nipple stimulation
- Sleep
- Coitus
- Exercise
- Baby crying

Drug-induced

Dopamine antagonists

- Antipsychotics (phenothiazines and butyrophenones)
- Antidepressants
- Antiemetics (e.g. metoclopramide, domperidone)

Dopamine-depleting drugs

- Reserpine
- Methyldopa

Oestrogens

- Oral contraceptive pill

Pathological

Common

- Disconnection hyperprolactinaemia (e.g. non-functioning pituitary macroadenoma)
- Prolactinoma (usually microadenoma)
- Primary hypothyroidism
- Polycystic ovary syndrome

Uncommon

- Pituitary tumour secreting prolactin and growth hormone
- Hypothalamic disease
- Renal failure

Rare

- Chest wall reflex (e.g. post herpes zoster)

Prolactin usually circulates as a free (monomeric) hormone in plasma but, in some individuals, prolactin becomes bound to an IgG antibody. This complex is known as macroprolactin and such patients have macroprolactinaemia (not to be confused with macroprolactinoma, a prolactin-secreting pituitary tumour of more than 1 cm in diameter). Since macroprolactin cannot cross blood-vessel walls to reach prolactin receptors in target tissues, it is of no pathological significance. Some commercial prolactin assays do not distinguish prolactin from macroprolactin and so macroprolactinaemia is a cause of spurious hyperprolactinaemia. Identification of macroprolactin requires gel filtration chromatography or polyethylene glycol precipitation techniques, and one of these tests should be performed in all patients with hyperprolactinaemia if the prolactin assay is known to cross-react.

Clinical assessment

In women, in addition to galactorrhoea, hypogonadism associated with hyperprolactinaemia causes secondary amenorrhoea and anovulation with infertility. Important points in the history include drug use, recent pregnancy and menstrual history. The quantity of milk produced is variable and it may be observed only by manual expression. In men there is decreased libido, reduced shaving frequency and lethargy. Unilateral galactorrhoea may be confused with nipple discharge, and breast examination to exclude malignancy or fibrocystic disease is important. Further assessment should address the features in Figure 20.28.

Investigations

Pregnancy should first be excluded before further investigations are performed in women of child-bearing potential. The upper limit of normal for many assays of serum prolactin is approximately 500 mIU/L (24 ng/mL). In non-pregnant and non-lactating patients, monomeric prolactin concentrations of 500–1000 mIU/L (24–47 ng/mL) are likely to be induced by stress or drugs, and a repeat measurement is indicated (a sample for prolactin taken from an intravenous cannula sited several hours before is helpful in identifying hyperprolactinaemia caused by the stress of venepuncture). Levels between 1000 and 5000 mIU/L (47–236 ng/mL) are likely to be due to drugs, a microprolactinoma or 'disconnection' hyperprolactinaemia. Levels above 5000 mIU/L (236 ng/mL) are highly suggestive of a macroprolactinoma.

Patients with prolactin excess should have tests of gonadal function (p. 709), and T4 and TSH should be measured to exclude primary hypothyroidism causing TRH-induced prolactin excess. Unless the prolactin falls after withdrawal of relevant drug therapy, a serum prolactin consistently above the reference range is an indication for MRI or CT scan of the hypothalamus and pituitary. Patients with a macroadenoma also need tests for hypopituitarism (see Box 20.51).

Management

If possible, the underlying cause should be corrected (e.g. cessation of offending drugs and giving levothyroxine replacement in primary hypothyroidism). If dopamine antagonists are the cause, then dopamine agonist therapy is contraindicated; if gonadal dysfunction is the primary concern, sex steroid replacement therapy may be indicated. Troublesome physiological galactorrhoea can also be treated with dopamine agonists (see Box 20.58). Management of prolactinomas is described below.

Prolactinoma

Most prolactinomas in pre-menopausal women are microadenomas because the symptoms of prolactin excess usually result in early presentation. Prolactin-secreting cells of the anterior pituitary share a common lineage with GH-secreting cells, so occasionally prolactinomas can secrete excess GH and cause acromegaly. In prolactinomas there is a relationship between prolactin concentration and tumour size: the higher the level, the bigger the tumour. Some macroprolactinomas can elevate prolactin concentrations above 100 000 mIU/L (4700 ng/mL). The investigation of prolactinomas is the same as for other pituitary tumours (see above).

Management

As shown in Box 20.56, several therapeutic modalities can be employed in the management of prolactinomas.

Medical

Dopamine agonist drugs are first-line therapy for the majority of patients (Box 20.58). They usually reduce serum prolactin concentrations and cause significant tumour shrinkage after several months of therapy (Fig. 20.29), but visual field defects, if present, may improve within days of first administration. It is possible to withdraw dopamine agonist therapy without recurrence of hyperprolactinaemia after a few years of treatment in some patients with a microadenoma. Also, after the menopause, suppression of prolactin is required in microadenomas only if galactorrhoea is troublesome, since hypogonadism is then physiological and tumour growth unlikely. In patients with macroadenomas, drugs can be withdrawn only after curative surgery or radiotherapy and under close supervision.

Ergot-derived dopamine agonists (bromocriptine and cabergoline) can bind to 5-HT_{2B} receptors in the heart and elsewhere and have been associated with fibrotic reactions, particularly tricuspid valve regurgitation, when used in high doses in patients with Parkinson disease. At the relatively low doses used in prolactinomas, most data suggest that systematic screening for cardiac fibrosis is unnecessary, but if dopamine agonist therapy is prolonged, periodic screening by echocardiography or use of non-ergot agents (quinagolide) may be indicated. Dopamine agonists can affect mood and behaviour, precipitating or worsening depression, psychosis and impulse control disorders (e.g. compulsive gambling), and patients should be warned about these potential side-effects.

Surgery and radiotherapy

Surgical decompression is usually necessary only when a macroprolactinoma has failed to shrink sufficiently with dopamine agonist therapy, and this may be because the tumour has a significant cystic component. Surgery may also be performed in patients who are intolerant of dopamine agonists. Microadenomas can be removed selectively by trans-sphenoidal

i 20.58 Dopamine agonist therapy: drugs used to treat prolactinomas

Drug	Oral dose*	Advantages	Disadvantages
Bromocriptine	2.5–15 mg/day 2–3 times daily	Available for parenteral use Short half-life; useful in treating infertility Proven long-term efficacy	Ergotamine-like side-effects (nausea, headache, postural hypotension, constipation) Frequent dosing so poor adherence Rare reports of fibrotic reactions in various tissues
Cabergoline	250–1000 µg/week 2 doses/week	Long-acting, so missed doses less important Reported to have fewer ergotamine-like side-effects	Limited data on safety in pregnancy Associated with cardiac valvular fibrosis in Parkinson disease
Quinagolide	50–150 µg/day Once daily	A non-ergot with few side-effects in patients intolerant of the above	Limited data on safety in pregnancy

*Tolerance develops for the side-effects. All of these agents, especially bromocriptine, must be introduced at low dose and increased slowly. If several doses of bromocriptine are missed, the process must start again.

surgery with a cure rate of about 80%, but recurrence is possible; the cure rate for surgery in macroadenomas is substantially lower.

External beam irradiation may be required for some macroadenomas to prevent regrowth if dopamine agonists are stopped.

Pregnancy

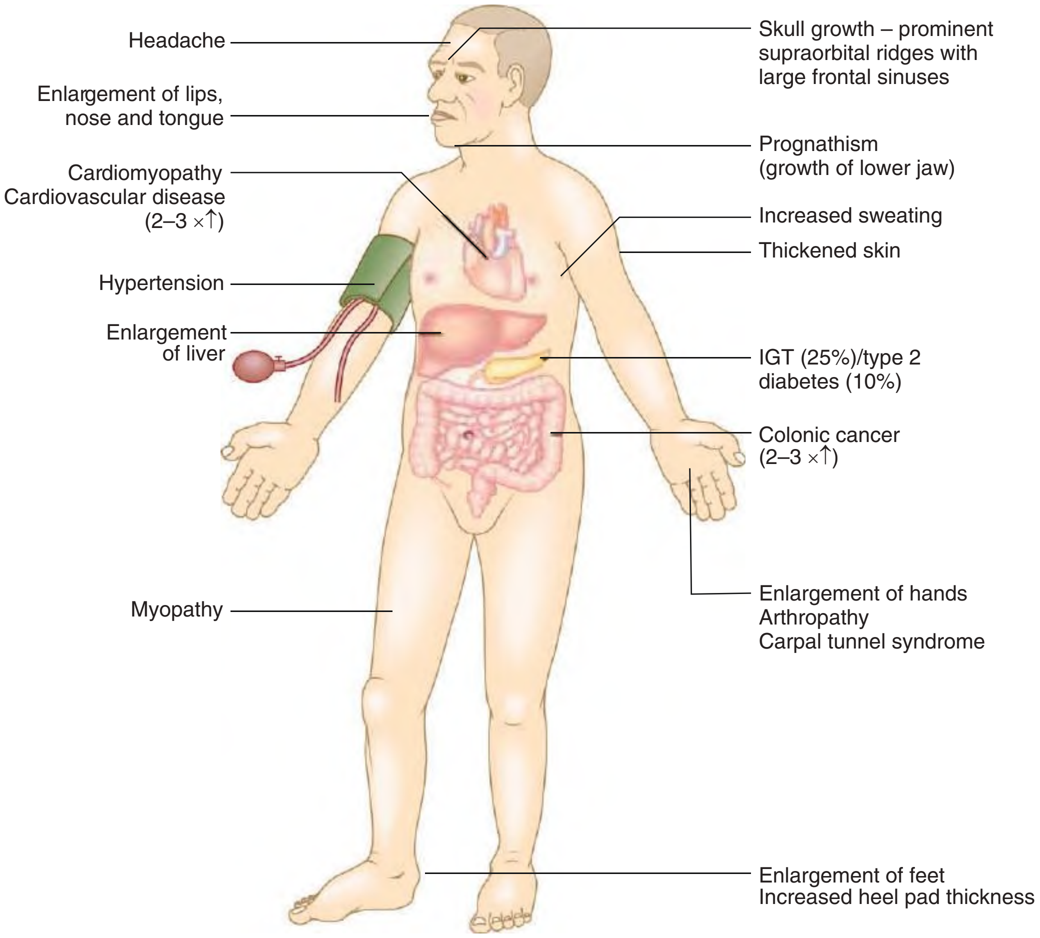
Hyperprolactinaemia often presents with infertility, so dopamine agonist therapy may be followed by pregnancy. Patients with microadenomas should be advised to withdraw dopamine agonist therapy as soon as pregnancy is confirmed. In contrast, macroprolactinomas may enlarge rapidly under oestrogen stimulation and so continued dopamine agonist therapy should be considered. Patients with macroprolactinomas need monitoring of visual fields during pregnancy. All patients should be advised to report headache or visual disturbance promptly.

Acromegaly

Acromegaly is caused by growth hormone (GH) secretion from a pituitary tumour, usually a macroadenoma, and carries an approximate twofold excess mortality when untreated.

Clinical features

If GH hypersecretion occurs before puberty, then the presentation is with gigantism. More commonly, GH excess occurs in adult life and presents with acromegaly. If hypersecretion starts in adolescence and persists into adult life, then the two conditions may be combined. The clinical features are shown in Figure 20.30. The most common complaints are headache and sweating. Additional features include those of any pituitary tumour (see Fig. 20.28).



Headache
Enlargement of lips, nose and tongue
Cardiomyopathy
Cardiovascular disease
(2–3 ×↑)
Hypertension
Enlargement of liver
Myopathy
Skull growth – prominent supraorbital ridges with large frontal sinuses
Prognathism
(growth of lower jaw)
Increased sweating
Thickened skin
IGT (25%)/type 2 diabetes (10%)
Colonic cancer
(2–3 ×↑)
Enlargement of hands
Arthropathy
Carpal tunnel syndrome
Enlargement of feet
Increased heel pad thickness

Fig. 20.30 Clinical features of acromegaly. (IGT = impaired glucose tolerance)

Investigations

The clinical diagnosis must be confirmed by measuring GH levels during an oral glucose tolerance test and measuring serum IGF-1. In normal subjects, plasma GH suppresses to below 0.5 μg/L (approximately 2 mIU/L). In acromegaly, GH does not suppress and in about 30% of patients there is a paradoxical rise; IGF-1 is also elevated. The rest of pituitary function should be investigated as described in Box 20.51. Prolactin concentrations are elevated in about 30% of patients due to co-secretion of prolactin from the tumour. Additional tests in acromegaly may include screening colonoscopy for colonic neoplasms, HbA1c for diabetes and echocardiography for cardiomyopathy.

Management

The main aims are to improve symptoms and to normalise serum GH and IGF-1 to reduce morbidity and mortality. Treatment is summarised in Box 20.56.

Surgical

Trans-sphenoidal surgery is usually the first line of treatment and may result in cure of GH excess, especially in patients with microadenomas. More often, surgery serves to debulk the tumour and further second-line therapy is required, according to post-operative imaging and GH/IGF-1 test results.

Medical

If acromegaly persists after surgery, medical therapy is usually employed to lower GH levels to below 1.0 μg/L (approximately 3 mIU/L) and to normalise IGF-1 concentrations. Medical therapy may be discontinued after several years in patients who have received radiotherapy once the latter has been effective. Somatostatin analogues (such as octreotide, lanreotide or pasireotide) can be administered as slow-release injections every few weeks. Somatostatin analogues can also be used as primary therapy for acromegaly either as an alternative or in advance of surgery, given evidence that they can induce modest tumour shrinkage in some patients. Dopamine agonists are less effective at lowering GH but may sometimes be helpful, especially with associated prolactin excess. Pegvisomant is a peptide GH receptor antagonist administered by daily self-injection and may be indicated in some patients whose GH and IGF-1 concentrations fail to suppress sufficiently following somatostatin analogue therapy.

Radiotherapy

External beam radiotherapy is increasingly employed as third-line treatment if acromegaly persists after surgery, to stop tumour growth and lower GH levels. However, GH levels fall slowly (over many years) and there is a risk of hypopituitarism.

Craniopharyngioma

Craniopharyngiomas are benign tumours that develop in cell rests of the Rathke pouch, and may be located within the sella turcica, or commonly in the suprasellar space. They are often cystic, with a solid component that may or may not be calcified (Fig. 20.31). In young people, they are diagnosed more commonly than pituitary adenomas. They may present with pressure effects on adjacent structures, hypopituitarism and/or AVP deficiency (cranial diabetes insipidus). Other clinical features directly related to hypothalamic damage may also occur. These include hyperphagia and obesity, loss of the sensation of thirst and disturbance of temperature regulation, and these features can be significant clinical challenges to manage.

Craniopharyngiomas often cause considerable morbidity, usually from hypothalamic obesity, water balance problems and/or visual failure. They can be treated by the trans-sphenoidal route, but surgery may also involve a craniotomy, with a relatively high risk of hypothalamic damage and other complications. If the tumour has a large cystic component, it may be safer to place a drain in the cyst cavity that is attached to a subcutaneous access device, rather than attempt a resection. Whatever form it takes, surgery is unlikely to be curative and radiotherapy may often be given to reduce the risk of relapse. Unfortunately, craniopharyngiomas often recur, requiring repeated surgery. The BRAF inhibitor dabrafenib (often in combination with the MEK inhibitor trametinib) has been shown to be highly effective in shrinking craniopharyngiomas with a BRAF V600E mutation. This has been used as a neoadjuvant therapy prior to less invasive surgery or radiotherapy.

Arginine vasopressin deficiency and resistance (diabetes insipidus)

This uncommon disorder is characterised by the persistent excretion of excessive quantities of dilute urine and by thirst. Since 2022, the condition (formerly known as diabetes insipidus) has been renamed as either AVP deficiency or AVP resistance, depending on the underlying aetiology:

- AVP deficiency (cranial diabetes insipidus): there is deficient production of vasopressin by the hypothalamus
- AVP resistance (nephrogenic diabetes insipidus): the renal tubules are unresponsive to vasopressin.

The underlying causes are listed in Box 20.59.

In patients presenting with polyuria–polydipsia syndrome, the other potential diagnosis to be excluded is primary polydipsia, caused by

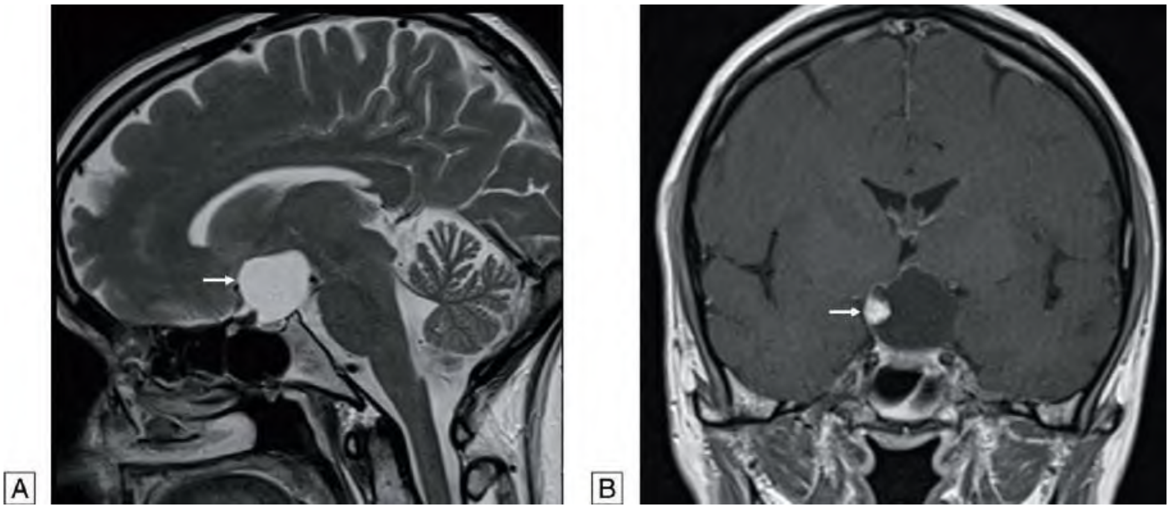


Fig. 20.31 **Craniopharyngioma.** A Sagittal T2 scan demonstrating a cystic signal suprasellar mass (arrow) indenting the hypothalamus. B The tumour is of corresponding low signal on the post-contrast coronal scan with a right-sided enhancing mural solid nodule (arrow) also noted.

20.59 Causes of AVP deficiency/resistance

AVP deficiency

Structural hypothalamic or high stalk lesion
- See Box 20.53

Idiopathic

Genetic defect
- Dominant (*AVP* mutation)
- Recessive (DIDMOAD syndrome – association of diabetes insipidus with diabetes mellitus, optic atrophy, deafness)

AVP resistance

Genetic defect
- V2 receptor mutation
- Aquaporin-2 mutation
- Cystinosis

Metabolic abnormality
- Hypokalaemia
- Hypercalcaemia

Drug therapy
- Lithium
- Demeclocycline

Poisoning
- Heavy metals

Chronic kidney disease
- Polycystic kidney disease
- Sickle-cell disorder
- Infiltrative disease

drinking excessive amounts of fluid in the absence of a defect in vasopressin or thirst control.

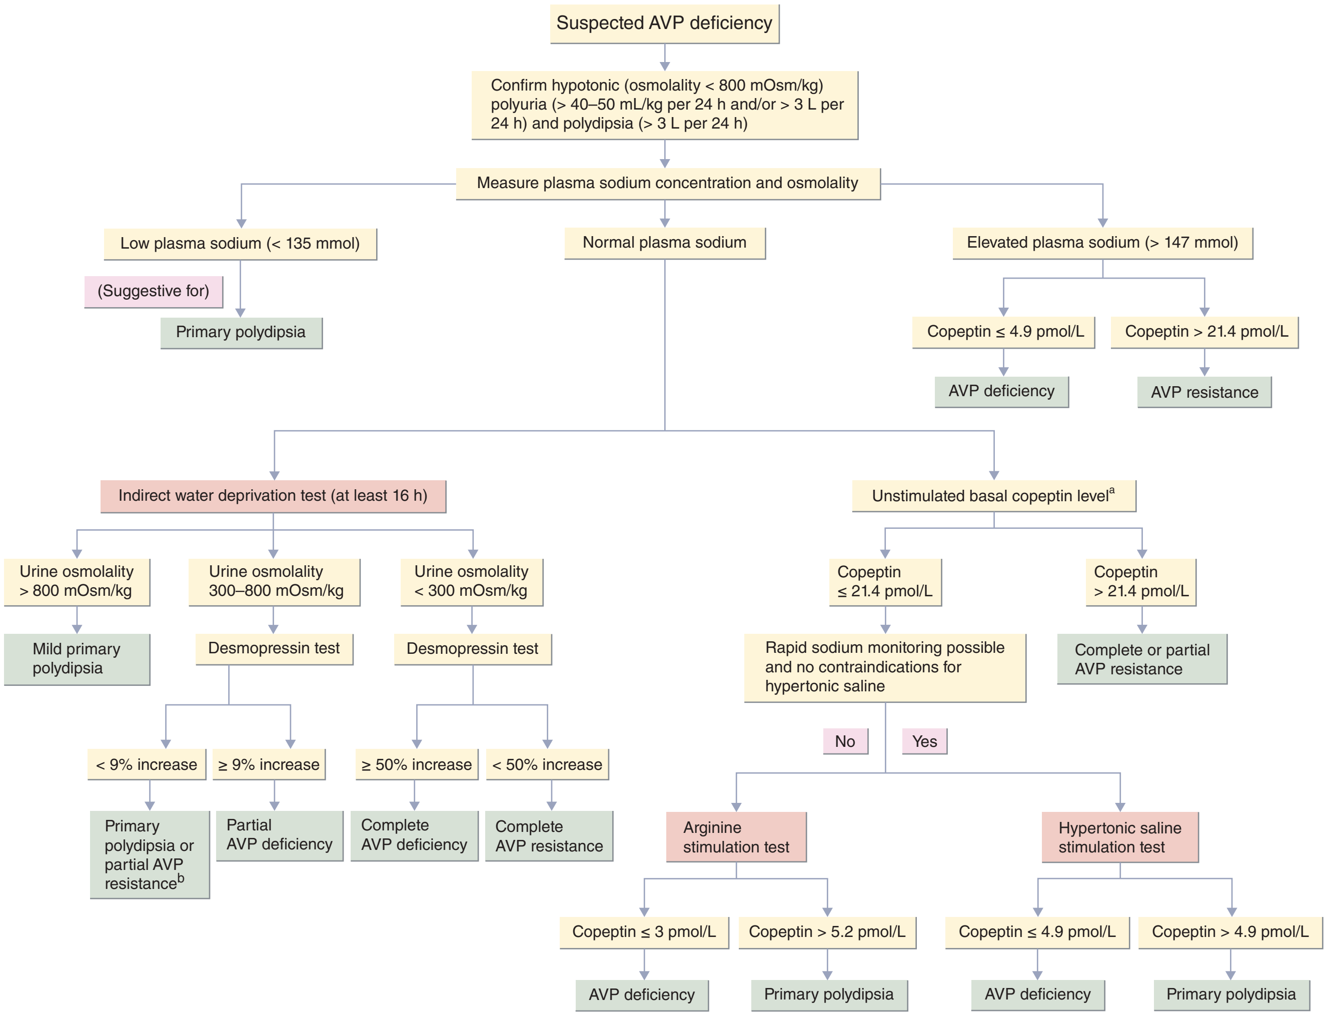
Clinical features

The most marked symptoms are polyuria (> 3 L per 24 hours) and polydipsia. The patient may pass 5–20 L or more of urine in 24 hours. This is of low specific gravity and osmolality. If the patient has an intact thirst mechanism, is conscious and has access to oral fluids, then they can maintain adequate fluid intake. However, in an unconscious patient or a patient with damage to the hypothalamic thirst centre, AVP deficiency/resistance is potentially lethal. If there is associated cortisol deficiency, then AVP deficiency/resistance may not be manifest until glucocorticoid replacement therapy is given.

Investigations

The diagnostic approach to patients with polyuria–polydipsia syndrome is outlined in Figure 20.32.

Measurement of AVP is challenging and not widely available in clinical practice; however, use of copeptin (an osmosensitive surrogate marker of AVP levels) has become routine; either basal or stimulated levels permit differentiation between AVP deficiency, AVP resistance and primary polydipsia. AVP deficiency/resistance is confirmed when the urine is not maximally concentrated (i.e. < 800 mOsmol/kg) in the presence of increased plasma osmolality (i.e. > 300 mOsmol/kg). Sometimes, the diagnosis can be confirmed or refuted by random simultaneous samples of blood and urine, but more often a dynamic test is required. The indirect water deprivation test has, historically, been the investigation of choice in determining the cause of polyuria–polydipsia syndrome.



Suspected AVP deficiency
Confirm hypotonic (osmolality < 800 mOsm/kg) polyuria (> 40–50 mL/kg per 24 h and/or > 3 L per 24 h) and polydipsia (> 3 L per 24 h)
Measure plasma sodium concentration and osmolality
Low plasma sodium (< 135 mmol)
Normal plasma sodium
Elevated plasma sodium (> 147 mmol)
(Suggestive for)
Primary polydipsia
Copeptin ≤ 4.9 pmol/L
Copeptin > 21.4 pmol/L
AVP deficiency
AVP resistance
Indirect water deprivation test (at least 16 h)
Unstimulated basal copeptin level[a]
Urine osmolality > 800 mOsm/kg
Urine osmolality 300–800 mOsm/kg
Urine osmolality < 300 mOsm/kg
Copeptin ≤ 21.4 pmol/L
Copeptin > 21.4 pmol/L
Mild primary polydipsia
Desmopressin test
Desmopressin test
Rapid sodium monitoring possible and no contraindications for hypertonic saline
Complete or partial AVP resistance
No
Yes
< 9% increase
≥ 9% increase
≥ 50% increase
< 50% increase
Primary polydipsia or partial AVP resistance[b]
Partial AVP deficiency
Complete AVP deficiency
Complete AVP resistance
Arginine stimulation test
Hypertonic saline stimulation test
Copeptin ≤ 3 pmol/L
Copeptin > 5.2 pmol/L
Copeptin ≤ 4.9 pmol/L
Copeptin > 4.9 pmol/L
AVP deficiency
Primary polydipsia
AVP deficiency
Primary polydipsia

Fig. 20.32 Investigation of suspected AVP deficiency. To convert copeptin from pmol/L to pg/mL, divide by 0.249. [a]Basal copeptin can only be evaluated if no physical or psychological distress and no severe nausea. [b]Plasma osmolality may be required to differentiate between these potential diagnoses. (AVP = arginine vasopressin)

However, recent evidence attests to the superior diagnostic accuracy of the hypertonic (3%) saline stimulation test (with copeptin measurement). Where hypertonic saline testing is not possible, arginine stimulation testing is an alternative although diagnostic accuracy is lower. Anterior pituitary function and suprasellar anatomy should be assessed in patients with AVP deficiency (see Box 20.51).

In primary polydipsia, the urine may be excessively dilute because of chronic diuresis, which 'washes out' the solute gradient across the loop of Henle, but plasma osmolality is low rather than high. DDAVP (see below) should not be administered to patients with primary polydipsia, since it will prevent excretion of water and there is a risk of severe water intoxication if the patient continues to drink fluid to excess.

In AVP resistance (nephrogenic diabetes insipidus), appropriate further tests may include plasma electrolytes, calcium, ultrasound of the kidneys and urinalysis.

Management

Treatment of AVP deficiency is with 1-deamino-8-D-arginine vasopressin (desmopressin, DDAVP), an analogue of vasopressin that has a longer half-life. For chronic replacement therapy DDAVP may be administered intranasally and orally, although the latter formulation has variable bioavailability. In sick patients, DDAVP should be given by intramuscular injection. The dose of DDAVP should be adjusted on the basis of serum sodium concentrations and/or osmolality. The principal hazard is excessive treatment, resulting in water intoxication and hyponatraemia. Conversely, inadequate treatment results in thirst and polyuria. The ideal dose prevents nocturia and excessive polyuria, but allows a degree of mild polyuria from time to time to allow excretion of excess water (e.g. DDAVP nasal dose 5 µg in the morning and 10 µg at night).

The polyuria in AVP resistance is improved by thiazide diuretics (e.g. bendroflumethiazide 5–10 mg/day), amiloride (5–10 mg/day) and NSAIDs (e.g. indometacin 50 mg 3 times daily), although the last of these carries a risk of reducing glomerular filtration rate.

Disorders affecting multiple endocrine glands

Multiple endocrine neoplasia

Multiple endocrine neoplasias (MEN) are rare autosomal dominant syndromes characterised by hyperplasia, adenomas and/or malignant tumours in multiple glands. They fall into four groups, as shown in Box 20.60. Some other genetic diseases also have an increased risk of endocrine tumours; for example, phaeochromocytoma is associated with von Hippel–Lindau syndrome and neurofibromatosis type 1.

The MEN syndromes should be considered in all patients with two or more endocrine tumours and in patients with solitary tumours who report other endocrine tumours in their family. Inactivating mutations in *MEN1* (*MENIN*), a tumour suppressor gene on chromosome 11, cause MEN 1, whereas MEN 2a (also known as MEN 2) and 2b (also known as MEN 3) are caused by gain-of-function mutations in the *RET* proto-oncogene on chromosome 10. These cause constitutive activation of the membrane-associated tyrosine kinase RET, which controls the development of cells that migrate from the neural crest. In contrast, loss-of-function mutations of the RET kinase cause Hirschsprung disease. MEN 4 is extremely rare and is associated with loss-of-function mutations in the *CDNK1B* gene on chromosome 12; this gene codes for the protein p27, which has putative tumour suppressor activity. Predictive genetic testing can be performed on relatives of individuals with MEN syndromes, after appropriate counselling.

Individuals who carry pathogenic variants associated with MEN should be entered into a surveillance programme. In MEN 1, this typically involves annual history, examination and measurements of serum calcium and prolactin, and MRI of the pituitary and pancreas every 2 years; some centres also perform regular CT or MRI scans of the chest. In individuals with MEN 2a and 2b, annual history, examination and measurement of serum calcium, calcitonin and urinary or plasma catecholamine metabolites should be performed. Because the penetrance of medullary carcinoma of the thyroid approaches 100% in individuals with a *RET* pathogenic variant, prophylactic thyroidectomy should be performed in early childhood in most patients. The precise timing of surgery in childhood should be guided by the specific mutation in the *RET* gene.

i 20.60 Multiple endocrine neoplasia (MEN) syndromes

MEN 1 (Wermer syndrome)

- Primary hyperparathyroidism
- Pituitary tumours
- Pancreatic neuroendocrine tumours (e.g. non-functioning, insulinoma, gastrinoma)
- Bronchial and thymic carcinoids
- Adrenal tumours
- Cutaneous lesions (e.g. lipomas, collagenomas, angiofibromas)

MEN 2a (Sipple syndrome)

- Primary hyperparathyroidism
- Medullary carcinoma of thyroid
- Phaeochromocytoma

MEN 2b (also known as MEN 3)

- As for MEN 2a above (though medullary thyroid cancer occurs earlier, even within the first year of life)
- Marfanoid habitus
- Skeletal abnormalities (e.g. craniosynostosis)
- Abnormal dental enamel
- Multiple mucosal neuromas

MEN 4

- Primary hyperparathyroidism
- Pituitary tumours
- Possible tumours in the adrenals, reproductive organs, kidneys
- Possible pancreatic, gastric, bronchial and cervical neuroendocrine tumours

Autoimmune polyendocrine syndromes

Two distinct autoimmune polyendocrine syndromes are known: APS types 1 and 2.

The most common is APS type 2 (Schmidt syndrome), which typically presents in women between the ages of 20 and 60. It is usually defined as the occurrence in the same individual of two or more autoimmune endocrine disorders, some of which are listed in Box 20.61. The mode of inheritance is autosomal dominant with incomplete penetrance and there is a strong association with HLA-DR3 and CTLA-4.

Much less common is APS type 1, which is also termed autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED). This is inherited in an autosomal recessive fashion and is caused by loss-of-function mutations in the autoimmune regulator gene *AIRE*, which is responsible for the presentation of self-antigens to thymocytes in utero. This is essential for the deletion of thymocyte clones that react against self-antigens and hence for the development of immune tolerance. The most common clinical features are described in Box 20.61, although the pattern of presentation is variable and other autoimmune disorders are often observed.

Endocrine effects of cancer immunotherapy

Immune checkpoint inhibitors (ICIs) have transformed outcomes in highly aggressive cancers such as melanoma and lung cancer. The most common targets for these therapies are cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) (e.g. ipilimumab) and programmed cell death protein 1 (PD-1) (e.g. nivolumab, pembrolizumab and cemiplimab). Hypophysitis occurs in up to 17% of people treated with ICI and

20.61 Autoimmune polyendocrine syndromes (APS)*

Type 1 (APECED)	
• Addison disease • Hypoparathyroidism • Type 1 diabetes • Primary hypothyroidism	• Chronic mucocutaneous candidiasis • Nail dystrophy • Dental enamel hypoplasia
Type 2 (Schmidt syndrome)	
• Addison disease • Primary hypothyroidism • Graves disease • Pernicious anaemia • Primary hypogonadism	• Type 1 diabetes • Vitiligo • Coeliac disease • Myasthenia gravis

*In both types of APS, the precise pattern of disease varies between affected individuals.
(APECED = autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy)

is most likely to occur within the first six months of therapy. Thyroid dysfunction is most common within the first 8–12 weeks of therapy and is more likely in individuals treated with combination ICIs (up to 16%). Thyroid disease typically manifests as mild primary hypothyroidism, although transient thyrotoxicosis can precede this in some cases. Less commonly (~1%), patients may present with adrenalitis resulting in primary adrenal insufficiency or incident type 1 diabetes. It is suggested that glucose, TSH, free T4, morning cortisol (+/– ACTH), prolactin, gonadotrophins and oestradiol/testosterone are measured at baseline and every month for the first six months of ICI therapy. The development of ICI-related endocrinopathy should be investigated and treated but need not result in discontinuation of ICIs.

Multiple Choice Questions

20.1. A 28-year-old man presents to his general practitioner with recent onset of weight loss, heat intolerance and palpitations. On examination a small goitre with a 2 cm discrete nodule is noted. Thyroid function tests show TSH < 0.01 mIU/L (RR 0.2–4.5 mIU/L), and free T4 25 pmol/L (RR 9–21 pmol/L. TSH receptor antibody (TRAb) is 1.1 IU/L (RR 0–1.6 IU/L). Prior to attendance at the endocrine clinic, a thyroid ultrasound is performed, which confirms a benign-looking 2 cm nodule in the context of a multinodular goitre. What would be the most appropriate next step?

A. Fine needle aspiration (FNA) of the nodule
B. Hemithyroidectomy
C. Carbimazole
D. Scintigraphy
E. Radio-iodine (400 MBq)

Answer: D.

The patient has thyrotoxicosis with an equivocal TRAb, no discriminatory clinical features of Graves disease and evidence of nodular thyroid disease. In this context, it is useful to perform scintigraphy to determine whether this is a 'hot' nodule (i.e. autonomously producing thyroid hormone). This has important implications, as 'hot' nodules are almost never malignant and treatment with radio-iodine has a high likelihood of restoring euthyroidism (as opposed to Graves disease, where the likeliest outcome is permanent hypothyroidism).

20.2. A 23-year-old recently married female presents to her family doctor with a 6-week history of 3 kg weight loss, an irregular menstrual cycle and anxiety. She has a fear of general anaesthesia due to a previous perioperative episode of anaphylaxis. She and her husband are keen to start a family. On examination a smooth goitre is palpable in her neck with bruit detected on auscultation. Thyroid function tests show TSH < 0.01 mIU/L (RR 0.2–4.5 mIU/L), and free T4 36 pmol/L (RR 9–21 pmol/L. TSH receptor antibody (TRAb) is 14 IU/L (RR 0–1.6 IU/L). What treatment for her thyrotoxicosis would you advise?

A. Carbimazole 20 mg once daily
B. 400 MBq radio-iodine
C. Subtotal thyroidectomy
D. Amiodarone 200 mg once daily
E. Propylthiouracil 100 mg twice daily

Answer: E.

The patient has clinical and biochemical evidence of Graves disease. Whilst carbimazole, radio-iodine and surgery are likely to be effective, they should be avoided in patients trying to conceive. Propylthiouracil has a lower risk of causing aplasia cutis in the developing embryo. An argument could be made for subtotal thyroidectomy to optimise thyroid status for conception, but her previous anaphylaxis shifts the risk–benefit in favour of medical management in the first instance. Amiodarone may make underlying thyrotoxicosis worse. Optimisation of thyroid status should be advised ahead of conception due to a higher risk of miscarriage, and a form of reliable contraception should be considered until she is euthyroid.

20.3. A 42-year-old male presented to his family doctor with a 6-month history of weight gain, fatigue and muscle weakness. The doctor noticed that he had centripetal obesity and abdominal striae and referred him to your endocrine clinic. The patient has no history of recent or current use of oral or inhaled steroids. You carry out some tests and find the following results:

Low-dose dexamethasone suppression test (LDDST): serum cortisol measured after 48 hours is 125 nmol/L (a normal response is a serum cortisol of < 50 nmol/L [1.8 μg/dL])
Late night (2300 hours) salivary cortisol: 18.4 nmol/L on the first occasion and 16.8 nmol/L on repeat testing (local RR < 3.6 nmol/L)
Plasma adrenocorticotrophic hormone (ACTH) at 0900 hours: undetectable (RR 1.5–13.9 pmol/L)

What would be the most appropriate next investigation to request in this patient?

A. Computed tomography (CT) of the adrenal glands
B. Corticotrophin-releasing hormone (CRH) stimulation test
C. High-dose dexamethasone suppression test (HDDST)
D. Magnetic resonance imaging (MRI) scan of the pituitary gland
E. Measurement of 24-hour urine free cortisol production

Answer: A.

The clinical features suggest Cushing syndrome, which is confirmed by the failure of cortisol suppression in the LDDST and the (repeated) high late-night cortisol level. The absence of detectable ACTH indicates an adrenal cause, with pituitary ACTH secretion being suppressed by high levels of cortisol. The most likely causes at this stage are a cortisol-secreting adrenal tumour (adenoma or, more rarely, carcinoma), so the most appropriate test is a CT scan of the adrenal glands.

There is no indication to carry out either a CRH stimulation test or an HDDST, as these tests are used to help to distinguish between pituitary-dependent Cushing syndrome and Cushing syndrome caused by ectopic ACTH secretion. Similarly, there is no indication for an MRI of the pituitary gland as the undetectable ACTH indicates an adrenal cause. 24-hour urine free cortisol production would be expected to be decreased, but this test is not necessary, as the diagnosis of Cushing syndrome has already been confirmed.

20.4. A 45-year-old man is incidentally found to have an elevated plasma calcium (2.7 mmol/L) on two separate occasions. Which of the following would make a diagnosis of familial hypocalciuric hypercalcaemia (FHH) more likely?

A. Normal plasma calcium recorded 5 years previously
B. PTH concentration within the reference range
C. Previous history of nephrolithiasis
D. Family history of hypercalcaemia in a first-degree relative
E. Previous history of osteoporosis

Answer: D.

FHH is an autosomal dominant condition caused by pathogenic variants in the calcium-sensing receptor (*CASR*) gene. It is typically associated with relatively modest hypercalcaemia and an absence of the end-organ damage associated with primary hyperparathyroidism. Previously normal calcium levels would be more consistent with the onset of primary hyperparathyroidism. PTH concentration in the upper half of the reference range is commonly encountered in primary hyperparathyroidism and does not help discriminate between this condition and FHH.

20.5. A 36-year-old man presents with frequent headaches and intermittent light-headedness and a single episode of syncope. On further questioning he notes some increased sweating and mentions there is a family history of hypercalcaemia in his mother and maternal aunt. His grandmother died suddenly at the age of 46 but the cause of death is not known. He is taking no medications. On assessment he is hypertensive with a blood pressure of 196/124 mmHg. He is clinically euthyroid and there are no discernable features of Cushing disease or acromegaly. Biochemical testing demonstrates TSH 2 mIU/L (RR 0.2–4.5 mIU/L), and free T4 14 pmol/L (RR 9–21 pmol/L); his corrected calcium is 2.72 mmol/L (RR 2.2–2.6 mmol/L); PTH is 7.2 pmol/L (RR 1.6–6.9 pmol/L). Plasma metanephrines are 2687 pmol/L (RR < 510 pmol/L). Testing of which gene is most likely to provide a definitive diagnosis?

A. *AIRE*
B. *RET*
C. *MENIN*
D. *VHL*
E. *CASR*

Answer: B.

The patient has symptoms and signs of phaeochromocytoma supported by raised plasma metanephrines. He also has asymptomatic hyperparathyroidism. The sudden death of his grandmother could have been the result of a hypertensive crisis. 40% of phaeochromocytomas are associated with pathogenic variants. Pathogenic variants in *AIRE* are associated with polyglandular autoimmunity and do not fit with this clinical picture. *CASR* pathogenic variants result in asymptomatic hypercalcaemia but are not associated with phaeochromocytoma. *MENIN* pathogenic variants are found in MEN 1, which is predominantly associated with pancreatic, parathyroid and pituitary lesions but not typically with phaeochromocytoma. Pathogenic variants in *VHL* increase the risk of phaeochromocytoma and haemangiomata but would not usually cause hyperparathyroidism. *RET* pathogenic variants are found in MEN 2a and MEN 2b. These conditions are typically associated with an increased risk of medullary thyroid carcinoma, phaeochromocytoma and primary hyperparathyroidism.

(Exudative maculopathy) Courtesy of Dr A.W. Patrick and Dr I.W. Campbell. Inset (Axillae) From James WD, Elston DM, Treat JR, Rosenbach M. Andrews' diseases of the skin. 14th ed. Elsevier; 2024.

Diabetes affects every system in the body. However, clinical assessment is dominated by history and investigation rather than clinical examination. In routine clinical practice, the most important aspects of clinical examination relate to complication screening:

- Blood pressure (BP) measurement
- Foot examination (for pulses and sensation) to determine risk of (or presence of) ulceration (p. 796)
- Insulin injection sites (if applicable): inspect to check they are not over-used as this leads to impaired or unpredictable insulin absorption (lipohypertrophy, see Box 8)
- Retinal screening (see Box 7): check this has been performed with appropriate frequency according to local guidelines

Other clinically useful information:

- Technology: clinical inspection of the arm and abdomen may reveal the use of a continuous glucose monitoring (CGM) device and/or insulin pump delivering a continuous subcutaneous insulin infusion (CSII)

Other relevant clinical signs:

- Hands: there may be thickening of the skin and tendons (due to non-enzymatic glycation of collagen from long-term hyperglycaemia, see Box 1)
- Skin (uncommon):
  - Acanthosis nigricans (axilla and neck): associated with forms of diabetes involving severe insulin resistance (see Box 4)
  - Necrobiosis lipoidica diabeticorum: rash with scarred central yellow area (red margin when active) over the shins (see Box 10)

7 Examination of the eyes

Visual acuity[1]

- Check distance vision using Snellen chart at 6 m
- Check near vision using standard reading chart

Lens opacification

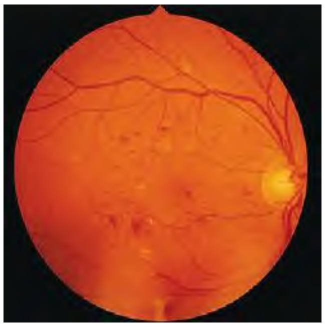
- Look for a normal red reflex using the ophthalmoscope held 30 cm from the eye

Fundal examination

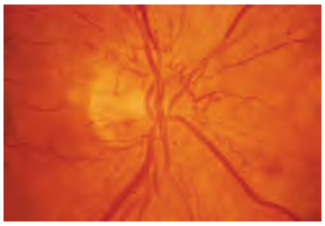
- Use digital retinal photography (where available)[2]
- Where not available (or in an emergency), dilate pupils with mydriatic drops (unless contraindicated) and use direct ophthalmoscopy in a darkened room
- Note features of diabetic retinopathy (p. 1256, including photocoagulation scars from previous laser treatment)

[1] Note that visual acuity can alter reversibly with acute hyperglycaemia due to osmotic changes affecting the lens. Most patients with retinopathy do not have altered visual acuity, except after a vitreous haemorrhage or in some cases of maculopathy

[2] The number of fields captured, the use of mydriatic drops (e.g. tropicamide) and how images are read depends on the setting and technology available



Background retinopathy. *Courtesy of Dr A.W. Patrick and Dr I.W. Campbell.*



Proliferative retinopathy. *Courtesy of Dr A.W. Patrick and Dr I.W. Campbell.*

1 Examination of the hands*

Several abnormalities are more common in diabetes than in the general population:

- Limited joint mobility ('cheiroarthropathy') causes painless stiffness. The inability to extend (to 180°) the metacarpophalangeal or interphalangeal joints of at least one finger bilaterally can be demonstrated in the 'prayer sign' (see opposite)
- Dupuytren contracture (p. 1089) causes nodules or thickening of the skin and knuckle pads
- Carpal tunnel syndrome presents with wrist pain radiating into the hand
- Trigger finger (flexor tenosynovitis) may be present
- Muscle-wasting/sensory changes may be present in peripheral sensorimotor neuropathy (more common in the lower limbs)

*Usually only examined if symptoms reported

8 Insulin injection sites*

Main areas used

- Anterior abdominal wall
- Upper thighs
- Upper outer arms

Inspection

- Bruising
- Subcutaneous fat deposition (lipohypertrophy)
- Erythema, infection (rare)

*If applicable, should be checked at all consultations

Lipohypertrophy.

11 Regular examination of the feet

Focus on detecting abnormal sensation and circulation to determine appropriate level of care required and prevent future ulceration/amputation.

Inspection

- Ulcers or skin breaks (require urgent referral for podiatry assessment and treatment)
- Localised bacterial or fungal infection (may require antibiotic/antifungal treatment)
- Discoloration (dusky colour) of the skin indicating critical ischaemia (if confirmed requires urgent vascular assessment)
- Callus (hard skin) formation on weight-bearing areas, ingrowing toenails (these require routine referral for podiatry to prevent ulceration)
- Fungal infection may affect skin between toes, and nails (topical or systemic antifungal treatment may be appropriate)
- Clawing of the toes/loss of the plantar arch (may reflect neuropathy)
- Severe deformity may reflect Charcot neuroarthropathy (see p. 797)

Circulation

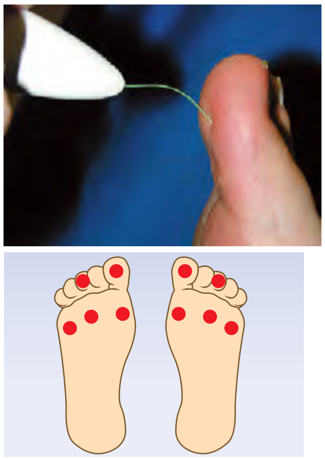
- Peripheral pulses – dorsalis pedis and posterior tibial (document at least annually). If neither is palpable, the foot is at 'moderate' risk of ulceration, even if sensation is normal
- Assess capillary refill in nail beds if pulses absent
- Skin temperature is raised in Charcot neuroarthropathy

Sensation

- 'Stocking' distribution in typical peripheral sensorimotor neuropathy
- Test light touch with a 10 g monofilament on the plantar surfaces of the toes and metatarsals. This is applied gently until it bends at each of five points on both feet. Areas of callus should be avoided as sensation is reduced. If absent in one or more of five places, the risk of foot ulceration is increased 5- to 10-fold ('moderate'), even if pulses are present (document at least annually)
- Testing of other sensation modalities (vibration, pain, proprioception) is not routine unless neuropathy is being fully evaluated

Reflexes (not routinely performed)

- Ankle reflexes are lost in severe sensorimotor neuropathy
- People with diabetes who have: (i) normal pulses and sensation, (ii) good foot care (nail cutting, lack of callus) and (iii) well-fitting footwear can be reassured and reviewed annually without regular podiatry



Monofilament testing.

Diabetes mellitus is a clinical syndrome with many causes (see Box 21.6), which is characterised by the presence of high blood glucose levels or hyperglycaemia (*mellitus* being Latin for 'sweet'). Type 2 diabetes accounts for around 90% of cases, while type 1 diabetes accounts for most of the remainder. In the United States, more than 20% of adults over the age of 65 years have type 2 diabetes. In the UK, people with diabetes occupy almost 20% of acute hospital beds.

All forms of diabetes are ultimately a consequence of *absolute* or *relative* insulin deficiency. Although type 1 and type 2 diabetes share the clinical phenotype of hyperglycaemia and carry risks of similar complications, their aetiology and pathophysiology are very different. In type 1 diabetes, there is an *absolute* deficiency of insulin because of an immune-mediated destruction of insulin-producing β cells in the pancreatic islets of Langerhans. In contrast, in type 2 diabetes, concentrations of circulating insulin are typically elevated, but there is a *relative* deficiency of insulin because there is reduced sensitivity to insulin in peripheral tissues (often due to obesity) and the β cells cannot make sufficient insulin to overcome this 'insulin resistance'.

Diabetes carries a heavy personal burden for those affected as well as high financial costs to health-care systems and society. In 2024, diabetes caused 3.4 million deaths globally (1 every 6 seconds) and health-care expenditure attributed to diabetes was estimated to be at least 727 billion US dollars, or 10% of total health-care expenditure. Acutely, hyperglycaemia results in marked symptoms of thirst, polydipsia and polyuria. If left untreated, it can lead to life-threatening metabolic decompensation requiring hospitalisation, especially in type 1 diabetes. Long-term hyperglycaemia is responsible for diabetes-specific 'microvascular' complications, particularly affecting the eyes (retinopathy), kidneys (nephropathy) and feet (neuropathy). These usually occur at a younger age in type 1 diabetes due to its earlier average age of onset.

Although the onset of clinical diabetes is often experienced as sudden in individual cases, there may have been a pre-clinical phase of months or even years when abnormal glucose values were not identified. Scientifically, there is no clear 'cut-off' between normal and abnormal glucose levels, so international bodies have derived diagnostic criteria for diabetes (Box 21.1) based on blood glucose concentrations above which there is an appreciable risk of developing diabetic retinopathy, the most common microvascular complication (Fig. 21.1). Lower levels of hyperglycaemia (above normal) are classified as 'prediabetes' (see Box 21.1).

The prevalence of diabetes is rising. Globally, it is estimated that in 2025, 830 million people have diabetes (10% of the world adult population). This figure is expected to reach 1.3 billion by 2050. Prevalence is highest in the Middle East and lowest in parts of Africa, varying around the world (Fig. 21.2) according to ethnicity as well as environmental factors (obesity, diet, habitual physical activity, urbanisation and economic development). A pronounced rise in the prevalence of type 2 diabetes occurs in migrant populations from low-income to industrialised countries. In many high-income countries, type 2 diabetes is no longer rare in children and adolescents, particularly in people of Hispanic, non-Hispanic Black and South Asian ethnicity. In some of these countries, increased survival is a factor underlying rising prevalence. Type 1 diabetes is also subject to geographical variation and is generally more prevalent in countries closer to the polar regions. Finland, for instance, has the highest incidence of type 1 diagnosis per year at > 60 per 100 000 of the population, whereas in China, India and Venezuela the incidence is only 0.1 per 100 000. The incidence of type 1 diabetes is also increasing and in 2019 there were close to 230 000 incident cases of childhood diabetes worldwide. Type 1 diabetes is more common in people of European descent than in other ethnic groups and, for reasons that are not understood, more people are diagnosed in the winter months.

21.1 Diagnostic criteria for diabetes and prediabetes

Diabetes is confirmed by international consensus as:

- plasma glucose in random sample or 2 hrs after a 75 g glucose load ≥ 11.1 mmol/L (200 mg/dL) *or*
- fasting plasma glucose ≥ 7.0 mmol/L (126 mg/dL) *or*
- HbA1c ≥ 48 mmol/mol

  In asymptomatic patients, two diagnostic tests are required to confirm diabetes

Definitions of 'prediabetes' vary between expert bodies:

- impaired fasting glucose:
  - fasting plasma glucose ≥ 6.1 mmol/L (110 mg/dL) and < 7.0 mmol/L (126 mg/dL) (World Health Organization) *or*
  - fasting plasma glucose ≥ 5.6 mmol/L (100 mg/dL) and < 7.0 mmol/L (126 mg/dL) (American Diabetes Association)
- impaired glucose tolerance:
  - fasting plasma glucose < 7.0 mmol/L (126 mg/dL) *and* 2-hr glucose after 75 g oral glucose drink ≥ 7.8 (140 mg/dL) and < 11.1 mmol/L (200 mg/dL)
- HbA1c:
  - 42–47 mmol/mol (National Institute for Health and Care Excellence [NICE] guidelines, UK) *or*
  - 39–47 mmol/mol (American Diabetes Association)

Functional anatomy and physiology

As a supply (and uptake) of glucose is essential for the functioning of all organs and tissues, a host of metabolic and physiological processes are involved in precise regulation of its levels in blood.

Insulin

Insulin is synthesised in the β cells of the pancreatic islets of Langerhans as a prohormone (pro-insulin), consisting of A- and B-chains, linked by C-peptide (see Fig. 21.24). C-peptide is cleaved by β-cell peptidases to create insulin (the A- and B-chains are joined by two disulfide bonds) and free C-peptide. In a healthy individual, around 10 days' supply of insulin is stored (~200–250 units) in the pancreatic islets. There are around one thousand β cells (approximately 70% of the islet cell population) in each of around one million islets scattered diffusely throughout the pancreas. The islets also contain α and δ cells, which synthesise glucagon and somatostatin, respectively; F cells (also known as PP cells) synthesise pancreatic polypeptide. The islets are highly metabolically active, but each individual has a total mass of less than 1 g (see Fig. 21.3B). They are highly vascularised, to allow synthesised hormones to enter the portal circulation. Despite making up only 1%–2% of total pancreatic mass, they receive 10%–15% of pancreatic blood flow.

Regulation of insulin secretion

Pancreatic β cells are designed to regulate blood glucose concentrations tightly by coupling glucose and other nutrient stimuli with insulin secretion (Fig. 21.3). Entry of glucose into a pancreatic β cell is by facilitated diffusion down its concentration gradient through

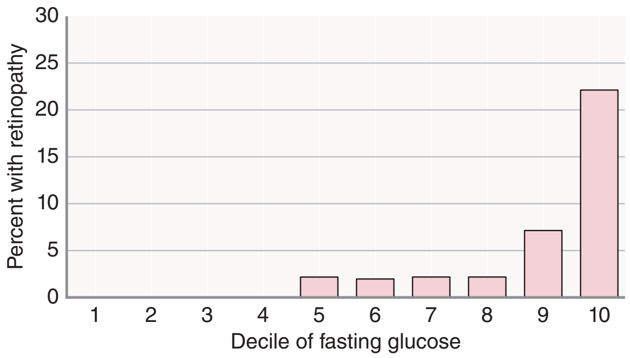


Fig. 21.1 Prevalence of retinopathy by decile of fasting glucose. There is a small inflection point at 4 mmol/L, but a major inflection at 8 mmol/L. *Adapted from World Health Organization and International Diabetes Federation. Definition and diagnosis of diabetes mellitus and intermediate hyperglycaemia: report of a WHO/IDF consultation. Geneva: World Health Organization; 2006. https://apps.who.int/iris/handle/10665/43588.*

insulin-independent cell membrane glucose transporters (GLUT1 or GLUT2). Glucose is metabolised by glycolysis and oxidative phosphorylation. The first step of the glycolytic pathway, the conversion of glucose to glucose-6-phosphate, is catalysed by the enzyme glucokinase (GK). The generation of glucose-6-phosphate is directly proportional to the concentration of glucose, thus making GK a very effective physiological glucose sensor in the β cell. When glucose is metabolised, adenosine triphosphate (ATP) is generated, closing an ATP-sensitive potassium channel (K_{ATP}). This depolarises the cell membrane, triggering release of calcium stored within the cell, which in turn activates voltage-sensitive calcium channels and ultimately secretion of insulin. Therefore, the amount of insulin released in response to this simple pathway at any given time is proportionate to the blood glucose concentration at that moment.

Insulin release can be potentiated by other nutrients and peptides and by neuronal control via the sympathetic and parasympathetic nervous system. Two important peptides that potentiate insulin release from β cells following ingestion of food are glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), also known as gastric inhibitory polypeptide. They are released from gastrointestinal L cells and K cells, respectively, when ingested nutrients reach the duodenum and upper jejunum. Thus, for a given ambient concentration of glucose sensed by the β cell, more insulin is secreted when the glucose has been ingested orally (when gut peptides are released) than when glucose was administered intravenously. This is termed the 'incretin effect' (Fig. 21.4A) and GLP-1 and GIP are known as 'incretin hormones'. The incretin effect is diminished in type 2 diabetes.

Insulin is secreted from β cells into the portal circulation (see Fig. 21.3) and classically this occurs in two phases (Fig. 21.4B). The rapid first phase represents release of pre-formed insulin from granules within the β cells, starting almost immediately following a rise in blood glucose, and is completed within 15 minutes. The second phase is more prolonged (occurring over the following 2–3 hours) and is a consequence of insulin synthesis.

Actions of insulin

Insulin is an anabolic hormone (i.e. it promotes the storage of nutrients) and has many or 'pleiotropic' effects on glucose, fat and protein metabolism (Box 21.2). It also stimulates cell proliferation and reduces apoptosis. The actions of insulin are mediated via the cell membrane insulin receptor. It belongs to the tyrosine kinase superfamily and is coupled to an extremely complicated intracellular signalling network. The key action of insulin to lower blood glucose is largely mediated by promoting the uptake of glucose into muscle and adipose tissue; at a cellular level, the binding of insulin to its receptor causes cell membrane glucose transporter GLUT4 to translocate from the cytoplasm to the cell membrane, permitting the uptake of glucose into adipose and muscle cells (Fig. 21.5).

Glucagon

Alpha (α) cells make up about 20% of the human islet cell population. Glucagon has opposite effects to insulin: for example, it acts on the liver to stimulate glycogenolysis, releasing stored glucose by breaking down stored glycogen (a component of 'hepatic glucose production')

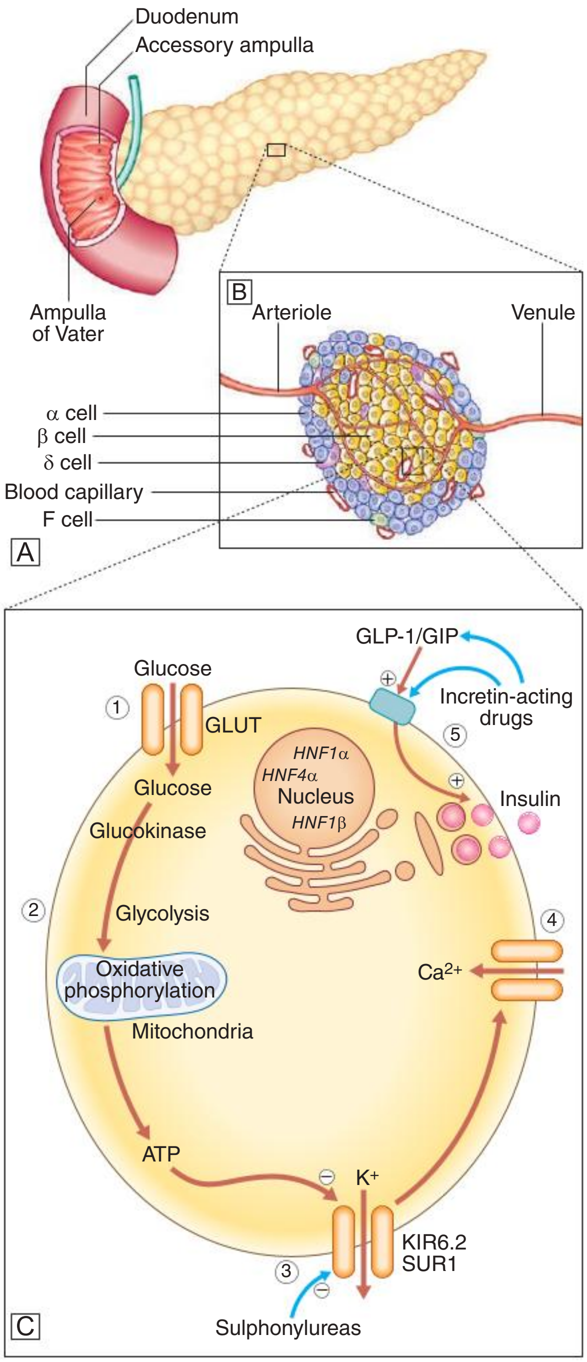

Fig. 21.3 Pancreatic structure and endocrine function. **A** The normal adult pancreas contains about 1 million islets, which are scattered throughout the exocrine parenchyma. Histology is shown in Figure 21.9. **B** The core of each islet consists of β cells that produce insulin and is surrounded by a cortex of endocrine cells that produce other hormones, including glucagon (α cells), somatostatin (δ cells) and pancreatic polypeptide (F or PP cells). **C** Schematic representation of the pancreatic β cell. (1) Glucose enters the cell via a glucose transporter (GLUT1 or GLUT2). (2) Glucose then enters glycolysis, and subsequent oxidative phosphorylation in the mitochondria results in a rise in intracellular adenosine triphosphate (ATP). (3) This ATP acts to close the K_{ATP} channel (which consists of four KIR6.2 subunits and four SUR1 subunits). This leads to membrane depolarisation. (4) The rise in membrane potential results in calcium influx due to opening of a voltage-gated calcium channel. This rise in intracellular calcium causes insulin secretory vesicles to fuse with the cell membrane, leading to insulin secretion. (5) Other stimuli, such as glucagon-like peptide-1 (GLP-1) or glucose-dependent insulinotropic polypeptide (GIP), act on G-protein-coupled receptors to increase cyclic adenosine monophosphate (cAMP) and amplify the insulin secretion. Genetic defects in the β cell result in diabetes. The primary genes are glucokinase (the initial step in glycolysis) and *HNF1α*, *HNF4α* and *HNF1β* (nuclear transcription factors). Two groups of drugs act on the β cell to promote insulin secretion. Sulphonylureas act to close the K_{ATP} channel, causing membrane depolarisation, calcium influx and insulin secretion. Incretin-acting drugs either increase the concentration of endogenous GLP-1 and GIP (the dipeptidyl peptidase-4, or DPP-4, inhibitors) or act as directly on the GLP-1 receptor (GLP-1 receptor agonists). Both of these drug groups act to augment insulin secretion, but only following an initial stimulus to insulin secretion through closure of β-cell K_{ATP} channels by glucose (or sulphonylureas).

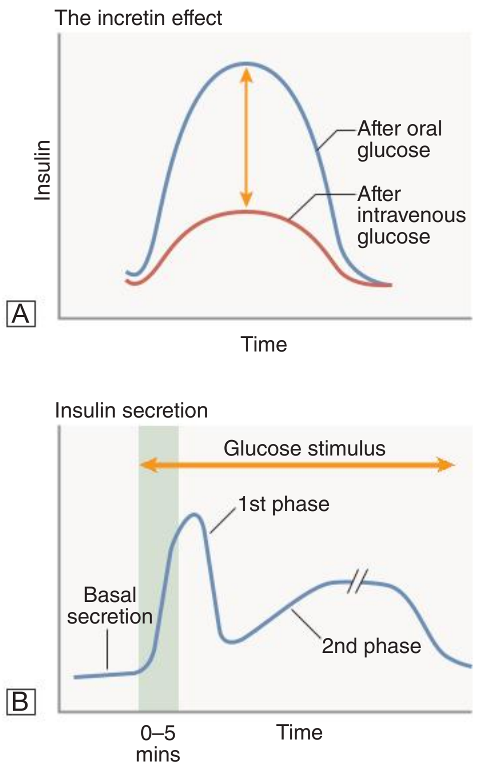

Fig. 21.4 Insulin secretion in response to elevated glucose. **A** The incretin effect describes the observation that insulin secretion is greater when glucose is given by mouth than when glucose is administered intravenously to achieve the same rise in blood glucose concentrations. The additional stimulus to insulin secretion is mediated by release of peptides from the gut and these actions are exploited in incretin-based therapies (p. 779). **B** An acute first phase of insulin secretion occurs in response to an elevated blood glucose, followed by a sustained second phase.

causing blood glucose levels to rise. Glucagon is critically important in the defence against low blood glucose (hypoglycaemia). Its secretion by α cells is inhibited locally by β-cell insulin secretion (i.e. a 'paracrine' effect) and also by somatostatin from δ cells. Glucagon secretion is also inhibited by islet amyloid polypeptide (amylin), which is co-secreted from β cells with insulin. Thus insulin and glucagon are tightly and reciprocally regulated, such that the ratio of insulin to glucagon in the portal vein is a major determinant of hepatic glucose production and other metabolic processes, including lipolysis and ketogenesis.

Blood glucose homeostasis

Blood glucose is precisely regulated and maintained within a narrow range (between 4.0 and 5.4 mmol/L (72–99 mg/dL)) when fasting (see Fig. 21.7). This is essential for ensuring a physiological continuous supply of glucose to the central nervous system. The brain has little capacity to store energy in the form of glycogen or triglyceride, while the blood–brain barrier is largely impermeable to fatty acids. Therefore, the brain depends on the liver for a constant supply of glucose for oxidation and hence generation of ATP.

i 21.2 Metabolic actions of insulin

Increase	Decrease
Carbohydrate metabolism	
Glucose transport (muscle, adipose tissue)	Gluconeogenesis
Glycogen synthesis	Glycogenolysis
Glycolysis	
Lipid metabolism

Fatty acid synthesis (liver)	Lipoprotein lipase (muscle)
Lipoprotein lipase activity (adipose tissue)	Ketogenesis
	Fatty acid oxidation (liver)
Protein metabolism	
Amino acid transport	Protein degradation
Protein synthesis	

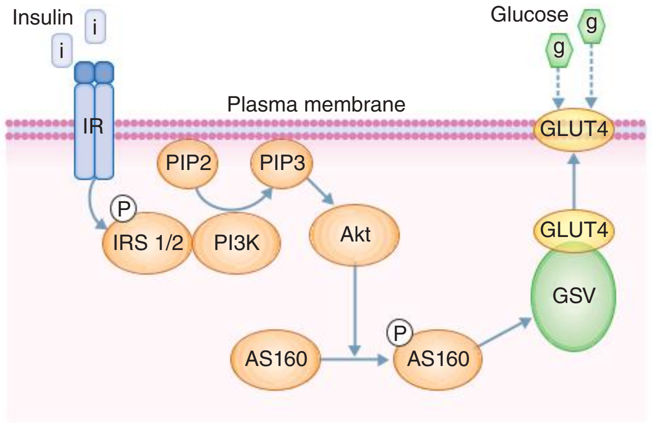

Fig. 21.5 Insulin receptor signalling. Insulin (i) binds to the insulin receptor (IR) triggering a complex signalling cascade including phosphorylation (P) of insulin receptor substrate (IRS) by tyrosine kinase. IRS associates with and activates phosphoinositide 3-kinase (PI3K). PI3K stimulates Akt, which phosphorylates and inactivates AS160. This leads ultimately to translocation of glucose transporter 4 (GLUT4) from GLUT4 storage vesicles (GSVs) to the cell surface, allowing cells to take up interstitial glucose (g). Note that there are many other elements of insulin receptor signalling (not shown) that mediate the other aspects of insulin's pleiotropic actions.

Glucose homeostasis is achieved through the coordinated actions of multiple organs, but mainly reflects a balance between the entry of glucose into the circulation from the liver, supplemented by intestinal absorption of glucose after meals, and the uptake of glucose by peripheral tissues, particularly skeletal muscle and brain. After ingestion of a meal containing carbohydrate, a substantial rise in blood glucose levels is prevented by:

- suppression of hepatic glucose production (by gluconeogenesis and glycogenolysis)
- stimulation of hepatic glucose uptake (and its subsequent storage as glycogen, i.e. glycogen synthesis)
- stimulation of glucose uptake by peripheral tissues (muscle and adipose) (Fig. 21.6).

These effects are mediated primarily by a post-prandial rise in portal vein insulin in response to increasing blood glucose (Fig. 21.7), augmented by incretin hormones, together with a fall in portal glucagon concentrations. Depending on the size of the carbohydrate load, around one-quarter to one-third of ingested glucose is taken up in the liver.

When intestinal glucose absorption declines between meals, blood glucose levels are maintained by increased hepatic glucose output via both gluconeogenesis (synthesis of glucose) and glycogenolysis. This is a consequence of falling portal vein insulin concentrations and rising glucagon levels. The main substrates for gluconeogenesis are glycerol and amino acids, as shown in Figure 21.6. At times of substantially increased metabolic demand for energy, such as during exercise or other acute stress, hepatic glucose output can be further transiently increased by activation of the sympathetic nervous system and release of hormones such as adrenaline (epinephrine), noradrenaline (norepinephrine), cortisol and growth hormone, which antagonise the actions of insulin (and so are known as 'counterregulatory hormones').

Fat metabolism

Adipocytes (and the liver) synthesise triglyceride from non-esterified (or 'free') fatty acids (NEFAs or FFAs) and glycerol. High circulating insulin levels after meals promote triglyceride accumulation and storage in adipose tissue. In contrast, in the fasting state, low insulin levels permit lipolysis and the release into the circulation of FFAs, which can be oxidised by many tissues. Their partial oxidation in the liver provides substrate (glycerol) and energy (in the form of ATP) to drive gluconeogenesis, but also production of ketones (acetoacetate, which can be reduced to 3-hydroxybutyrate or decarboxylated to acetone) in hepatocyte mitochondria. Ketones (also known as ketone bodies) are organic acids that can be oxidised and utilised as an alternative metabolic fuel for the brain when glucose is not available (e.g. during illness and prolonged fasting). Thus, when insulin levels are low (and glucagon and catecholamine levels are high), increased lipolysis and delivery of FFAs to the liver increases production of ketones (see Fig. 21.6). However, the rate at which ketones can be utilised by peripheral tissues is 'capped': blood ketone concentrations can therefore rise excessively (hyperketonaemia) when the rate of production by the liver exceeds their removal.

Investigations

Urine glucose

While a colorimetric test for glucose is included in all standard urine 'dipsticks', it is no longer used for screening or glucose monitoring and is rarely of clinical value. If glucose is detected in the urine ('glycosuria'), it will always require further assessment by blood testing (see below), as false positive tests can be caused by cross-reaction with β-lactam antibiotics, levodopa and salicylates. Some individuals have a high 'renal threshold' for glucose excretion, i.e. glucose is not detected in their urine despite a high blood glucose concentration. A low renal threshold for glucose (i.e. decreased reabsorption following filtration in the glomerulus) is common during pregnancy and in healthy young adults, and is usually of no consequence.

Blood glucose

Measurement of blood glucose concentration is the cornerstone of diabetes diagnosis, but varies markedly according to whether taken in the fasted or fed state. Glucose concentrations are slightly lower in venous than in arterial or capillary blood, as tissues extract glucose. Whole-blood glucose concentrations are lower than separated plasma concentrations because red blood cells contain relatively little glucose. Venous plasma measurements are the most reliable for diagnostic purposes (Boxes 21.1 and 21.3). Laboratory venous plasma glucose testing utilises a simple enzymatic reaction (glucose oxidase) and is cheap, reliable and usually automated.

Glucose can also be measured in capillary blood from a 'fingerprick' sample using test strips read with a portable electronic meter. This has been the method by which people with type 1 diabetes adjust their insulin doses and detect impending hypoglycaemia for many decades. The same applies for people with insulin-treated type 2 diabetes and to a lesser extent for those treated with sulphonylureas (in whom hypoglycaemia occurs about 10 times less frequently, but is nevertheless a risk). The main limitation of capillary glucose monitoring (other than the transient pain associated with fingerpricking) is the practical limit on the number of

Fig. 21.6 **Major metabolic pathways of fuel metabolism and the actions of insulin.** ⊕ indicates stimulation and ⊖ indicates suppression by insulin. In response to a rise in blood glucose, e.g. after a meal, insulin is released, suppressing gluconeogenesis and promoting glycogen synthesis and storage. Insulin promotes the peripheral uptake of glucose, particularly in skeletal muscle, and encourages storage (as muscle glycogen). It also promotes protein synthesis and lipogenesis, and suppresses lipolysis. The release of intermediate metabolites, including amino acids (glutamine, alanine), 3-carbon intermediates in oxidation (lactate, pyruvate) and free fatty acids (FFAs), is controlled by insulin. In the absence of insulin, e.g. during fasting, these processes are reversed and favour gluconeogenesis in liver from glycogen, glycerol, amino acids and other 3-carbon precursors.

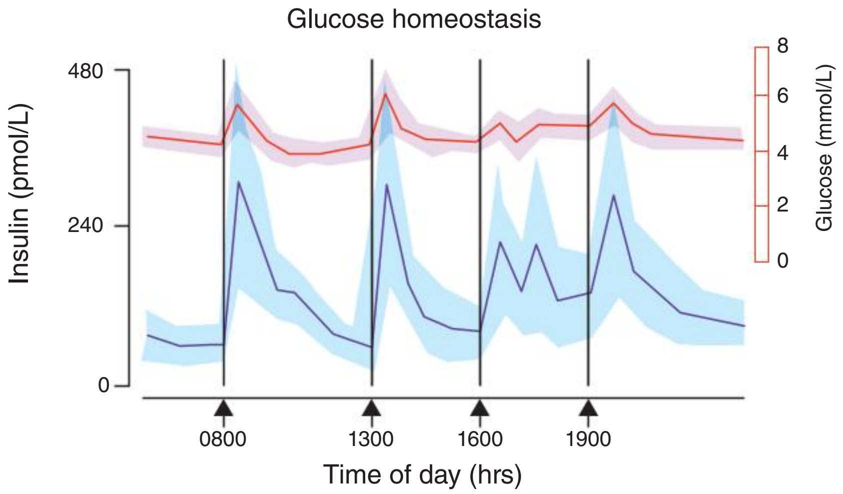

Fig. 21.7 Fasting and post-prandial blood glucose regulation (red, right y-axis) in health is maintained within physiological ranges (see text) primarily by changes in insulin secretion (blue, left y-axis). *Adapted from Owens DR, Zinman B, Bolli GB. Insulins today and beyond. Lancet 2001;358:739–746.*

measurements that can be performed over a 24-hour period. Blood glucose can be extremely variable, especially in people with type 1 diabetes, and so intermittent testing (such as 4–6 capillary measurements per day) may miss substantial peaks and troughs in blood glucose, especially overnight when no 'routine' measurements are usually performed.

Capillary blood glucose testing is also used as a 'near-patient test' to monitor glucose levels at the bedside in hospitalised patients with diabetes and in situations where hyperglycaemia or hypoglycaemia is a potential consequence of a medical condition or its treatment, e.g. intravenous insulin therapy (hyper- and hypoglycaemia), high-dose glucocorticoids (hyperglycaemia) and acute liver failure (hypoglycaemia). When arterial blood is sampled and analysed 'near-patient' in critical care and emergency situations, glucose levels are reported along with several other analytes and can be useful in monitoring risk of hyper- and/or hypoglycaemia.

It is important to note, however, that capillary and arterial whole blood glucose measurements are *less accurate* than laboratory venous plasma glucose measurements, providing an *approximation* of the prevailing blood glucose. Where high levels of precision are required, e.g. when making a diagnosis of diabetes (which will have substantial implications for the patient) or in the evaluation of 'spontaneous' hypoglycaemia (see Ch. 20), venous plasma blood glucose concentrations should be measured in the laboratory.

21.3 How to perform an oral glucose tolerance test (OGTT)

Preparation before the test

- Unrestricted carbohydrate diet for 3 days
- Fasted overnight for at least 8 hours
- Rest for 30 mins
- Remain seated for the duration of the test, with no smoking

Sampling

- Measure plasma glucose before and 2 hours after a 75 g oral glucose drink

Interstitial glucose

An increasingly established approach to measuring glucose in people with diabetes is continuous glucose monitoring (CGM). CGM systems use a tiny sensor inserted under the skin to measure glucose in interstitial fluid. CGM devices display both the current glucose and trend arrows by transmitting a signal to a receiver, smartphone or smartwatch application. CGM data are stored in and viewed from the cloud and extracts can be downloaded. The use of CGM has accelerated in recent years and is a standard of care in type 1 diabetes management in high-income countries. CGM can be intermittently scanned (isCGM or 'flash' CGM) or provide 'real-time' CGM (rtCGM). Sensors, once inserted, can stay in place for up to two weeks before being replaced and provide measurements of glucose levels every 5 minutes for rtCGM or every 15 minutes for isCGM. Some less expensive isCGM devices still require to be scanned at least once every 8 hours or the data stored in the sensor are lost (Fig. 21.8).

Interstitial glucose correlates well with blood glucose, but has a 10- to 15-minute lag when blood glucose is rapidly changing. This can lead to discrepancies between simultaneous CGM and capillary blood glucose measurements; these can also occur due to intrinsic inaccuracies (neither is as accurate as a laboratory measurement). However, accuracy of CGM devices is constantly improving, with newer devices reporting mean absolute relative difference (MARD) of interstitial fluid and blood glucose of < 10.

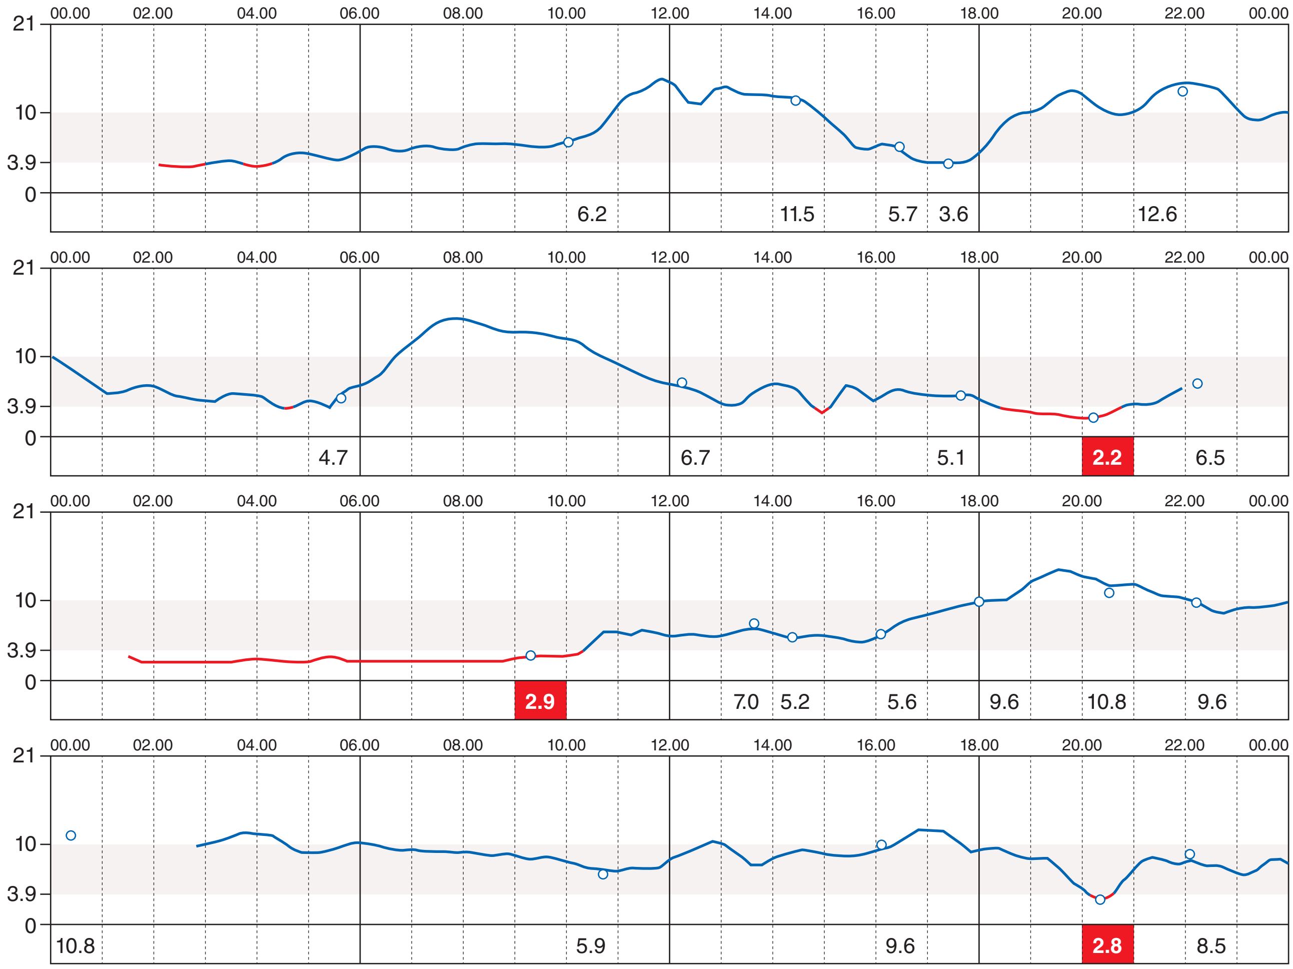

Fig. 21.8 Download from intermittently scanned ('flash') continuous glucose monitor (isCGM). Glucose data from four consecutive days are shown. Each small open circle (o) on the graph represents an occasion when the sensor has been scanned by the patient and there is a corresponding glucose level displayed at the bottom of the graph. The grey section represents the ideal target range of 3.9–10.0 mmol/L. Low glucose episodes are in red. Note the substantial variation in glucose within each 24-hour period (with frequent episodes of low and high glucose) and the variation between comparable time points on different days. Such variation could not be detected by intermittent capillary glucose testing. Each daily graph has a short period when no data are provided; this is because the time between sensor scans exceeded 8 hours.

Daily use of CGM improves glycaemic control in type 1 diabetes, providing useful information on daily glucose profiles and, in particular, night-time glucose patterns. It can reveal high and low glycaemic excursions that are not identified by capillary glucose testing. A particular benefit for people living with diabetes is incorporation of alarms, which can be set to warn of impending low glucose or high glucose levels. Alarms are particularly important during the night (when periods of even quite severe biochemical hypoglycaemia may go undetected) and for people with impaired awareness of hypoglycaemia. Early identification of low glucose (by alarm or a trend arrow showing rapidly declining glucose) allows prompt corrective action (i.e. ingesting sugar-containing foods and drinks), and thus may prevent a mild episode of hypoglycaemia becoming a severe episode. Identification of high glucose also allows self-administration, if appropriate, of additional 'correction' doses of insulin. The alarms can, however, become intrusive for some people, especially overnight, and some people prefer not to have them activated.

Initiation of CGM requires education and support to overcome potential knowledge overload and extract meaningful information from the extensive data generated. For many people with diabetes, this can be done via group education and/or remotely via videoconferencing. Various online educational resources are available. A functionality that is increasingly incorporated in CGM systems is the ability to share glucose levels remotely with family members (e.g. a child with diabetes can share data with a parent), caregivers and their diabetes specialist team (e.g. facilitating remote consultations). CGM devices are also increasingly designed to communicate with continuous subcutaneous insulin infusion (CSII) devices ('insulin pumps') via Bluetooth to create a hybrid closed-loop (HCL) system, i.e. one that automatically regulates the rate of background insulin infusion according to the current blood glucose level; such systems can be life-transforming for people with type 1 diabetes, both in terms of decreased psychological stress and improved glycaemic control (see p. 785).

Urine and blood ketones

Like glucose, ketones are increasingly measured in blood using portable electronic meters (integrated into some capillary glucose meters) rather than in urine. However, colorimetric tests are still incorporated into standard urine 'dipsticks.' These detect acetoacetate (by the nitroprusside reaction), while blood testing strips detect beta-hydroxybutyrate (β-OHB), the major ketone found in blood during diabetic ketoacidosis (DKA). Blood testing is particularly useful to guide self-management during 'sick days' as an early warning sign of incipient DKA, but also to guide emergency inpatient management (see p. 764), e.g. monitoring resolution of DKA (Box 21.4).

It should be noted that ketonuria/ketonaemia is not pathognomonic of diabetes and can be found after exercise in non-diabetic people who have been fasting or exercising strenuously, repeated vomiting, or eating a 'ketogenic' diet (with a macronutrient composition that is both high in fat and low in carbohydrate).

21.4 Interpretation of capillary blood ketone measurements

Measurement	Interpretation
< 0.6 mmol/L	Normal; no action required
0.6–1.5 mmol/L	Suggests metabolic control may be deteriorating; the patient should continue to monitor and seek medical advice if sustained/progressive
1.5–3.0 mmol/L	High risk of diabetic ketoacidosis; seek medical advice
> 3.0 mmol/L	Severe ketosis suggests presence of diabetic ketoacidosis; seek urgent medical advice

Glycated haemoglobin

Glycated haemoglobin (known as HbA1c) is accepted as the international standard method for assessing glycaemic control in diabetes as it reflects average blood glucose over a period of weeks or months.

During hyperglycaemia, slow non-enzymatic covalent attachment of glucose to haemoglobin (glycation) increases the proportion in the HbA1 (and specifically HbA1c) fraction, relative to non-glycated adult haemoglobin (HbA0). These fractions can be separated by chromatography or other laboratory methods. The rate of formation of HbA1c is directly proportional to ambient blood glucose concentration: a rise of 11 mmol/mol in HbA1c corresponds to an approximate average increase of 2 mmol/L (36 mg/dL) in blood glucose. HbA1c concentration is very stable as it reflects the integrated blood glucose control over the lifespan of erythrocytes (typically 120 days), but is most sensitive to changes in glycaemic control occurring in the month before measurement.

Since 2011, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) has developed a standard system for reporting HbA1c (IFCC-standardised HbA1c) in mmol/mol. However, the older 'percentage' units are still important as they are more familiar to many people with long-standing diabetes (many specialist publications provide data in both units) (Box 21.5).

HbA1c may be erroneously low (i.e. lower than would be anticipated for the prevailing average blood glucose) in conditions associated with shorter red cell lifespan (e.g. chronic blood loss, sickle-cell disorder, thalassaemia, pregnancy) and after blood transfusion (as transfused red cell concentrate comes from non-diabetic donors). Conversely, HbA1c may be erroneously high in conditions that increase red cell lifespan (iron, vitamin B_{12} or folate deficiency anaemia, splenectomy). It may be difficult to interpret with some assay methods in patients who have uraemia or a haemoglobinopathy. It is particularly important to be aware of this in pregnancy care and also in health-care settings in which red cell disorders and nutritional deficiency are prevalent, especially if HbA1c is used in the diagnosis of diabetes (see below). CGM data can be very useful in this context and many systems provide a remarkably accurate estimate of HbA1c (e.g. 'glucose management indicator') as a standard read-out.

Islet autoantibodies

As type 1 diabetes is characterised by inflammatory infiltration of pancreatic β cells, it can be useful when making a diagnosis of diabetes to identify evidence of autoimmunity. The most commonly measured islet antibodies are: anti-insulin, anti-glutamic acid decarboxylase (GAD), anti-protein tyrosine phosphatase-related proteins (IA-2) and anti-zinc transporter 8 (ZnT8). They are generally measured using specific immunoassays and, as with other such assays, 'false-positive' results can occur due to assay interference. Islet antibodies may also be found in healthy individuals and although some of these may go on and develop type 1 diabetes in the future (particularly if they have first-degree relatives

21.5 Conversion between DCCT and IFCC units for HbA1c

DCCT units (%)	IFCC units (mmol/mol)
4	20
5	31
6	42
7	53
8	64
9	75
10	86

IFCC HbA1c (mmol/mol) = [DCCT HbA1c(%) − 2.15] × 10.929

(DCCT = Diabetes Control and Complications Trial; IFCC = International Federation of Clinical Chemistry and Laboratory Medicine) with type 1 diabetes), many will not develop diabetes. The significance of islet antibodies is greater when they are detected at concentrations greater than the 95th centile of the general population (i.e. in 'high titre') and if multiple antibodies are detectable. A single positive autoantibody confers a 5-year risk of type 1 diabetes of 20%–25%, rising to 50%–60% risk with two autoantibodies and 70% with three autoantibodies. Conversely, as autoantibody levels can wane over time, they may be negative in people with established type 1 diabetes. Pragmatically, if anti-GAD and anti-IA-2 antibodies are measured together, either or both will be 'positive' in approximately 85% of newly diagnosed type 1 diabetes; measurement of anti-ZnT8 antibodies at the same time increases sensitivity to over 90% (i.e. fewer than 10% of cases will be triple antibody negative). Islet autoantibody testing is becoming standard in some high-income countries for people commenced on insulin therapy within 3 years of diagnosis. A negative autoantibody result should prompt consideration of an alternative diagnosis to type 1 diabetes; however, as type 1 diabetes can still occur in people with negative antibodies, the clinical diagnosis of type 1 diabetes should not immediately be rejected.

C-peptide

C-peptide (see Fig. 21.24) can be readily measured in blood and urine. It is secreted by β cells in equimolar concentrations to insulin, but is not a constituent of synthetic insulin. Therefore C-peptide is a useful marker of endogenous insulin secretion, particularly in insulin-treated individuals (in whom a measurement of serum insulin concentration does not distinguish therapeutically administered insulin from endogenously produced insulin).

Severe endogenous insulin deficiency (typically serum C-peptide <200 pmol/L) is found in type 1 diabetes, diabetes secondary to other pancreatic disorders and some forms of monogenic diabetes (see p. 762). 'Undetectable' serum C-peptide was traditionally considered pathognomonic of type 1 diabetes; however, the use of modern high-sensitivity C-peptide immunoassays (e.g. with a lower limit of detection of 3 pmol/L) has demonstrated that there is a spectrum of retained endogenous insulin secretion in type 1 diabetes. Persistent endogenous insulin secretion, in any form of diabetes, even though insufficient to maintain normoglycaemia, can have a smoothing effect on blood glucose, i.e. peaks and troughs in glucose are reduced because there is some retained ability to vary insulin secretion (upwards or downwards) in response to prevailing blood glucose.

In type 2 diabetes, C-peptide concentrations are usually significantly elevated (typically >900 pmol/L), reflecting increased insulin secretion in response to tissue insulin resistance. However, in forms of type 2 diabetes where there is a degree of endogenous insulin deficiency (such as with long diabetes duration), lower levels of C-peptide may occur.

Although there is overlap between C-peptide levels in the different forms of diabetes, a one-off measurement of random (non-fasting) serum C-peptide can be used to identify individuals who have been misclassified, e.g. labelled as type 1 diabetes, when they have type 2 diabetes or vice versa. If C-peptide is used in this way, blood glucose must be checked simultaneously to ensure it is >4.0 mmol/L (>72 mg/dL), as hypoglycaemia lowers endogenous insulin secretion and thus C-peptide, resulting in continued misclassification. C-peptide measurement is also used in the diagnosis of hypoglycaemic disorders in people without diabetes (p. 731).

Urine albumin ('microalbuminuria')

Standard urine dipstick testing detects urinary albumin at concentrations above 300 mg/L, but much lower concentrations can be measured using specific albumin dipsticks or quantitative biochemical laboratory tests, permitting detection of microalbuminuria (≥30 mg/L, see Box 18.11). Microalbuminuria (in the absence of urinary tract infection) has therapeutic implications as it is an important early indicator of diabetic nephropathy and a risk marker for macrovascular complications. Microalbuminuria may progress to overt (dipstick-positive) proteinuria.

Establishing the diagnosis of diabetes

Glycaemia can be classified into three categories: normal, impaired (prediabetes) and diabetes (see Box 21.1). The glycaemia cut-off that defines diabetes is based on a level above which there is a significant risk of microvascular complications, particularly retinopathy (see Fig. 21.1). People categorised with prediabetes have blood glucose levels that carry a negligible risk of microvascular complications, but are at increased risk of developing diabetes (5%–10% in this category develop diabetes each year).

Diabetes has traditionally been diagnosed using venous plasma glucose measurements (random or fasting) and (if required) a 75 g oral glucose tolerance test (OGTT; see Box 21.3). When a person has symptoms of diabetes, the diagnosis can be confirmed with either a fasting glucose of ≥7.0 mmol/L (126 mg/dL) or a random glucose of ≥11.1 mmol/L (200 mg/dL) (see Box 21.1). Asymptomatic individuals should have a second confirmatory test. Diabetes should not be diagnosed on capillary blood glucose results. In 2011, the World Health Organization (WHO) began to advocate the use of glycated haemoglobin (HbA1c) as a diagnostic test, with an HbA1c of ≥48 mmol/mol indicative of diabetes. This has been adopted in some countries, including the UK, where it is recommended by the National Institute for Health and Care Excellence (NICE). However, in part due to the analytical issues raised by prevalent haemoglobinopathies and other factors that affect HbA1c independent of average blood glucose (see p. 754), diagnosis by HbA1c has not been adopted globally by the International Diabetes Federation. As HbA1c reflects the last 2–3 months of glycaemia, it should not be used to diagnose diabetes when the duration of onset of hyperglycaemia has been short (e.g. suspected type 1 diabetes, glucocorticoid-induced diabetes, gestational diabetes); in this context, blood glucose measurements are still required to confirm or safely rule out a diagnosis.

The diagnostic criteria for diabetes in pregnancy (gestational diabetes) are more stringent (see Box 30.12).

Prediabetes

Prediabetes has two forms based on blood glucose criteria, namely 'impaired glucose tolerance' (IGT) and 'impaired fasting glucose' (IFG). In IGT, fasting glucose is normal, but 2-hour glucose is elevated above normal (but not high enough for diabetes). In IFG, fasting glucose is elevated above normal (not high enough for diabetes), but 2-hour glucose is normal. Prediabetes may also be diagnosed using HbA1c but criteria vary between international bodies (see Box 21.1). Although prediabetic states are not associated with a substantial risk of microvascular disease, they are associated with an increased risk of conversion to diabetes (particularly IFG) and an increased risk of macrovascular disease, i.e. myocardial infarction, stroke and peripheral vascular disease (particularly IGT). Individuals in whom prediabetes is detected (often when screening for diabetes) should be advised of their risk of progression to diabetes, given advice about lifestyle modification including weight management to reduce this risk, and screened for treatable cardiovascular risk factors such as hypertension and dyslipidaemia. Slow-release metformin can be prescribed to delay the onset of type 2 diabetes in overweight individuals with IGT and/or IFG who are at high cardiovascular risk and who are at high risk of progressing to frank diabetes despite lifestyle change.

Aetiology and pathogenesis of diabetes

Diabetes is always a consequence of *absolute* or *relative* deficiency of insulin, although the underlying genes, precipitating environmental factors and pathophysiology differ substantially amongst the various forms. In type 1 diabetes and diabetes secondary to pancreatic pathology (type 3c diabetes) there is an *absolute* insulin deficiency that requires treatment with insulin. At the other end of the spectrum, rare mutations in the insulin receptor cause diabetes due to severe insulin resistance (e.g.

21.6 Aetiological classification of diabetes mellitus

Type 1 diabetes[1]

Type 2 diabetes[1]

Other specific types[2]

- Genetic defects of β-cell function (see Box 21.8)
- Genetic defects of insulin action (e.g. lipodystrophies)
- Mitochondrial DNA mutations (maternally inherited e.g. m3243A>G)
- *Pancreatic disease*[3] (e.g. pancreatitis, pancreatectomy, neoplastic disease, cystic fibrosis, haemochromatosis, fibrocalculous pancreatopathy)
- Excess endogenous production of hormonal antagonists to insulin, e.g:
  - Growth hormone – acromegaly
  - Glucocorticoids – Cushing syndrome
  - Glucagon – glucagonoma
  - Catecholamines – phaeochromocytoma
  - Thyroid hormones – thyrotoxicosis
- Drug-induced (e.g. *glucocorticoids*, thiazide diuretics, HIV drugs, immune checkpoint inhibitors)
- Associated with genetic syndromes (e.g. Down syndrome, Klinefelter syndrome, Turner syndrome, DIDMOAD (Wolfram syndrome), Friedreich ataxia, myotonic dystrophy)
- *Gestational diabetes*

[1] The World Health Organization also recognises 'slowly evolving, immune-mediated diabetes of adults' and 'ketosis-prone type 2 diabetes' as 'hybrid' forms of diabetes.

[2] *Italics* = more common.

[3] Sometimes referred to as 'type 3c diabetes'.

(DIDMOAD = diabetes insipidus, diabetes mellitus, optic atrophy, nerve deafness)

Rabson–Mendenhall and Donohue syndromes); such individuals have extremely high levels of insulin, but a *relative* deficiency because insulin cannot exert a functional effect via an abnormal receptor. In type 2 diabetes, there is usually a combination of both β-cell dysfunction and insulin resistance, although here the insulin resistance is not at the insulin receptor level (see below). Although it is generally helpful to classify diabetes on an aetiological basis (Box 21.6), many individuals have a combination of factors, e.g. an individual with type 1 diabetes who becomes obese and insulin resistant (sometimes known as 'double diabetes') or an individual with significant obesity *and* a previous distal pancreatectomy.

Pathogenesis of diabetes

Insulin resistance and the metabolic syndrome

The precise mechanisms causing insulin resistance are complicated. Abnormalities have been reported in many post-receptor intracellular signalling pathways downstream from the insulin receptor, including phosphoinositide 3-kinase (PI3K), but none of the common abnormalities are sufficient to cause type 2 diabetes in the absence of other abnormalities. A single abnormality is often compensated for by other pathways ('redundancy'), so 'multiple hits' may be necessary for significant insulin resistance to occur. The exact combination of abnormalities present differs between individuals (i.e. the condition is 'heterogeneous') and there is a wide range of physiological insulin sensitivity even in non-diabetic individuals. Factors associated with insulin resistance are shown in Box 21.7.

Obesity is a major cause of insulin resistance. Intra-abdominal 'central' adipose tissue is metabolically active and releases large quantities of FFAs, which may induce insulin resistance because they compete with (or inhibit use of) glucose as a fuel supply for oxidation, e.g. in muscle. In addition, adipose tissue releases a number of hormones (including a variety of peptides, called 'adipokines') that act on specific receptors to influence sensitivity to insulin in other tissues. Examples of adipokines promoting insulin resistance include leptin, interleukin-6 and tumour necrosis factor alpha. Venous drainage of visceral adipose tissue is into the portal vein and so central obesity may have a particularly potent influence on hepatic insulin sensitivity and thereby adversely affect hepatic glucose and lipid metabolism.

21.7 Factors associated with insulin resistance and insulin deficiency

Insulin resistance	Insulin deficiency
Genetic factors*	Genetic factors*
Single gene mutations	Single gene mutations
Multiple gene variants	Multiple gene variants
Central obesity	Increasing age
Ethnicity	Autoimmune destruction
Reduced physical activity	Pancreatic pathology (see Box 21.6)
Hormone excess (see Box 21.6)	Toxins, e.g. alcohol, cytokines
Drugs, e.g. glucocorticoids	Infections, e.g. SARS-CoV-2
	Glucotoxicity
	Lipotoxicity
	Deposition of islet amyloid polypeptide

*Single gene mutations generally have a large effect size, while gene variants individually have a small effect size, but collectively the effect size can be important.

Some ethnic groups, e.g. South Asians and certain indigenous peoples of America and Australasia, have a very high prevalence of insulin resistance. In part this may simply relate to genetic and environmental factors associated with increased obesity. However, a common feature in these groups is that for a given body mass index, there is a greater degree of central rather than peripheral adiposity when compared, for example, to people of European descent.

Physical activity is another important determinant of insulin sensitivity. Inactivity is associated with down-regulation of intracellular insulin-sensitive kinases (enzymes that increase the activity of other enzymes by phosphorylation) and may promote accumulation of FFAs within skeletal muscle. Sedentary people are more insulin-resistant than active people with the same degree of obesity. Moreover, physical activity allows non-insulin-dependent glucose uptake into muscle, reducing the 'demand' on pancreatic β cells to produce insulin.

The pathogenic mutations in single genes with a large effect on insulin sensitivity mentioned above are extremely rare, but genetic factors nevertheless play a very important role in the pathogenesis of insulin resistance. Genome-wide association studies have shown that many common and rare gene variants are associated with increased and decreased sensitivity to insulin. Obesity has a strong genetic element (see p. 96), often relating to impaired hypothalamic mechanisms of appetite and satiety, and so many of the gene variants discovered to be associated with obesity are also associated with insulin resistance. Ethnic differences in adipose deposition are also likely to have a genetic basis, although this has not yet been conclusively proven (many genetic studies to date have included mainly participants of European descent). Non-obesity-related genetic variants associated with insulin resistance are mostly either directly involved in glucose metabolism or in the intracellular insulin signalling cascade.

Increasing age is associated with reduced insulin sensitivity, probably as a consequence of increased adiposity and reduced lean muscle mass. Drugs (notably glucocorticoids) and excess of hormones such as cortisol and growth hormone (see Box 21.6) can also antagonise the action of insulin.

As well as being associated with hyperglycaemia, insulin resistance is also associated with a cluster of other conditions. These include hypertension, dyslipidaemia (elevated small dense low-density lipoprotein (LDL) cholesterol, elevated triglycerides and low high-density lipoprotein (HDL) cholesterol), metabolic dysfunction–associated steatotic liver disease (MASLD) (Ch. 23) and, in women, polycystic ovarian syndrome. This cluster has been termed the 'insulin resistance syndrome' or 'metabolic syndrome' and is usually associated with central obesity, impaired glucose tolerance and an increased risk of macrovascular disease. Severe insulin resistance can be associated with acanthosis nigricans (see p. 746), i.e. dark pigmentation of skin body folds and creases, particularly in the axillae, groins and neck.

β-cell dysfunction

Insulin deficiency occurs across a spectrum that ranges from complete deficiency (e.g. following a total pancreatectomy), through the severe insulin deficiency of type 1 diabetes, to more minor degrees of insulin insufficiency that only become important if increased demand is placed upon the pancreas, e.g. by obesity-induced insulin resistance. In this latter situation, insulin deficiency is more relative than absolute, i.e. the β cells produce substantial amounts of insulin, but not in sufficient quantities to overcome an insulin-resistant state. Insulin deficiency may be the consequence of a number of different factors, some of which are listed in Box 21.7.

There is wide variation in the capacity of the pancreas to produce insulin, because of natural variation in β-cell mass and the inherent efficiency of the β cells. Single gene mutations with a large effect on β-cell mass and function are uncommon, but form the basis of most forms of monogenic diabetes (Box 21.8). Variation in β-cell mass and function is mediated by multiple genes, each with a very small effect. However, where a large number of adverse genetic variants are inherited, their cumulative effect can be significant. Individuals with genetically lower β-cell mass and function may not have abnormal blood glucose at birth, but are more susceptible to developing diabetes in later life, particularly if the individual becomes insulin resistant or acquires additional loss of β cells (e.g. through exposure to a toxin, such as alcohol, or following pancreatic surgery). Genetic variants may also code for proteins that increase susceptibility of β cells to environmental toxins or pro-inflammatory cytokines.

i 21.8 Monogenic diabetes mellitus

Functional defect	Main type[1]	Gene mutated[1]
(a) Maturity-onset diabetes of the young (MODY)		
β-cell glucose sensing	MODY2	*GCK*
The set point for basal insulin release is altered, causing a high fasting glucose, but sufficient insulin is released after meals. As a result, the HbA1c is often normal and microvascular complications are rare. Treatment is rarely required.		
β-cell transcriptional regulation	MODY3 MODY5 MODY1	*HNF1α* *HNF1β* *HNF4α*
Diabetes develops during adolescence/early adulthood and can be managed with diet and tablets for many years, but ultimately insulin treatment is required. The *HNF1α* and *4α* forms respond particularly well to sulphonylurea drugs. All types are associated with microvascular complications. *HNF1β* mutations also cause renal cysts and renal failure.		
(b) Neonatal diabetes		
β-cell K_{ATP} channels do not close in response to high glucose	Permanent neonatal diabetes[2]	*KCNJ11*

[1] Other gene mutations are described at diabetesgenes.org.
[2] Likely diagnosis when diabetes occurs before the age of six months (most cases have learning difficulties).

Autoimmune destruction and other disorders of the pancreas leading to loss of β-cell mass are discussed in subsequent sections. Increasing age is associated with a decline in β-cell mass and function and exposure to certain chemicals (notably alcohol) can also be toxic to β cells.

Elevated plasma glucose and FFAs exert toxic (and potentially reversible) effects on pancreatic β cells, respectively known as glucotoxicity and lipotoxicity. These effects may manifest as severe hyperglycaemia (and even ketoacidosis) at the time of diagnosis of diabetes.

In type 2 diabetes, deposition of a peptide known as islet amyloid polypeptide may be observed in islets. It is not entirely clear if this has a causal role in declining β-cell function in type 2 diabetes or if it is secondary to other insults to the pancreas. Adipokines released from adipose tissue (including IL-1β, IFN-γ, TNF-α, leptin and resistin) may also contribute to β-cell dysfunction in type 2 diabetes.

Type 1 diabetes

Pathogenesis

Type 1 diabetes is an immune-mediated disorder involving T-cell destruction of β cells in the pancreatic islets ('insulitis'). The natural history of type 1 diabetes is classically based on a 'gene–environment interaction' model, i.e. genetically susceptible individuals develop β-cell autoimmunity following exposure to an environmental trigger. This results in a progressive loss of β cells over a period of months or years (Fig. 21.9). Clinically this process is described by 3 stages. In stage 1, there is histological evidence of 'insulitis' with some loss of β-cell mass; although insulitis is a T-cell-mediated response, circulating autoantibodies to islet and/or β-cell antigens can be detected (see p. 754); blood glucose is normal. In stage 2, there is further loss of β-cell mass with some reduction in insulin secretory capacity; glucose levels are not in the diabetes range, but are higher than normal (dysglycaemia); the individual is asymptomatic. In stage 3, there is substantial loss of β-cell mass with very reduced insulin secretion; glucose levels are in the diabetes range and the individual is symptomatic.

The histological appearance of insulitis is of an inflammatory infiltrate of mononuclear cells (activated macrophages, helper cytotoxic and suppressor T lymphocytes, natural killer cells and B lymphocytes) within

islets (see Fig. 21.9). The specific mechanisms inducing this process are unknown, but a leading hypothesis that it is triggered in susceptible individuals by enteroviral infection has been supported by detection of specific mRNA in fresh pancreatic tissue samples from recently diagnosed adults. Even when type 1 diabetes is established, heavily infiltrated islets may be seen adjacent to unaffected lobules. Although the principal metabolic effect of insulitis is β-cell destruction, inflammation can also be detected in adjacent exocrine (acinar) tissue.

A key goal of diabetes research for several decades has been to detect individuals at high risk of developing type 1 diabetes (e.g. by detecting autoantibodies in family members) and use immunotherapy to delay its onset. In 2022 teplizumab was approved in the USA. Teplizumab delays the progression from stage 2 to stage 3 by about 2 years and may be introduced in other countries in the coming years, with other immunotherapies (and combinations) to follow.

Genetic predisposition

Type 1 diabetes is strongly influenced by genetic factors, but does not follow a simple Mendelian pattern of inheritance. Monozygotic twins have a concordance rate of 30%–50% for the condition, while dizygotic twins have a concordance of 6%–10%. In the United States, the risk of developing type 1 diabetes is 1:20 for those with a first-degree relative, compared with 1:300 in the general population. Children of mothers with type 1 diabetes have a 1%–4% risk of developing type 1 diabetes, but children of fathers with type 1 diabetes have a 10% risk. If both parents have the condition the risk is up to 30%. Notwithstanding clear genetic influence, 80%–85% of new cases do not have a family history.

The above observations are consistent with polygenic inheritance (see Box 21.6); over 20 different regions of the human genome have an association with type 1 diabetes risk. Most interest has focused on the human leucocyte antigen (HLA) region within the major histocompatibility complex on the short arm of chromosome 6. The HLA haplotypes *DR3* and/or *DR4* are associated with increased susceptibility to type 1 diabetes in people of European descent and are in 'linkage disequilibrium' (i.e. tend to be inherited together) with the neighbouring alleles of the *HLA-DQA1* and *DQB1* genes. The latter may be the main determinants of genetic susceptibility, since these HLA class II genes code for proteins on the surface of cells that present foreign and self-antigens to T lymphocytes (p. 75). However, candidate gene studies and genome-wide association studies have also implicated many other genes, e.g. *CD25*, *PTPN22*, *SH2B3*, *IL2RA* and *IL-10*. The majority of these risk loci are involved in immune responsiveness, such as recognition of pancreatic islet antigens, T-cell development and immune regulation. The genes associated with type 1 diabetes overlap with those for coeliac disease and thyroid disease, consistent with the known clustering of these conditions in individuals or families.

Environmental predisposition

Wide geographical and seasonal variations in incidence, and the rapid acquisition of local disease incidence rates in migrants from low- to high-incidence countries, suggest that environmental factors have an important role in precipitating the development of type 1 diabetes.

Although there are many hypotheses, the nature of these environmental factors is unknown. They may trigger type 1 diabetes through direct toxicity to β cells or by stimulating an autoimmune reaction directed against β cells. Potential candidates fall into four main categories:

1. Viruses: in addition to enteroviruses (e.g. Coxsackie B4), other viruses including mumps, rubella (in utero), cytomegalovirus, Epstein–Barr virus and retroviruses.
2. Toxins: various dietary nitrosamines (found in smoked and cured meats) and coffee. Bovine serum albumin (BSA), a major constituent of cow's milk, has also been implicated, since children who are given cow's milk early in infancy are more likely to develop type 1 diabetes than those who are breastfed. BSA may cross the neonatal gut wall and raise antibodies that cross-react with a heat-shock protein expressed by β cells.
3. 'Hygiene hypothesis': it has been proposed that reduced exposure to microorganisms in early childhood may play a role in limiting maturation of the immune system, increasing susceptibility to autoimmune disease.
4. Vitamin D: as the highest incidences are in areas where there is less sunlight (including northern Europe), low levels of vitamin D may be important. However, no clear cause–effect relationship has been identified.

Some immune checkpoint inhibitor drugs used in oncology can trigger the development of autoimmune disorders, including type 1 diabetes (see Ch. 8). Immune-mediated destruction of the pancreas seems to occur at an accelerated rate compared to the standard trajectory of type 1 diabetes, and there is often very severe insulin deficiency resulting in marked glycaemic variability.

Metabolic disturbances in type 1 diabetes

Type 1 diabetes presents when progressive β-cell destruction has crossed a threshold at which adequate insulin secretion and normal blood glucose levels can no longer be sustained. Above a certain threshold, high glucose levels are toxic to the remaining β cells (glucotoxicity), so that profound insulin deficiency rapidly ensues, causing the metabolic sequelae shown in Figure 21.10. Hyperglycaemia leads to glycosuria and dehydration, while glycosuria, lipolysis and proteolysis result in weight loss. Ketoacidosis occurs when generation of ketones exceeds the capacity for their metabolism. Elevated blood H^+ ions drive K^+ out of the intracellular compartment. Thus, new cases of type 1 diabetes usually present with a short history (typically a few weeks) of hyperglycaemic symptoms (see Box 21.9) and weight loss, and in the most severe cases (usually when the diagnosis is delayed) DKA can develop (p. 764).

Clinical course of type 1 diabetes

Stage 2 type 1 diabetes is a period of (usually) clinically undiagnosed prediabetes involving loss of first-phase insulin secretion (see Fig. 21.9). As population screening is not currently in place, the diagnosis is not usually made until the onset of symptoms at stage 3: in many cases, the condition will present urgently or even as an emergency with DKA. By this point, more than 80%–90% of β-cell mass has usually been destroyed. It has been calculated that population screening (for autoantibodies) would be cost-effective if case detection and prompt treatment resulted in 20% fewer cases presenting as DKA. As this could lead to better outcomes, and would allow systematic detection of stage 2 cases for immunotherapy (to delay progression to stage 3), a number of feasibility studies are in progress. Screening of siblings has been used in research and can be used opportunistically, but has the disadvantage that 90% of new cases of type 1 diabetes do not have an affected sibling.

Following initiation of insulin therapy, there may be a 'honeymoon period' lasting several weeks or months, during which there is a partial recovery in β-cell function as glucotoxicity is reversed by correction of hyperglycaemia. During the honeymoon period, the production of significant endogenous insulin means that exogenous insulin requirements may be very low and some individuals may even be able to stop insulin for a few weeks or months. Typically glycaemic control is good during this period, with modest glucose variability and a low risk of hypoglycaemia. In most patients, the immune-mediated process eventually destroys the majority of remaining β cells, resulting in severe insulin deficiency, increased requirements for exogenous insulin and more marked glycaemic variability.

It is increasingly recognised that a proportion of individuals with type 1 diabetes retain in the long term a subset of viable β cells with a capacity to secrete small amounts of endogenous insulin. The resulting spectrum of retained endogenous insulin production can be identified by measuring C-peptide (see p. 755). A shorter duration of diabetes and a later age of onset are associated with increased likelihood of significant detectable C-peptide. As exemplified by the honeymoon period, higher C-peptide concentrations are associated with reduced glucose

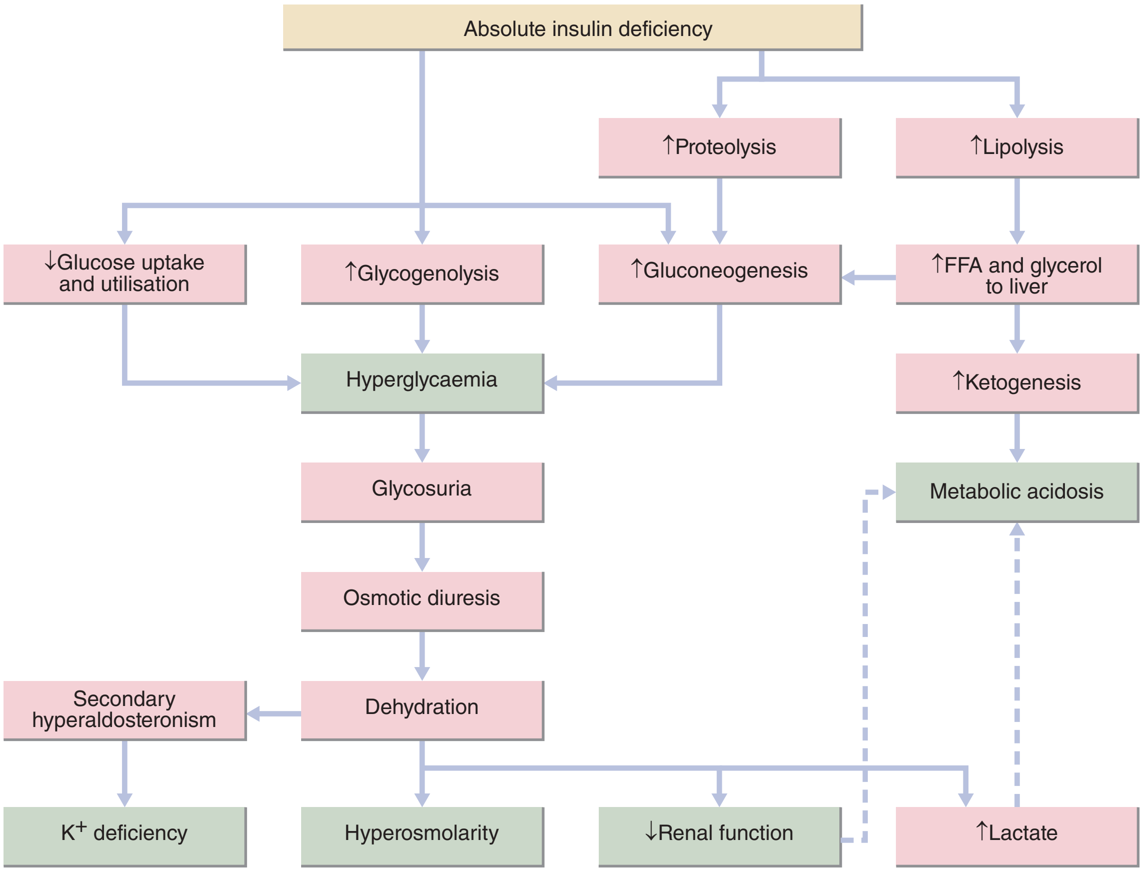

Fig. 21.10 **Acute metabolic complications of insulin deficiency.** (FFA = free fatty acid)

21.9 Symptoms of hyperglycaemia

- Polyuria
- Nocturia
- Thirst, dry mouth
- Polydipsia
- Tiredness, fatigue, lethargy
- Change in weight (usually weight loss)

- Pruritus vulvae, balanitis (genital candidiasis)
- Nausea
- Headache
- Hyperphagia; predilection for sweet foods
- Mood change, irritability, difficulty in concentrating, apathy

variability and hypoglycaemia, and increased time in range (Fig. 21.11). Higher C-peptide concentrations are also associated with lower HbA1c and reduced exogenous insulin requirements, frequency of DKA and microvascular complications. As well as delaying progression of stage 2 to stage 3 diabetes, immunotherapy has the potential to halt or slow the further decline in endogenous insulin production in stage 3 diabetes, but further research is required.

Type 1 diabetes presenting in adults

While type 1 diabetes is classically thought of as a disease of children and young adults (most commonly presenting between 5 and 7 years of age and at or near puberty), it can manifest at any age. Over 40% of cases develop in adults over 30 years of age – although some of these diagnoses may be incorrect, with a small proportion actually having misclassified type 2 diabetes or monogenic diabetes.

Some adults have a more insidious onset of hyperglycaemia and have ‘slowly evolving immune-mediated diabetes of adults’, previously known as ‘latent autoimmune diabetes of adulthood’ (LADA). This is essentially a subset of type 1 diabetes usually with a single islet autoantibody present in high titre (usually anti-GAD), greater retention of β-cell function and hyperglycaemia that does not require immediate commencement of insulin therapy. Affected individuals often have features of the metabolic syndrome and are initially managed with a working diagnosis of type 2 diabetes, recognised retrospectively as having progressed more rapidly to insulin treatment than is typical for type 2 diabetes.

Type 2 diabetes

Pathogenesis

Type 2 diabetes is a heterogeneous condition characterised by varying degrees of insulin resistance and β-cell dysfunction, commonly associated with obesity. Approximately 40% of overall type 2 diabetes risk is determined by genetic factors, with the rest due to environmental (acquired) factors. Both insulin resistance and β-cell dysfunction have genetic and environmental determinants (see relevant sections above). The relative contribution of insulin resistance and β-cell dysfunction varies between individuals, with most having an important contribution from both factors, but some having severe insulin resistance with less marked β-cell dysfunction, and others having significant insulin deficiency and minimal insulin resistance. For example, type 2 diabetes is increasingly seen in children and young adults, usually driven by insulin resistance due to obesity, often on a background of an ethnic predisposition to diabetes. By contrast, type 2 diabetes may also occur in non-obese individuals (who have more pronounced β-cell dysfunction), particularly in the elderly. Many of the rarer types of diabetes (see Box 21.6) were previously categorised as type 2 diabetes, and it is likely that this list will expand in time as genetic studies provide more insights into the aetiology of diabetes. The natural history of ‘typical’ type 2 diabetes is shown in Figure 21.12. Individuals at high risk of type 2 diabetes usually have a degree of genetic predisposition to either pancreatic β-cell dysfunction (measured as β-cell glucose sensitivity), insulin resistance (measured

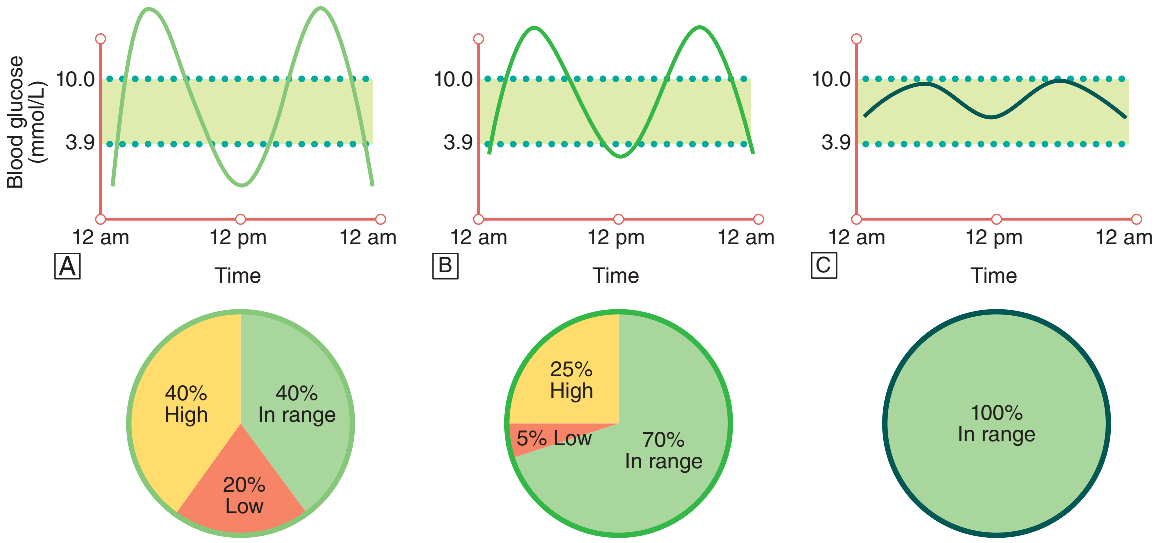

Fig. 21.11 Patterns of glycaemic variability in type 1 diabetes. Three patterns of glycaemic variability are shown, all associated with the same average blood glucose (8.6 mmol/L). **A** High variability with only 40% time in range (TIR). **B** Acceptable variability with 70% TIR. **C** Ideal profile with 100% TIR. Glycaemic variability is affected by many factors including individual behaviours (carbohydrate intake, timing and dose of insulin) and C-peptide status (high C-peptide associated with low glycaemic variability).

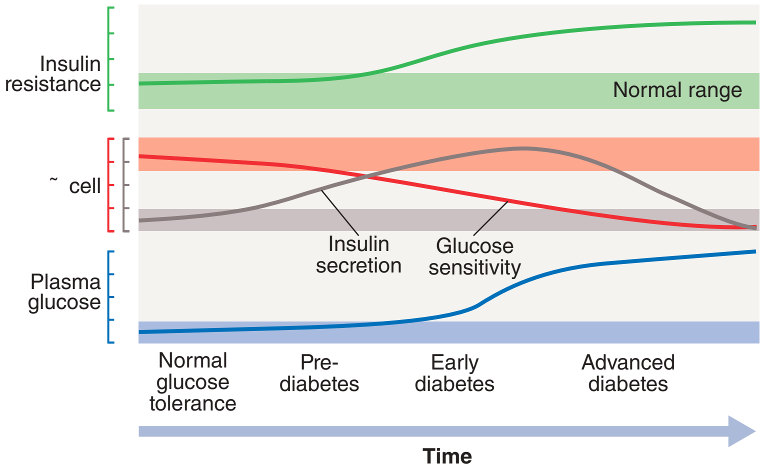

Fig. 21.12 Natural history of type 2 diabetes. Individuals predisposed to type 2 diabetes may have insulin levels at the lower end of normal and higher than normal insulin resistance, due to genetic factors. As insulin resistance increases (green) there is a compensatory increase in insulin secretion (grey), which initially maintains plasma glucose (blue) in the normal range. Eventually, the β cells are unable to compensate adequately and blood glucose rises, producing hyperglycaemia. Normal ranges are shown by horizontal bars shaded in the same colours. *Adapted and redrawn with permission from the original courtesy of Professor E. Ferrannini, University of Pisa.*

as insulin-mediated glucose uptake) or both. Each of these metabolic phenotypes declines with age with the trajectory of decline particularly determined by weight gain. The resulting rise in glucose levels over time (initially small) is compensated by an increase in insulin secretion rate, which is (teleologically) a homeostatic attempt to maintain normal blood glucose levels.

However, unless weight gain can be reversed at an early stage, β-cell function continues to decline such that a relative state of insulin deficiency in prediabetes and early diabetes becomes absolute. This is mediated by obesity-associated factors such as glucotoxicity, lipotoxicity, pro-inflammatory cytokines and possibly deposition of amyloid polypeptide in pancreatic islets. At the time of diagnosis of type 2 diabetes, approximately 50% of β-cell function has been lost; as β-cell function continues to decline over time, there is an escalating requirement for glucose-lowering therapy. In the most extreme form, there is pancreatic β-cell 'exhaustion' and, as in type 1 diabetes, insulin therapy is required to prevent ketoacidosis.

Risk factors for type 2 diabetes

Genetic predisposition

Genetic factors are important in type 2 diabetes, as shown by marked differences in susceptibility in different ethnic groups and by studies in monozygotic twins in whom concordance rates for type 2 diabetes approach 100%. People with an affected sibling with onset before the age of 40 have a 50% lifetime risk, declining to 30% if the sibling's age is > 65 years. Genome-wide association studies have identified > 400 gene variants that are associated with type 2 diabetes, each exerting a small effect, but together explaining only about 10% of the overall genetic variance. Most code either for proteins involved in β-cell function or in regulation of cell cycling and turnover (i.e. β-cell mass); a smaller proportion affect control of appetite and satiety (i.e. individual susceptibility to weight gain) and insulin resistance. Thus, the major genetic susceptibility relates to how well an individual's pancreas produces insulin. The largest population genetic effect described to date is a variation in *TCF7L2* (a transcription factor involved in glucose metabolism in pancreas and liver); 10% of the population have two copies of the risk variant for this gene and have a nearly twofold increase in risk of developing type 2 diabetes. Other common variants explain much lower risk than this, with many explaining less than a 10% increase. An individual with a high genetic burden (e.g. more than 40 risk variants) compared to one with very few is more than 2.5 times more likely to develop diabetes. Rarer variants tend to have larger effects on type 2 diabetes risk than common variants: e.g. in Greenland 3% of people carry a homozygous variant in an insulin signalling gene, *TBC1D4*, that results in muscle insulin resistance and a 10-fold increased risk of type 2 diabetes.

Lifestyle factors and obesity

Epidemiological studies show that type 2 diabetes is associated with reduced physical activity and a diet high in saturated fats and refined sugars, and low in fresh fruit and vegetables. Type 2 diabetes is also strongly associated with economic deprivation, social disadvantage, excess alcohol consumption and smoking. These factors are all in turn associated with obesity, which is strongly linked with insulin resistance. The risk of developing type 2 diabetes increases with rising body mass index (BMI), such that risk is increased 10-fold in people with a BMI of more than 30 kg/m^2 (Ch. 5). However, although the majority of individuals with type 2 diabetes are obese, only a minority of obese people develop diabetes, as most obese people are able to increase insulin secretion to compensate for the increased demand resulting from obesity and insulin resistance. As discussed above, those who develop type 2 diabetes are less able to produce sufficient insulin to overcome insulin resistance because of genetic and/or acquired factors.

Age

Type 2 diabetes is more common with increasing age (see Fig. 21.13). In the UK, it now affects approximately 25% of people aged between 60 and 80 years. In 2019, over 80% of all cases of type 2 diabetes in Scotland occurred after the age of 50 years. This association reflects declining β-cell mass and function with increasing age and the increasing tendency to insulin resistance due to greater obesity and reduced lean muscle mass.

Ethnicity

The prevalence of type 2 diabetes varies considerably according to ethnicity. For example, Fig. 21.13 shows that within the United States the prevalence of diabetes is lowest in those of non-Hispanic White ethnicity and increases across the categories of non-Hispanic Black, Hispanic, Asian and finally indigenous peoples. Genetic factors are likely to explain some of this variance, but environmental factors are also important, such as cultural practices and socio-economic status, which in turn are reflected in diet, physical activity and levels of obesity.

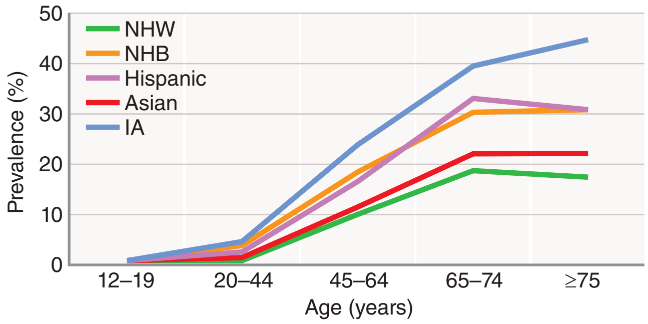

Fig. 21.13 Age-specific prevalence of diagnosed type 2 diabetes in the United States by ethnicity. (IA = Indigenous American; NHB = non-Hispanic Black; NHW = non-Hispanic White.) *Adapted from Golden SH, Yajnik C, Phatak S, et al. Interaction of risk factors for type 2 diabetes

In addition to the risk factors described above, type 2 diabetes is also more common in women with gestational diabetes, those with hypertension and/or dyslipidaemia, and those with previous 'stress hyperglycaemia' (see Fig. 21.31). All the risk factors for type 2 diabetes are inter-related and usually have additive effects. For example, increasing BMI is associated with a younger age of onset of type 2 diabetes (Fig. 21.14), because increased insulin resistance unmasks the genetic inability of the pancreas to produce adequate amounts of insulin. Type 2 diabetes also occurs at a younger age and lower BMI in people whose father and mother are both affected, presumably because they have inherited an increased number of genetic variants associated with β-cell dysfunction and insulin resistance. The threshold of weight gain at which type 2 diabetes occurs is lower for South Asians (BMI > 23 kg/m^2 rather than > 25 kg/m^2), who develop the condition on average 5–10 years earlier than people of European descent.

General population screening for type 2 diabetes has not been shown to be cost-effective, but is recommended in higher prevalence groups mentioned above (including adults aged > 40 years and those listed in Fig. 21.31). Decisions on who to screen in a general practice can be supported by a simple probability calculator, e.g. the Cambridge Risk Score (see www.mdcalc.com/calc/4001/cambridge-diabetes-risk-score) based on age, sex, BMI, smoking, family history and personal history of hypertension treatment or glucocorticoid treatment.

Clinical course and metabolic disturbances in type 2 diabetes

In comparison with type 1 diabetes, the risk of acute metabolic decompensation is low in type 2 diabetes in view of insulin deficiency that is relative rather than absolute: even small amounts of insulin are sufficient to suppress lipolysis and proteolysis, so profound weight loss and DKA are much less common. Hyperglycaemia may therefore be detected incidentally on screening, or even following detection of retinal abnormalities at a routine optician appointment, i.e. before the onset of symptoms. The proportion of cases in a population remaining undetected at any one time varies among health-care systems, but can be as high as 20%. At diagnosis, there may be a history of fatigue and 'osmotic symptoms' (thirst, polyuria and nocturia) for many months.

However, despite the 'typical' natural history of type 2 diabetes, it is important to remember that some people with type 2 diabetes develop marked and acute osmotic symptoms and weight loss. This may be a late presentation with advanced β-cell failure (and absolute insulin deficiency), but more often acute decompensation reflects a 'vicious spiral' of decline which is at least in part reversible. In this scenario, severe hyperglycaemia is associated with a craving for sugar, with large volumes of sugary drinks consumed in an effort to quench thirst. This causes glucotoxicity leading to reduced insulin secretion and increased lipolysis with high circulating FFAs aggravating the decompensation (lipotoxicity).

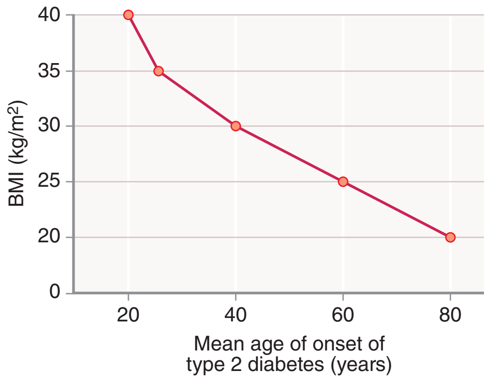

Fig. 21.14 Relationship between age of onset of type 2 diabetes and body mass index. On average, type 2 develops at a younger age in people with increased body mass index.

Education and dietary intervention can lead to rapid symptomatic improvement, but in the most severe instances, hyperglycaemic hyperosmolar state (p. 766) and even diabetic ketoacidosis (DKA) can occur.

Ketosis and DKA in type 2 diabetes is referred to as 'ketosis-prone' diabetes or 'Flatbush syndrome'. This was named after the Flatbush neighbourhood of New York, which had a large population of people of African American and African Caribbean origin and in which presentation with DKA was noted in the 1980s to be as common with type 2 diabetes as with type 1 diabetes. It remains unclear whether ketosis-prone diabetes is a unique type or a subset of more severe type 2 diabetes, but it is now recognised to occur in sub-Saharan African, South Asian and Hispanic populations. Importantly in this scenario, insulin treatment is required initially, but as glucose and lipid levels are controlled, β cells recover and oral treatments such as metformin can be effective within 3 months, i.e. insulin treatment can be carefully discontinued.

Intercurrent illness, e.g. infection (including with COVID-19; p. 349) or acute myocardial infarction increases the production of stress hormones that oppose insulin action. This can precipitate an acute exacerbation of insulin resistance and insulin deficiency, and result in more severe hyperglycaemia and dehydration with ketosis (p. 787). If the hyperglycaemia resolves following successful treatment of the illness, then this is retrospectively termed 'stress hyperglycaemia'. Affected individuals have a significantly increased risk of type 2 diabetes in subsequent years, presumably because they had pre-existing β-cell dysfunction and/or insulin resistance. In some individuals, hyperglycaemia persists, probably because of undiagnosed type 2 diabetes that was exacerbated by the acute illness.

Other forms of diabetes

Other causes of diabetes are shown in Box 21.6. These can broadly be classified as:

- genetic disorders, e.g. monogenic (mutation in or deletion of a single gene) or part of another genetic syndrome
- secondary to endocrine disorders, e.g. excess secretion of counter-regulatory hormones (those that oppose the effects of insulin)
- secondary to more generalised diseases of the pancreas (most commonly pancreatitis and cystic fibrosis)
- drug-induced causes, e.g. glucocorticoid therapy, which may precipitate hyperglycaemia ('steroid-induced diabetes') in susceptible individuals (i.e. with pre-existing insulin-resistance and/or β-cell dysfunction). Affected individuals who recover normal glucose tolerance after cessation of the precipitating drug remain at increased risk of type 2 diabetes.

Pancreatic (type 3c) diabetes

Diabetes due to more generalised pancreatic disease is a common form of 'secondary diabetes', increasingly referred to as type 3c diabetes, which is often not accurately distinguished from other forms of diabetes. It may be caused by acute or chronic pancreatitis, either due to alcohol excess or to gallbladder (stone) disease. While chronic pancreatitis may be associated with recurrent abdominal pain, it can also be asymptomatic in many patients. As it may go unrecognised, it is important to be aware of the possibility of pancreatic exocrine deficiency in all cases of diabetes; this can be detected by screening for low faecal enzyme elastase in a stool sample, particularly in the presence of chronic diarrhoea (see p. 868). Adequate oral pancreatic enzyme replacement can reduce abdominal pain, reduce diarrhea, improve absorption of ingested nutrients and enhance well-being. This may facilitate adjustment of insulin doses and reduces risk of hypoglycaemia in affected individuals, who usually require insulin therapy.

In some geographical regions, including South Asia, a form of chronic calcific pancreatitis heralded by chronic abdominal pain can present in adolescence or early adulthood (known as fibrocalculous pancreatic diabetes). It is associated with pathogenic variants in the gene *SPINK1*, which codes for an anti-protease enzyme and is therefore now thought to result from slow pancreatic auto-digestion. It is also associated with a high risk of pancreatic cancer.

Diabetes may also be a consequence of other disorders involving the pancreas, including haemochromatosis ('bronze diabetes'), cystic fibrosis and pancreatic carcinoma.

Monogenic diabetes

Monogenic diabetes accounts for approximately 4% of diabetes in those diagnosed under the age of 30 in the UK. While there are a number of rare monogenic disorders of insulin action, the most common are caused by defects in insulin secretion.

Maturity-onset diabetes of the young (MODY) and neonatal diabetes

The genes involved in MODY and neonatal diabetes are shown in Figure 21.3C and Box 21.8.

The term MODY was coined in 1974 to signify non-insulin-requiring diabetes developing under the age of 25 years in at least one family member. It is dominantly inherited, which means that many cases have a family history of diabetes spanning three generations or more. MODY has been recognised since the 1990s to be a heterogeneous condition, with multiple single gene subtypes. One form is caused by a mutation in the β-cell glucose sensor enzyme glucokinase (see Fig. 21.3C), with affected individuals having an altered set-point for glucose. Glucokinase MODY results in a high fasting glucose (usually >5.5 mmol/L (99 mg/dL)), but a normal post-prandial response and slight elevation of HbA1c. It is important to identify these individuals as they do not develop diabetes complications and do not require glucose-lowering drug therapy and monitoring. The other forms of MODY are mostly caused by defective transcription factors that play a key role in β-cell development and function (hepatocyte nuclear factor (HNF) 1α, 1β and 4α). Patients with transcription factor MODY develop progressive diabetes in adolescence or early adulthood. Patients with HNF1α and 4α MODY are extremely sensitive to sulphonylureas, so this is the treatment of choice for these individuals. Many cases have been described in which after genetic diagnosis it has been possible to discontinue long-term insulin therapy. As HNF1β is a critical transcription factor, not only in pancreatic development but also in renal and genital tract development in utero, individuals with *HNF1β* pathogenic variants often have renal cystic disease and genital tract malformation including infertility. Insulin therapy is usually required.

Neonatal diabetes is variably defined as diabetes that presents in the first 6 months of life, presenting as profound insulin deficiency with hyperglycaemia and DKA. Approximately 50% of cases have a transient form that remits by about one year of age, with diabetes recurring in adolescence or early adulthood; the remainder have permanent neonatal diabetes. Approximately two-thirds of individuals with the permanent form have an activating mutation in genes encoding the KIR6.2 and SUR1 subunits of the K_{ATP} channel (see Fig. 21.3C). These cause it to be insensitive to glucose-mediated increases in intracellular ATP; as a result, pancreatic β cells do not secrete insulin, and insulin treatment is required from soon after birth. However, as affected individuals respond to sulphonylureas, genetic diagnosis can transform their lives, with over 90% controlled on oral sulphonylurea treatment. The K_{ATP} channel is also expressed in neurons, so mutations can severely affect brain function causing developmental delay and epilepsy. Early sulphonylurea treatment can in some cases prevent or improve these neurological consequences.

Mitochondrial diabetes

Pathogenic variants in mitochondrial genes can also cause diabetes, typically presenting between ages 20 and 50 years. The commonest variant is m3243A>G and like other mitochondrial disorders, inheritance is down the maternal line (p. 47). Sensorineural deafness is common, leading to a syndrome of maternally inherited diabetes and deafness (MIDD). Other features include neurological manifestations (headache, ataxia, myopathy, stroke), cardiomyopathy, conduction defects, macular dystrophy, renal disease (proteinuria) and gastrointestinal disease (most commonly constipation). Most individuals require insulin to treat the diabetes and metformin should be avoided, because it can affect mitochondrial function and there is a theoretical risk of lactic acidosis.

Presenting problems in diabetes

Hyperglycaemia

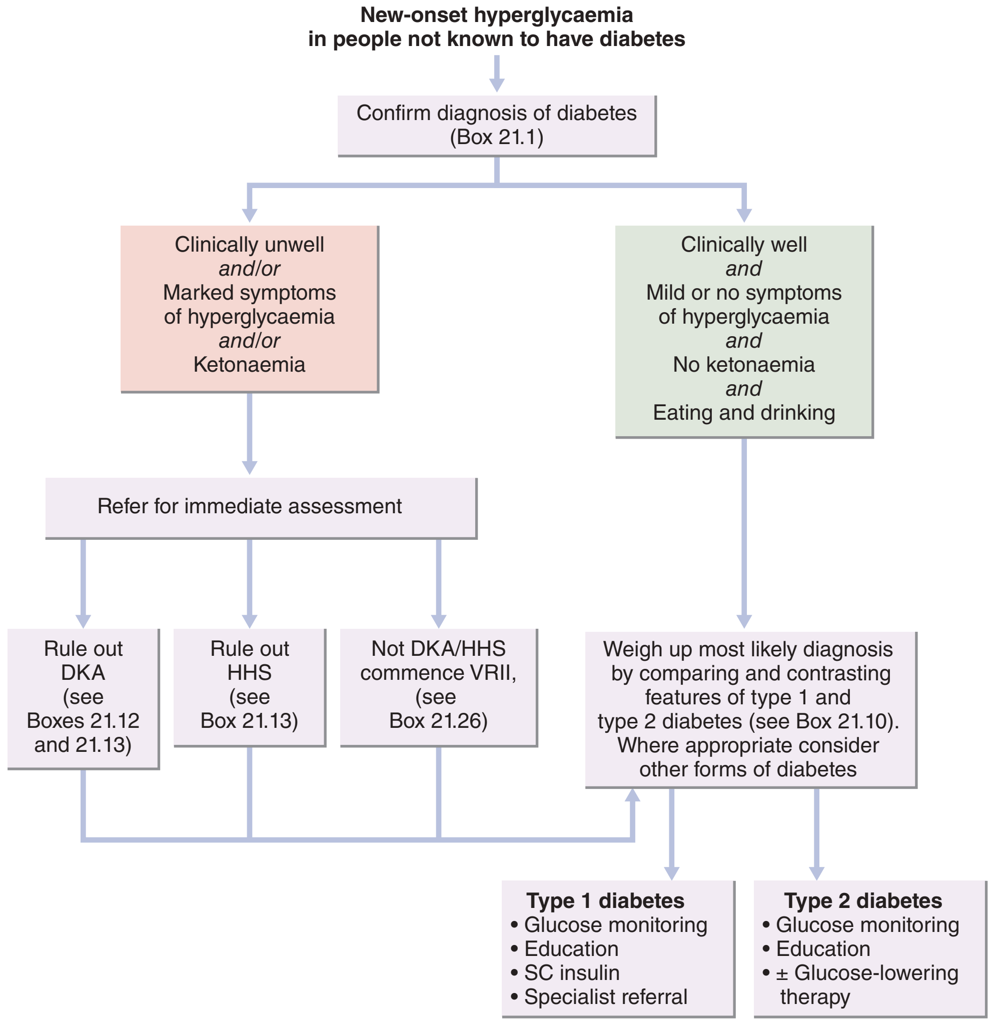
Although the presence or absence of diabetes is simply based on confirmation of hyperglycaemia above the diagnostic threshold, defining which type of diabetes has developed can be more complex in some individuals. Initial management involves a careful clinical assessment to decide whether (and, if so, what type of) immediate treatment is required (Fig. 21.15). Failure to initiate insulin treatment when it is required can result in the development of DKA and even death. Hyperglycaemic crises (DKA and hyperglycaemic hyperosmolar state) are discussed below.

Therefore, when the cause of diabetes is in doubt, it may be necessary to start precautionary insulin treatment with a view to later withdrawal if it becomes apparent that alternative glucose-lowering therapy is sufficient. Such decisions require careful discussion and explanation at a time of high stress.

The classical symptoms of hyperglycaemia and clinical features of type 1 and type 2 diabetes are shown, respectively, in Boxes 21.9 and 21.10. The classic 'osmotic symptoms' of polyuria (including nocturia), thirst and polydipsia are a consequence of the diuretic effect of significant glycosuria. Weight loss is due to dehydration and loss of calories in urine from glycosuria and, in type 1 diabetes, proteolysis and lipolysis. Severe osmotic symptoms and rapid weight loss are classically associated with the onset of type 1 diabetes, but type 2 diabetes may also present with these symptoms. Uncontrolled hyperglycaemia is associated with increased susceptibility to infection, such as skin infection (boils), genital candidiasis (with pruritus) or urine infection (see p. 792).

At the extremes of age, the distinction between type 1 and type 2 diabetes is usually obvious, but uncertainty can occur, particularly between the ages of 25 and 50 years. Type 2 diabetes is classically a condition of middle and old age, but is increasingly diagnosed in children and young adults. Type 1 diabetes most commonly occurs in younger people, but can occur at any age and may develop more insidiously in older individuals (p. 759). Family history of diabetes is common in type 2 diabetes and monogenic diabetes, and there may be a family history of autoimmune conditions in type 1 diabetes. Ethnic group and obesity may point to a diagnosis of type 2 diabetes, but type 1 diabetes can present in any race and at any weight, and it is important not to assign an incorrect diagnostic label at an early stage simply based on stereotypical features. Other causes of diabetes (see Box 21.6), such as type 3c diabetes, should not be forgotten, particularly if there are suggestive symptoms or signs (e.g. history of alcohol excess).

All patients presenting with hyperglycaemia should be tested for ketonuria (urine dipstick) or ketonaemia (fingerprick blood with blood ketone meter). The presence of raised ketones implies absolute insulin deficiency and indicates the need for referral to a secondary care



New-onset hyperglycaemia
in people not known to have diabetes
Confirm diagnosis of diabetes (Box 21.1)
Clinically unwell and/or Marked symptoms of hyperglycaemia and/or Ketonaemia
Clinically well and Mild or no symptoms of hyperglycaemia and No ketonaemia and Eating and drinking
Refer for immediate assessment
Rule out DKA (see Boxes 21.12 and 21.13)
Rule out HHS (see Box 21.13)
Not DKA/HHS commence VRII, (see Box 21.26)
Weigh up most likely diagnosis by comparing and contrasting features of type 1 and type 2 diabetes (see Box 21.10). Where appropriate consider other forms of diabetes
Type 1 diabetes

i 21.10 Typical characteristics of type 1 and type 2 diabetes[1]

	Type 1	Type 2
Age at onset	< 40 years	> 50 years
Duration of symptoms	Weeks	Months to years
Body weight	Normal or low	Obese
Ketonuria	Yes	No
Non-fasting serum C-peptide[2]	< 200 pmol/L	> 900 pmol/L
Rapid ketosis/decompensation without insulin treatment	Yes	No
Autoantibodies	Positive	Negative
Family history of diabetes	Less common	Common
Other autoimmune disease	Common	Uncommon

[1] The data in this table are typical examples; however, none of these are perfect discriminators, e.g. obese people can get type 1 diabetes; young adults can get type 2 diabetes.
[2] C-peptide is most discriminatory when used > 3 years after diagnosis. C-peptide may be > 200 pmol/L in people with type 1 diabetes in the 'honeymoon period' and may be < 600 pmol/L in people with type 2 diabetes who have a marked hyperglycaemia (due to glucotoxicity).

centre for further assessment and treatment. This will usually indicate a diagnosis of type 1 diabetes, but it should be remembered that 10%–15% of cases of DKA occur in people with type 2 diabetes. Islet autoantibody and C-peptide testing can be helpful in establishing the underlying cause of diabetes (p. 755), although C-peptide is most discriminatory when used at least 3 years after diagnosis (see Box 21.10). Sometimes it may be necessary for clinicians to counsel patients that their diabetes diagnosis is provisional and that a definitive diagnosis will only be possible once time has elapsed, the results of supplementary investigations are available and the responsiveness to different therapies has been assessed.

Diabetic ketoacidosis

DKA is an acute metabolic complication of diabetes that is a consequence of *absolute* insulin deficiency. It is a medical emergency with important complications including hypoglycaemia, hypokalaemia, pulmonary oedema, acute respiratory distress syndrome and cerebral oedema. Although mortality rates have fallen in the UK over the past two decades, a single episode of DKA is associated with an approximate 5% risk of death, rising to almost 25% in those with recurrent DKA, particularly in low- and middle-income countries. Death most commonly relates to the underlying precipitating illness rather than direct metabolic complications. DKA most commonly occurs in people with type 1 diabetes and can be the first presentation of the condition (see Box 21.10). It can also occur in type 2 diabetes, particularly if it has been long-standing or in individuals who are ketosis-prone (i.e. have significant β-cell dysfunction) or who have been misclassified as type 2 rather than type 1 diabetes. In established diabetes, DKA may be precipitated by an underlying illness or physiological stress. Infection (e.g. pneumonia and urinary tract infection) is the most common of these. Acute myocardial infarction, cerebrovascular disease and pancreatitis are other common examples of a precipitating illness. Examples of physiological stress include surgery, trauma and pregnancy. Another common cause of DKA is insulin deficiency due to discontinuation (accidental or deliberate) or inadequate delivery (error in administration, insulin pump failure, pen malfunction, out of date or inadequate storage) of insulin therapy. Drug and social history may reveal glucocorticoid, sodium-glucose co-transporter 2 (SGLT2) inhibitors or use of recreational drugs, all of which have been associated with DKA. Particularly in young people with recurrent episodes of DKA, psychological or personality factors are frequent causes of insulin omission and infrequent or absent monitoring of glucose levels.

Pathogenesis

A clear understanding of the biochemical basis and pathophysiology of DKA is fundamental for its efficient treatment (see Fig. 21.10). DKA is characterised by the cardinal biochemical triad of:

- hyperglycaemia (blood glucose > 11.1 mmol/L (200 mg/dL)) or known diabetes* *and*
- hyperketonaemia (≥ 3.0 mmol/L on fingerprick testing) or ketonuria (more than 2+ on urine dipstick testing) *and*
- metabolic acidosis (venous bicarbonate < 15 mmol/L and/or venous pH < 7.3 ($H^+ > 50$ nmol/L)).

*DKA can occur without hyperglycaemia ('euglycaemic DKA', i.e. glucose < 11 mmol/L (< 198 mg/dL)); this occurs in fewer than 5% of cases overall, but 70% of cases associated with SGLT2 inhibitors.

Severe hyperglycaemia (in some cases > 100 mmol/L (1800 mg/dL)) causes a profound osmotic diuresis leading to dehydration and electrolyte loss, particularly of sodium and potassium. Ketosis is a consequence of insulin deficiency, exacerbated by elevated catecholamines and other stress hormones, leading to unrestrained lipolysis and consequent excess supply of free fatty acids (FFAs) for hepatic ketogenesis. When the capacity to metabolise acidic ketones is outstripped by their rate of production, they accumulate in blood. The resulting metabolic acidosis forces hydrogen ions into cells, displacing potassium ions.

There are significant deficits of water and electrolytes in DKA. The average loss of water in moderately severe DKA in an adult is around 100 mL/kg. About half the deficit of total body water is derived from the intracellular compartment and occurs comparatively early in the development of acidosis with few clinical features. The remainder represents loss of extracellular fluid sustained in the later stages, when marked contraction of extracellular fluid volume occurs, with haemoconcentration, a decreased blood volume, and finally a fall in blood pressure and subsequent oliguria (< 0.5 mL/kg/hr). There are also deficits in sodium (7–10 mmol/kg), chloride (3–5 mmol/kg) and potassium (3–5 mmol/kg). The plasma concentration of potassium gives very little indication of the total body deficit and may even be raised initially due to disproportionate loss of water, catabolism of protein and glycogen, combined with displacement of potassium from the intracellular compartment by H^+ ions. However, soon after treatment is started, there is likely to be a precipitous fall in the plasma potassium due to dilution of extracellular potassium by administration of intravenous fluids, the movement of potassium into cells induced by insulin, and the continuing renal loss of potassium (due to secondary hyperaldosteronism caused by reduced renal perfusion).

The level of hyperglycaemia does not correlate with the severity of the metabolic acidosis, i.e. moderate elevation of blood glucose may be associated with life-threatening ketoacidosis. Type 1 diabetes in pregnancy and the use of sodium-glucose co-transporter 2 (SGLT2) inhibitors are two situations in which euglycaemic DKA can occur. Conversely, in other situations, hyperglycaemia predominates and acidosis is minimal, resulting in a hyperosmolar state (p. 766).

Clinical assessment

The clinical features of ketoacidosis are listed in Box 21.11. These usually progress rapidly over the course of several hours. DKA should be considered if there are the typical presenting symptoms of diabetes in association with nausea, vomiting, abdominal pain, hyperventilation, dehydration or reduced consciousness. In a severe and rapidly progressing case, the striking features are volume depletion, sunken eyes, dry mucous membranes (mouth and nose), dry axillae, decreased skin turgor (e.g. at the subclavicular area), reduced jugular venous pressure, tachycardia and hypotension. Breathing may be deep and sighing (Kussmaul breathing) due to the compensatory hyperventilation of severe metabolic acidosis. The breath may have the sweet smell of acetone, similar to nail polish remover or pear drops. Acute confusion, a reduced conscious level, or even coma may be present. In infected patients, including those with sepsis, pyrexia may not be present initially because

21.11 Clinical features of diabetic ketoacidosis

Symptoms

- Polyuria, thirst
- Weight loss
- Weakness
- Nausea, vomiting
- Leg cramps
- Blurred vision
- Abdominal pain

Signs

- Dehydration
- Hypotension (postural or supine)
- Cold extremities/peripheral cyanosis
- Tachycardia
- Air hunger (Kussmaul breathing)
- Smell of acetone
- Hypothermia
- Delirium, drowsiness, coma (10%)

of vasodilatation secondary to acidosis (indeed there may be mild hypothermia). Abdominal pain and vomiting are common features of DKA and may mimic an acute abdomen (see Ch. 10). It is important to examine for signs of a precipitant: auscultation of the chest for signs of consolidation, examination of the abdomen for peritonism or obstruction and inspection of the skin for cellulitis or wounds. Careful examination of the feet for new ulceration or ischaemia is imperative.

Investigations

Initial assessment should include the following:

- *Venous blood*: for urea and electrolytes, glucose, bicarbonate and acid–base status to confirm the presence of hyperglycaemia and acidosis. Hyponatraemia and hyperkalaemia are common. Serum amylase and lipase are often elevated in DKA but rarely indicate coexisting pancreatitis.
- *Blood (or urine if unavailable) analysis for ketones* (p. 751).
- *Electrocardiogram (ECG)* to look for evidence of acute myocardial infarction or electrolyte abnormalities.
- *Chest X-ray* to look for evidence of lung consolidation or pulmonary oedema.
- *Infection screen*: full blood count, blood and urine culture, C-reactive protein, viral throat swab. (N.B. Leucocytosis occurs commonly in DKA, but generally represents a stress response rather than infection.)
- *Pregnancy test*: in all women of childbearing potential.

Assessment of severity

The presence of one or more of the features listed in Box 21.12 is indicative of severe DKA.

Management

DKA is a medical emergency that should be treated in hospital, preferably in a high-dependency area. The aims of DKA management are to correct circulating volume and electrolyte imbalance while halting lipolysis and suppressing ketogenesis. It is important to identify and treat precipitating causes as well as to prevent complications. The central tenets of the management of DKA include intravenous insulin, intravenous fluid and potassium replacement. An agreed evidence-based protocol should be in place. A referral to the diabetes specialist team should be made as early as possible with review within 24 hours. Regular clinical and biochemical review is essential, particularly during the first 24 hours of treatment. Monitoring for complications is paramount during management. Vital signs including cardiac monitoring should be regularly assessed: low oxygen saturations may suggest the development of pulmonary oedema and acute respiratory distress syndrome (ARDS). In children and adolescents, the Glasgow Coma Scale (GCS) should be monitored hourly for cerebral oedema. Supportive measures may include nasogastric tube insertion for persistent vomiting or reduced level of consciousness and urinary catheter insertion to assess urine output and monitor treatment of oliguria (< 0.5 mL urine/kg/hr). An example of a UK guideline for the management of DKA is shown in Figure 21.16.

21.12 Indicators of severe diabetic ketoacidosis

- Blood ketones > 6 mmol/L
- Bicarbonate < 5 mmol/L
- Venous/arterial pH < 7.0 ($H^+ > 100$ nmol/L)

May also be:

- Persistent hypotension or oliguria
- Hypokalaemia (< 3.5 mmol/L)
- Glasgow Coma Scale score < 12
- O_2 saturation < 92% on air
- Systolic blood pressure < 90 mmHg
- Heart rate > 100 or < 60 beats per minute
- Anion gap > 16 mmol/L

(pH 7.0–7.25 = moderate DKA; pH 7.26–7.30 = 'mild' DKA)

Fluid replacement

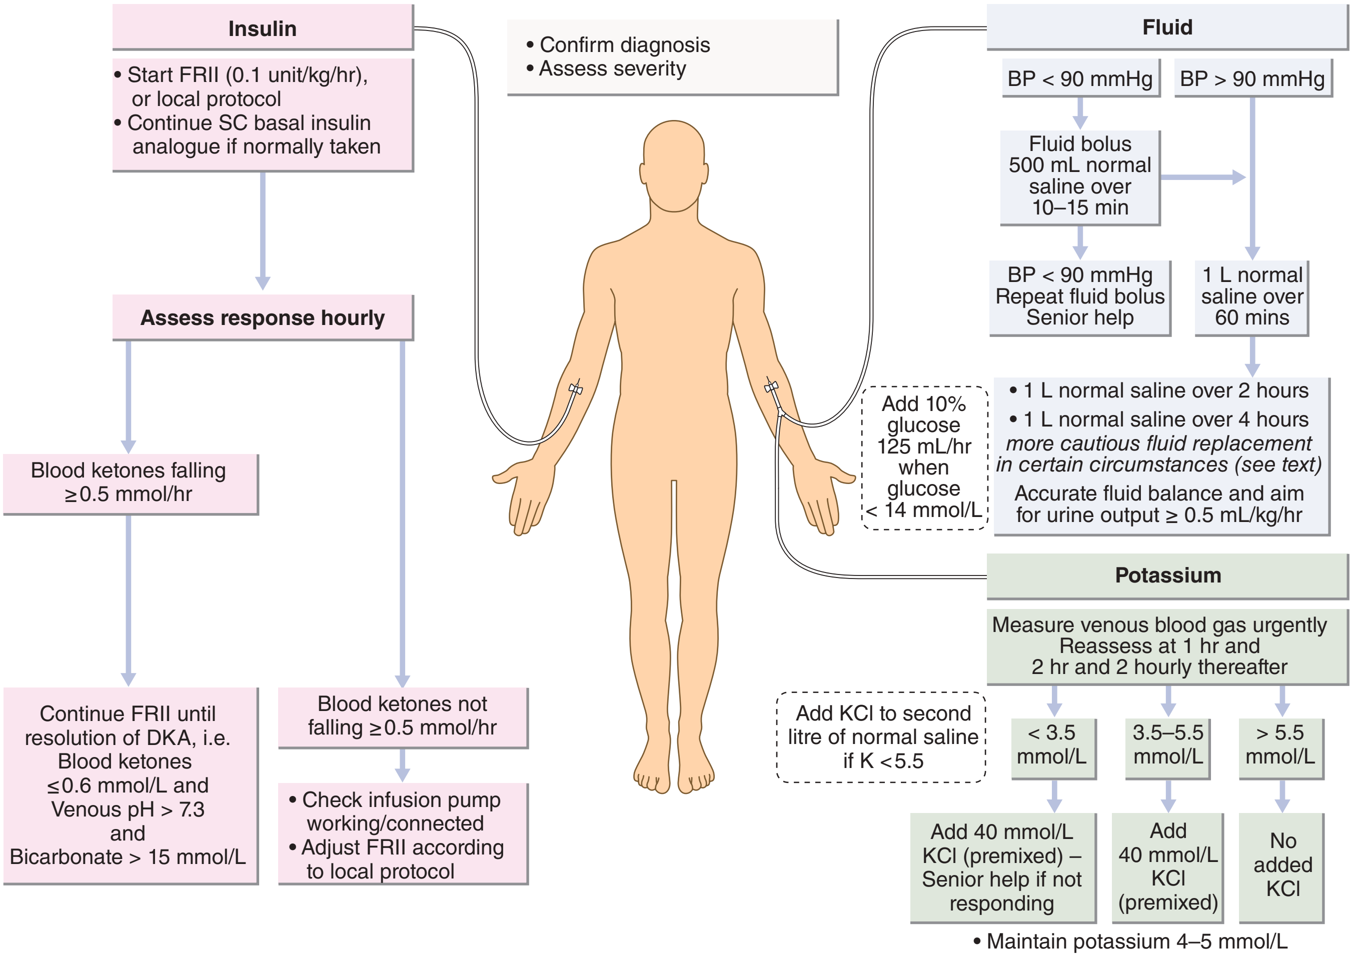
In adults, rapid fluid replacement should be commenced as soon as a diagnosis of DKA is confirmed (see Fig. 21.16). A rapid fluid bolus over 10–15 minutes may be required if systolic blood pressure is < 90 mmHg. A more cautious approach is advised in young adults, in pregnancy, in older adults and those with a history of kidney or heart failure. Most guidelines favour correction of the extracellular fluid deficit with isotonic saline (0.9% sodium chloride). Introduction of 10% glucose is recommended when the blood glucose falls below 14 mmol/L (252 mg/dL). The 0.9% saline infusion should be continued to correct circulating volume, with glucose infusion concurrently to prevent hypoglycaemia during rapid uptake of circulating glucose into cells.

Insulin replacement

A fixed-rate intravenous insulin infusion should be commenced according to local protocols (for example a UK guideline recommends 0.1 U/kg body weight/hr) (see Fig. 21.16). Blood glucose and blood ketones should be monitored hourly. Response to treatment should be assessed by a blood ketone concentration falling by at least 0.5 mmol/L/hr. Venous bicarbonate measurement can be used if blood ketone testing is unavailable (aiming for an increase of 3.0 mmol/L/hr). If blood ketones are not falling by at least 0.5 mmol/L/hr then the insulin infusion should be increased according to local protocols (after checking for malfunction or interruption of the insulin infusion). A long-acting insulin analogue in a dose equivalent to the individual's usual regimen should be administered subcutaneously during the initial management of DKA. This provides basal insulin for when the intravenous insulin is discontinued and reduces the risk of 'rebound' hyperglycaemia (or even DKA) recurring in hospital due to insulin interruption or omission. The fixed rate insulin infusion should be continued until DKA has resolved, defined as blood ketone < 0.6 mmol/L, bicarbonate > 15 mmol/L and venous pH > 7.3.

Potassium replacement

Careful monitoring of potassium is essential to the management of DKA as both hypo- and hyperkalaemia can occur (see above) and are life-threatening. Potassium is not usually recommended with the initial 1 litre of 0.9% sodium chloride infused as the primary focus at this stage is on restoring circulating volume and renal failure may be present. Potassium should be measured urgently on a venous blood gas sample and then reassessed after 1 hour, 2 hours and 2 hourly thereafter. Treatment with 0.9% sodium chloride with potassium chloride 40 mmol/L is recommended if the serum potassium is between 3.5 and 5.5 mmol/L and there is no evidence of oliguria (see Fig. 21.16). If potassium is > 5.5 mmol/L then potassium is not added to fluid replacement. If potassium is < 3.5 mmol/L at presentation then cardiac monitoring should be commenced and the critical care team involved as additional potassium will be required. Most guidelines aim to maintain potassium between 4.0 and 5.0 mmol/L.



Insulin
• Start FRII (0.1 unit/kg/hr), or local protocol
• Continue SC basal insulin analogue if normally taken
Assess response hourly
Blood ketones falling ≥0.5 mmol/hr
Continue FRII until resolution of DKA, i.e. Blood ketones ≤0.6 mmol/L and Venous pH > 7.3 and Bicarbonate > 15 mmol/L
Blood ketones not falling ≥0.5 mmol/hr
• Check infusion pump working/connected
• Adjust FRII according to local protocol
• Confirm diagnosis
• Assess severity
Fluid
BP < 90 mmHg
BP > 90 mmHg
Fluid bolus 500 mL normal saline over 10–15 min
BP < 90 mmHg Repeat fluid bolus Senior help
1 L normal saline over 60 mins
• 1 L normal saline over 2 hours
• 1 L normal saline over 4 hours
more cautious fluid replacement in certain circumstances (see text)
Accurate fluid balance and aim for urine output ≥ 0.5 mL/kg/hr
Add 10% glucose 125 mL/hr when glucose < 14 mmol/L
Potassium
Measure venous blood gas urgently Reassess at 1 hr and 2 hr and 2 hourly thereafter
Add KCl to second litre of normal saline if K <5.5
< 3.5 mmol/L
3.5–5.5 mmol/L
> 5.5 mmol/L
Add 40 mmol/L KCl (premixed) – Senior help if not responding
Add 40 mmol/L KCl (premixed)
No added KCl
• Maintain potassium 4–5 mmol/L

Fig. 21.16 Emergency management of diabetic ketoacidosis. (BP = blood pressure; FRII = fixed rate insulin infusion; KCl = potassium chloride; SC = subcutaneous)

Intravenous bicarbonate and phosphate

Adequate fluid and insulin replacement should resolve the acidosis. The use of intravenous bicarbonate therapy is not generally recommended (due to lack of evidence of benefit), but may be considered in the context of a pH of <6.9 following discussion with a senior specialist clinician. A degree of acidosis may reflect an adaptive response, improving oxygen delivery to the tissues, and excessive bicarbonate may induce a paradoxical fall in cerebrospinal fluid pH; this has been implicated in the pathogenesis of cerebral oedema in children and young adults. There is little evidence for intravenous phosphate replacement, but levels of <0.6 mmol/L are often corrected, particularly in the presence of respiratory or muscle weakness.

Ongoing management

Restoration of the usual insulin regimen, by subcutaneous injection, should not be instituted until the patient is: (i) biochemically stable and (ii) able to eat and drink normally. The fixed rate insulin infusion should be continued for 30 minutes after short-acting (or premixed) insulin is given at a mealtime. If using an insulin pump, then the infusion should be started during the daytime at the usual basal rate (commencement overnight is not recommended as non-specialist ward staff may be unfamiliar with this method of insulin delivery) and the fixed insulin rate infusion should be continued until the next meal bolus is given.

It is important to consider the precipitating factors that led to DKA (above). Glycaemic control, glucose monitoring, insulin injection technique and injection sites should all be reviewed. If insulin pump therapy is used, then it is important to ensure that there is an adequate supply of equipment, the insulin pump is working (for example not out of warranty) and that there is access to 'back up' insulin (and that it is within expiry date) via pen injector devices. DKA prevention should be discussed and written guidance on 'sick day rules' provided or reinforced. A blood ketone meter should be provided. A telephone number for the diabetes specialist team should be made available at the point of discharge from hospital. Given the mortality rates associated with DKA, early educational assessment and the provision of a personalised management plan are critical. Specialist psychological support may also be necessary.

Hyperglycaemic hyperosmolar state

Hyperglycaemic hyperosmolar state (HHS) is a medical emergency that is a consequence of prolonged *relative* insulin deficiency and so requires a different management approach from DKA. There is no precise definition of HHS, but it is characterised by hypovolaemia, severe hyperglycaemia (>30 mmol/L (>540 mg/dL)) and hyperosmolarity (serum osmolality >320 mOsmol/kg), without significant ketonaemia (<3 mmol/L) or acidosis (pH >7.3 (H^+ <50 nmol/L), bicarbonate >15 mmol/L). It most often occurs in older people (often in long-term care) who may have impaired thirst perception, cognitive impairment, frailty or reduced ability to drink water. Conscious level is often impaired, particularly when osmolality is >340 mOsmol/L. Mortality rates are higher than DKA (up to 20%) reflecting the population affected, but it is increasingly seen in younger adults particularly at the time of diagnosis of type 2 diabetes.

The pathogenesis of HHS is incompletely understood. As with DKA, there is glycosuria, leading to an osmotic diuresis, but renal loss of water is in excess to that of sodium and potassium (hypernatraemia is a common finding). In HHS, hyperglycaemia usually develops over a longer period than in DKA (see below), causing more profound hyperglycaemia and dehydration (fluid loss may be 10–22 L in a person weighing 100 kg). The reason that people with HHS do not develop significant ketoacidosis is unclear, although it has been speculated that insulin levels, although too low to stimulate glucose uptake in insulin-sensitive tissues, are still sufficient to prevent lipolysis and subsequent ketogenesis. Differentiating HHS and DKA in individual cases can be challenging, particularly in the setting of severe intercurrent illness that can be complicated by starvation ketosis, non-ketotic acidosis (acute kidney injury, lactic acidosis) and prescription of SGLT2 inhibitors. The clinical features of HHS and DKA are compared and contrasted in Box 21.13. A mixed picture of HHS and DKA can occur in up to one-third of hyperglycaemic crises. If the predominant diagnosis is unclear, then early specialist input is required to guide management and if necessary adjust local protocols.

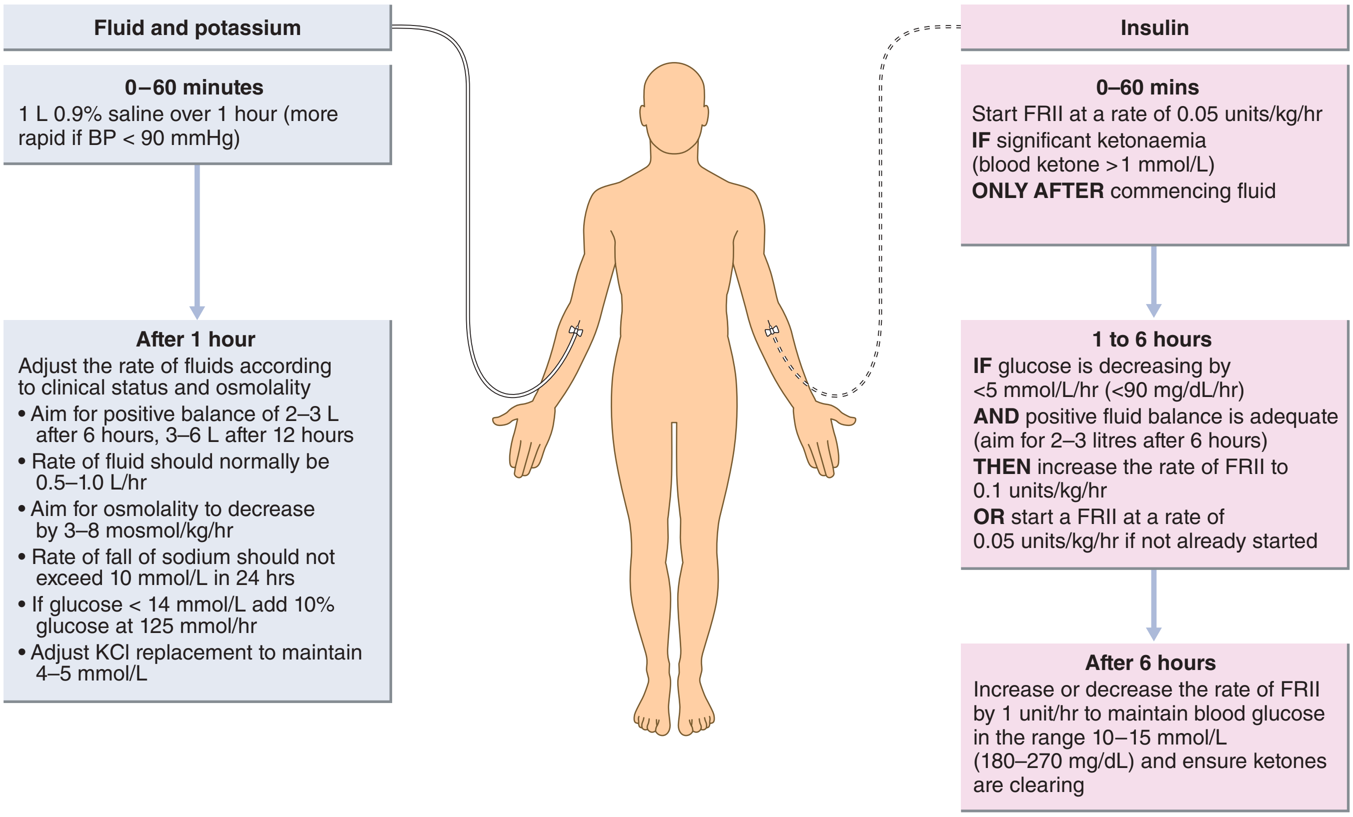
i 21.13 Typical characteristics of HHS and DKA

	HHS	DKA
Age	Older	Younger
Classification	Established prediabetes/ type 2 diabetes or first presentation	Established type 1 diabetes or first presentation
Duration of onset	Days to weeks	Hours to days
Abdominal pain	Uncommon	Common
Volume depletion	10%–20%	5%–10%
Insulin deficiency	Relative	Absolute
Glucose	Usually > 30 mmol/L	Usually > 11.1 mmol/L
Ketonaemia	< 3.0 mmol/L	> 3.0 mmol/L
Acidosis	Bicarbonate > 15 pH > 7.3	Bicarbonate < 15 pH 7.0–7.3

(DKA = diabetic ketoacidosis; HHS = hyperglycaemic hyperosmolar state)

HHS is more likely to occur when high glucose levels are sustained over many weeks or months. Common precipitating factors include infection (such as pneumonia or urinary tract infection) and other acute illness (such as acute myocardial infarction, cerebrovascular events), leading to an increase in counter-regulatory hormones. HHS can also occur in the context of drug therapy, such as glucocorticoids, and post-operatively in hospital. Poor prognostic signs include hypothermia, hypotension (systolic blood pressure < 90 mmHg), tachy- or bradycardia, severe hypernatraemia (sodium > 160 mmol/L), serum osmolality > 360 mOsmol/kg, and the presence of multiple comorbidities.

The principles of therapy are shown in Figure 21.17. The aims are to normalise osmolality and blood glucose, replace fluid and electrolyte losses, and prevent life-threatening complications such as arterial or venous thrombosis (via subcutaneous thromboprophylaxis), foot ulceration (with careful protection of feet; see p. 796), cerebral oedema and central pontine myelinolysis (see Ch. 19). Comorbidities also need to be taken into account; for example, rapid fluid replacement may precipitate cardiac failure in patients with coronary artery disease, while delirium commonly occurs in older patients. Historically, management of HHS was modelled on DKA protocols, but there is increasing recognition of better outcomes using a slower approach to correction of the electrolyte and other metabolic abnormalities (in contrast to DKA, there is no urgent need to correct ketoacidosis). As HHS occurs in people whose brains are at higher risk of injury, rapid shifts in osmolality should be avoided with less aggressive fluid replacement and rate of glucose lowering guided by serial calculations of serum osmolarity. Key recommendations are that 0.9% sodium chloride solution alone is used for initial treatment and that insulin is introduced only when the rate of fall in blood glucose has plateaued.



Fluid and potassium

0–60 minutes
1 L 0.9% saline over 1 hour (more rapid if BP < 90 mmHg)

After 1 hour
Adjust the rate of fluids according to clinical status and osmolality
- Aim for positive balance of 2–3 L after 6 hours, 3–6 L after 12 hours
- Rate of fluid should normally be 0.5–1.0 L/hr
- Aim for osmolality to decrease by 3–8 mosmol/kg/hr
- Rate of fall of sodium should not exceed 10 mmol/L in 24 hrs
- If glucose < 14 mmol/L add 10% glucose at 125 mmol/hr
- Adjust KCl replacement to maintain 4–5 mmol/L

Insulin

0–60 mins
Start FRII at a rate of 0.05 units/kg/hr
IF significant ketonaemia
(blood ketone > 1 mmol/L)
ONLY AFTER commencing fluid

1 to 6 hours
IF glucose is decreasing by <5 mmol/L/hr (<90 mg/dL/hr)
AND positive fluid balance is adequate (aim for 2–3 litres after 6 hours)
THEN increase the rate of FRII to 0.1 units/kg/hr
OR start a FRII at a rate of 0.05 units/kg/hr if not already started

After 6 hours
Increase or decrease the rate of FRII by 1 unit/hr to maintain blood glucose in the range 10–15 mmol/L (180–270 mg/dL) and ensure ketones are clearing

Fig. 21.17 Emergency management of hyperglycaemic hyperosmolar state. Dashed intravenous infusion line represents 'if required'. (FRII = fixed rate insulin infusion; KCl = potassium chloride)

Serum osmolarity can be calculated using the following equation:

Calculated serum osmolarity = (2 × [sodium]) + [glucose] + [urea]*

*All in mmol/L.

A limitation of this approach is that hyperglycaemia, by increasing serum osmolality, causes the movement of water out of cells into plasma, reducing Na^+ levels by dilution. Therefore, in the presence of hyperglycaemia, a corrected [Na^+] can be calculated for use in this formula by adding 1.6 mmol/L to the measured [Na^+] for every 5.55 mmol/L (100 mg/dL) increment of serum glucose above normal.

Hypoglycaemia

Hypoglycaemia has been defined by the American Diabetes Association in three distinct levels (Box 21.14) – level 1 (alert value), level 2 (clinically significant) and level 3 (severe). Hypoglycaemia rarely occurs in people without diabetes (see p. 731), but is very common in people with diabetes as a complication of therapies, mainly insulin and (to a lesser extent) sulphonylureas. Unlike endogenous insulin, secretion of which is down-regulated when blood glucose falls, these therapies continue to act even when blood glucose is low.

More than 10% of people with type 1 diabetes treated with conventional pen-injected insulin report an episode of level 3 hypoglycaemia every year. CGM devices show more frequent episodes of level 2 hypoglycaemia – up to every 2 days in some studies. Importantly this is more frequent than hypoglycaemia measured by self-reported events or capillary blood glucose monitoring. This finding is likely related to the improved detection by CGM. There may be an element of over-reporting at lower levels of interstitial fluid glucose, owing to lower reliability of some CGM devices, but accuracy of CGM devices is constantly improving. The frequency of hypoglycaemia is generally substantially reduced in people using HCL systems for insulin delivery.

The critical importance of glucose as a fuel source for the brain means that, in health, a number of mechanisms are in place to ensure that glucose homeostasis is maintained. If blood glucose falls, three primary physiological defence mechanisms operate:

- endogenous insulin release from pancreatic β cells is suppressed
- release of glucagon from pancreatic α cells is increased
- the autonomic nervous system is activated, with release of catecholamines both systemically and within tissues.

In addition, stress hormones, such as cortisol and growth hormone, are released into the blood. These actions reduce peripheral glucose uptake and increase hepatic glucose production, maintaining a glucose supply to the brain. Retained endogenous insulin secretion in people with type 1 diabetes (measured using C-peptide) has a glucose 'smoothing' effect that reduces the frequency of hypoglycaemia, as insulin secretion is inhibited by falling blood glucose levels. However, in most individuals with type 1 diabetes, endogenous insulin production falls to minimal amounts within a few years of diagnosis, increasing glucose variability and the risk of hypoglycaemia. In addition, within 5 years of diagnosis, many people with type 1 diabetes lose their ability to release glucagon during hypoglycaemia. The reasons for this are unknown and may result from loss of α-cell regulation by insulin or other products of the β cell.

21.14 Levels of hypoglycaemia

- Level 1 hypoglycaemia (*alert value*) as <3.9 mmol/L but ≥ 3.0 mmol/L (<70 mg/dL but ≥ 54 mg/dL)
- Level 2 hypoglycaemia (*clinically significant*) is defined as <3.0 mmol/L (<54 mg/dL). This level is unequivocally low and suggests clinically important biochemical hypoglycaemia
- Level 3 hypoglycaemia (*severe*) is defined as any low blood glucose level leading to cognitive impairment and the need for external assistance to provide glucose, glucagon or other corrective activity

Rates of hypoglycaemia are generally lower in insulin-treated type 2 diabetes than in type 1 diabetes, particularly in individuals with shorter duration of diabetes. This is likely due to preservation of significant endogenous insulin release for longer in most individuals, but also to differences in insulin regimens, i.e. more frequent use of intermediate- or longer- (rather than short-) acting insulins.

Level 3 hypoglycaemia is about 10 times less common in people with type 2 diabetes treated with sulphonylureas than in those treated with insulin therapy. As these agents were previously widely prescribed, the proportion of cases of hypoglycaemia attributable to their use was high. However, with decreasing use of sulphonylureas over the last 20 years (due to the advent of newer agents), this proportion has dramatically fallen. Nevertheless, hypoglycaemia remains a significant risk in older people who are taking these agents, particularly those with renal impairment.

Clinical assessment

Symptoms of hypoglycaemia (Box 21.15) comprise two main groups: those related to acute activation of the autonomic nervous system and those secondary to glucose deprivation of the brain (neuroglycopenia). Symptoms of hypoglycaemia are idiosyncratic, differing with age and duration of diabetes, as well as the circumstances in which it occurs. Hypoglycaemia also affects mood, inducing a state of increased tension and low energy. Learning to recognise the early onset of hypoglycaemia is an important aspect of education for people with diabetes managed with insulin.

Awareness of hypoglycaemia

For most individuals, the glucose level (threshold) at which they first become aware of hypoglycaemia is not constant, but varies according to the circumstances in which it arises (e.g. during the night or during exercise). In addition, with longer duration of diabetes, and particularly in response to frequent hypoglycaemia, the threshold for generation of symptomatic responses to hypoglycaemia shifts to a lower glucose concentration. This cerebral adaptation has a similar effect on the counter-regulatory hormonal response to hypoglycaemia. Taken together, this means that individuals with type 1 diabetes may develop reduced (impaired) awareness of hypoglycaemia. Symptoms can be experienced less intensely, or even be absent, despite very low blood glucose concentrations. Such individuals are at an especially high risk of level 3 hypoglycaemia. The prevalence of impaired awareness of hypoglycaemia increases with time; overall, it affects around 20%–25% of people with type 1 diabetes and under 10% with insulin-treated type 2 diabetes.

21.15 Most common symptoms of hypoglycaemia

Autonomic

- Sweating
- Trembling
- Pounding heart
- Hunger
- Anxiety

Neuroglycopenic

- Delirium
- Drowsiness
- Speech difficulty
- Inability to concentrate
- Incoordination
- Irritability, anger

Non-specific

- Nausea
- Tiredness
- Headache

N.B. Symptoms differ with age; children exhibit behavioural changes (such as naughtiness or irritability), while older people experience more prominent neurological symptoms (such as visual disturbance and ataxia).

Risk factors and causes of hypoglycaemia

Risk factors and causes of hypoglycaemia in patients taking insulin or sulphonylurea drugs are listed in Box 21.16. Hypoglycaemia is one of the main limiting factors in glycaemic management for people with type 1 diabetes: it is unpleasant, so fear of the lived experience and its consequences is understandable. In some people with diabetes, fear can have a major impact on their willingness and ability to achieve target glucose levels. Level 3 hypoglycaemia can cause serious morbidity (e.g. convulsions, coma, cerebral oedema, focal neurological lesions) and has a mortality of up to 4% in people treated with insulin. Rarely, sudden death during sleep occurs in otherwise healthy young patients with type 1 diabetes ('dead-in-bed syndrome'); this may be a consequence of hypoglycaemia-induced cardiac arrhythmia. The need to avoid hypoglycaemia can dominate normal life and daily activities including employment, driving (see Box 21.22), travel, sport and personal relationships.

Nocturnal hypoglycaemia in people with type 1 diabetes is common, but can go undetected without monitoring as it may not cause waking from sleep. People with diabetes may describe poor quality of sleep, morning headaches and vivid dreams or nightmares, or a partner may observe profuse sweating, restlessness, twitching or even seizures. The only reliable way to identify and monitor blood glucose concentration overnight is to use a CGM device with a low glucose alarm.

21.16 Hypoglycaemia in diabetes: common causes and risk factors

Excess insulin

- Erroneous injection of insulin (e.g. dose miscalculation or injection of incorrect insulin type)
- Deliberate overdose
- Lipohypertrophy at injection sites (causing variable insulin absorption)
- Bariatric surgery (can cause hyperinsulinaemia)

Increased sensitivity to insulin

- Exercise
- Weight loss
- Sudden reduction in glucocorticoids
- Unrecognised adrenal insufficiency

Reduced carbohydrate intake/increased metabolic demand

- Irregular or missed meal
- Gastroparesis due to autonomic neuropathy causing variable carbohydrate absorption
- Bariatric surgery
- Malabsorption, e.g. coeliac disease
- Eating disorder
- Early pregnancy
- Breast feeding

Reduced gluconeogenesis and/or glycogen reserves

- Alcohol
- Chronic kidney disease*
- Advanced liver disease*

Increased glucose variability

- Absent/minimal endogenous insulin secretion (reduced C-peptide)
- Long-duration type 1 diabetes/insulin-treated type 2 diabetes
- Young age of onset of type 1 diabetes

Reduced ability to detect hypoglycaemia

- Impaired awareness of hypoglycaemia
- Rapid improvement in and/or strict glycaemic control
- Previous severe hypoglycaemia
- Long-duration type 1 diabetes/duration of insulin-treated type 2 diabetes
- Older age
- Dementia
- Sleep
- No or inadequate glucose monitoring

*Also cause reduced insulin clearance.

In healthy individuals, muscle contraction during exercise causes insulin-independent glucose uptake into muscle. Suppression of endogenous insulin secretion is key to the normal physiological response to exercise as glucose derived from hepatic glucose production can be transported into muscle via other pathways; this physiological mechanism also minimises any risk of 'spontaneous' exercise-induced hypoglycaemia. However, in insulin-treated diabetes, circulating insulin levels may actually increase with exercise (probably because of improved blood flow at the site of injection), causing a significant risk of hypoglycaemia. This occurs most commonly with prolonged and/or aerobic exercise. In addition, the 'double hit' of hypoglycaemia and exercise is responsible for the additional increased risk of nocturnal hypoglycaemia that can occur after exercise, probably as a result of glycogen depletion. In contrast, high-intensity exercise may initially cause blood glucose to rise significantly because of stimulation of adrenaline (epinephrine) production. Close monitoring of blood glucose, education and learning from lived experience (usually with an element of trial and error) are key in preventing exercise-induced hypoglycaemia.

Unfortunately, hypoglycaemia sometimes occurs within the hospital setting. This may result from errors in insulin dose or type of insulin prescribed or infusion of IV insulin without glucose. In addition, hypoglycaemia may occur due to changes in meal timings (e.g. fasting for procedures) or meal components (e.g. low carbohydrate), failure to provide usual snacks, reduced carbohydrate intake because of vomiting or reduced appetite, or factors related to the hospital admission, e.g. concurrent illness, discontinuation of long-term glucocorticoid therapy. The diabetes team has a role in continuing education of health-care staff in all areas to prevent these situations occurring; regular review of any adverse events is also critical to prevention.

Management

Reversing hypoglycaemia

Treatment of hypoglycaemia depends on its severity and on whether the patient is conscious and able to swallow (Box 21.17). Levels 1 and 2 hypoglycaemia should be reversed by ingestion of fast-acting carbohydrate, repeated measurements of glucose and, if necessary, adjustment of glucose-lowering therapy. There is an understandable tendency to 'over-treat' episodes of hypoglycaemia, resulting in significant hyperglycaemia afterwards. Level 3 hypoglycaemia may also be treated with oral carbohydrate if the patient does not have impaired consciousness. If parenteral therapy is required, then as soon as the individual is able to swallow, oral glucose should also be given. Full recovery may not occur immediately and reversal of cognitive impairment may not be complete until 60 minutes after normoglycaemia is restored. When hypoglycaemia has occurred in a patient treated with a long- or intermediate-acting insulin or a long-acting sulphonylurea, such as glibenclamide, the possibility of recurrence should be anticipated; to prevent this, infusion of 10% dextrose titrated to blood glucose concentration, or provision of additional oral carbohydrate may be necessary.

If a person with diabetes fails to regain consciousness after blood glucose is restored to normal, then cerebral oedema and other causes of impaired consciousness – such as alcohol intoxication, a post-ictal state or cerebral haemorrhage – should be considered. Cerebral oedema is associated with a high mortality and morbidity.

Following recovery, it is important to try to identify a cause and make appropriate adjustments to therapy. Unless the reason for a hypoglycaemic episode is clear, people with diabetes should be advised to reduce the next dose of insulin by 10%–20% and seek further and more specialist advice about further adjustments in dose.

The management of self-poisoning with oral glucose-lowering agents is described on page 266.

Reducing future risk of hypoglycaemia

Every diabetes consultation should include gathering information about any low glucose levels measurements, the nature of symptoms with the measured levels of hypoglycaemia and whether there have been any

21.17 Emergency treatment of hypoglycaemia

Biochemical or symptomatic hypoglycaemia (Levels 1 and 2)

In the UK, it is recommended that all glucose levels < 4.0 mmol/L[1] are treated ('4 is the floor'). People with diabetes who recognise developing hypoglycaemia are encouraged to treat immediately. Options available include:

- Oral fast-acting carbohydrate (10–15 g) is taken as glucose drink or tablets or confectionery, e.g. 5–7 Dextrosol tablets (or 4–5 Glucotabs)
- Repeat capillary glucose measurement 10–15 mins later. If still < 4.0 mmol/L, repeat above treatment
- If blood glucose remains < 4.0 mmol/L after three cycles (30–45 mins), contact a doctor. Consider glucagon 1 mg IM or IV 10% glucose (600–800 mL/hour – caution in renal and cardiac disease)
- Once blood glucose is > 4.0 mmol/L, take additional long-acting carbohydrate of choice
- Do not omit insulin injection if due but review regimen

Severe (Level 3)

This means individuals are either unconscious or unable to treat hypoglycaemia themselves. Treatment is usually by a relative or by paramedical or medical staff. Immediate treatment as below is needed.

- If patient is unconscious/fitting or very aggressive or nil by mouth, parenteral treatment is required:
  - IV 75 mL 20% dextrose over 15 mins (= 15 g)[2]
  - *Or*
  - IV 150 mL 10% dextrose over 15 mins
  - *Or*
  - IM glucagon (1 mg) – may be ineffective in undernourished people, severe liver disease and in repeated hypoglycaemia. Caution in hypoglycaemia induced by oral glucose-lowering therapy.
- If patient is conscious and able to swallow, but confused, disorientated or aggressive:
  - Give 2 tubes of 40% glucose gel – squeezed into mouth between teeth and gums
  - Repeat blood glucose measurement after 10–15 mins and, if ineffective after 3 cycles, call doctor and consider IM glucagon (1 mg) or IV 10% glucose

[1] 4.0 mmol/L = 72 mg/dL.

[2] Use of 50% dextrose is no longer recommended.

(IM = intramuscular; IV = intravenous)

Adapted from updated JBDS Diabetes at the Front Door guideline, March 2020. Available at: abcd.care/sites/default/files/site_uploads/JBDS_Guidelines_Archive/JBDS_16_Diabetes_Front_Door_amended_FINAL_27032020_Archive.pdf.

episodes of level 3 hypoglycaemia. It is important for doctor and patient to review blood glucose monitoring and CGM data (where available) together to determine the details around each episode: recognition of patterns can be aided by increasing the number of measurements and triangulation with recordings of insulin dosing, carbohydrate intake and physical activity. The lived experience of previous hypoglycaemia and any resultant fear should be acknowledged and explored. Education is fundamental to hypoglycaemia prevention and should focus on risk factors and appropriate methods of treatment. The importance of regular glucose monitoring, flexible insulin regimens and the need to have glucose (and glucagon) readily available should be reinforced. Family and friends also need to be familiar with the symptoms and signs of hypoglycaemia and should be instructed in how to help (including how to inject glucagon).

The goal is always to minimise the risk of hypoglycaemia while still reaching target glucose levels and HbA1c. Adjustments in insulin regimen based on patterns of glucose should be agreed with the person with diabetes over time to achieve their goals. HbA1c targets should be individualised to balance the short-term risk of hypoglycaemia with the long-term risk of complications. The use of CGM devices (particularly those with low glucose alarms) is invaluable, and (at least in higher income countries) it is increasingly considered a standard of care. CGM values and trend arrows provide important information upon which to base decisions on doses of short-acting (bolus) insulin to be administered in relation to planned carbohydrate ingestion; thus, glucose can be kept to target while hypoglycaemia is prevented. The use of HCL systems can substantially reduce the frequency of hypoglycaemia. Whole pancreas or islet transplantation can be considered in cases of severe and intractable hypoglycaemia (see p. 785).

Management of diabetes

Contemporary specialist diabetes care is delivered by a multidisciplinary team including medical staff, specialist nurses, nursing assistants, dietitians, podiatrists, pharmacists, retinal screeners, psychologists, health-care assistants and administrative staff. Ideally these staff are co-located in an ambulatory care or diabetes centre, which need not necessarily be on a hospital site, and there should be close and dynamic links with primary care and community-based diabetes specialist nurses, all involved in continuing professional development.

The aims for both types 1 and 2 diabetes are initially to relieve osmotic symptoms (see p. 768) and then to minimise the risks of long-term microvascular and macrovascular complications. In general, microvascular complications are prevented by targeting hyperglycaemia, but control of macrovascular complications also requires management of associated risk factors, particularly hypertension, dyslipidaemia and cigarette smoking. Initial investigation and management is outlined in Figure 21.21.

Due to the risk of complications, people with all forms of diabetes should be kept under review with regular monitoring, adjustment of treatment, and screening to detect treatable complications as early as possible. Diabetes care is delivered in primary care for the majority of people with type 2 diabetes, but should usually involve specialist centres for those with complex treatment regimens and/or complications and for all with type 1 diabetes. A checklist for follow-up visits is given in Box 21.18. Frequency of appointments usually ranges from 3-monthly to annually depending on whether targets are being achieved.

Type 2 diabetes Where there are no 'red flags' of ketosis or rapid weight loss, initial management of type 2 diabetes involves dietary and lifestyle advice, which should aim at inducing remission of the condition (see p. 775). However, adding in oral glucose-lowering drugs is more likely to be required at an early stage for those who have symptomatic hyperglycaemia or a high HbA1c. Education is key to achieving and maintaining a healthy lifestyle in type 2 diabetes. Management should be individualised, taking account of personal and cultural beliefs, individual circumstances, comorbidities and other factors.

Type 1 diabetes People with a new diagnosis of type 1 diabetes require substantial initial education and support around diet, self-monitoring of blood glucose and ketones, the technicalities of insulin administration and dose adjustment, and the recognition and treatment of hypoglycaemia (Box 21.19). A diagnosis of type 1 diabetes is life-altering, not least because individuals have often previously been healthy and have now been diagnosed with a long-term condition that requires restrictions to diet and lifestyle, regular fingerpricks (at least until CGM is initiated) and multiple daily injections. Hypoglycaemia is unpleasant, can be socially embarrassing and is associated with significant morbidity and indeed mortality. A diagnosis of type 1 diabetes brings with it significant challenges in relation to employment, education, driving, overseas travel and family planning. It is likely to result in increased travel- and life-insurance premiums. Therefore, people living with type 1 diabetes often have higher levels of psychological and psychiatric morbidity ('diabetes distress') and require substantial ongoing support and encouragement from diabetes health-care professionals, ideally including psychological support.

As duration of type 1 diabetes increases, maintenance of good glycaemic control can become progressively more challenging, despite accumulating lived experience of managing insulin therapy. Hypoglycaemia tends to become more frequent, as protective counter-regulatory hormone responses and warning symptoms diminish. Maintaining strict glycaemic control, with minimal hypoglycaemia, is extremely challenging even with the most advanced modalities of insulin therapy and requires

21.18 How to review a patient in the diabetes clinic

Approach to the diabetes consultation

Introduction (agenda-setting)	'How are you?' 'What matters to you?' (Is translator required?)
Demographics	Age, type of diabetes, duration of diabetes
Microvascular complications	Retinopathy/maculopathy Renal function (eGFR) Microalbuminuria/proteinuria Foot examination
Macrovascular complications	Cardiovascular disease Cerebrovascular disease Peripheral vascular disease
Metabolic	BMI/weight trajectory Diet (quality/calories)/CHO counting Current glucose-lowering treatment (adherence/ administration) HbA1c Step-wise approach to glucose monitoring (frequency, timing, representativeness or reliability of data) Hypoglycaemia (frequency, timing, symptoms, context, episodes of level 3 hypoglycaemia, consequences, driving) Hyperglycaemia (frequency, timing, symptoms, context, episodes of DKA/HHS, consequences) Glycaemic variability if AGP available
Cardiovascular risk	BP Cholesterol Smoking cessation
Other	Pregnancy/contraception Exercise Sexual dysfunction Alcohol Driving
Summarise	Main action points Goal setting Changes to treatment Referrals within team Other referrals Accessing support prior to next appointment

Remember:

- Person-centred (lifestyle, occupation, travel, behaviour)
- Language matters
- Start with the 'good news'
- Culturally sensitive
- Collaborative
- Empathetic
- Empowering
- Reassuring
- Non-judgemental

(AGP = Ambulatory Glucose Profile; BMI = Body Mass Index; CHO = carbohydrate; DKA = diabetic ketoacidosis; eGFR = estimated glomerular filtration rate; HHS = hyperglycaemic hyperosmolar state)

21.19 Learning outcomes on the day of type 1 diabetes diagnosis

- Explain what is type 1 diabetes
- Explore any fears and anxieties and ask questions
- Be able to check blood glucose/ketones
- Be able to administer insulin and understand the correct storage of insulin
- Understand the target blood glucose
- Understand the role of rapid-acting insulin and its relationship with food
- Understand how to safely dispose of used needles and lancets
- Appreciate that people with diabetes should follow similar dietary recommendations as appropriate for non-diabetic people and that insulin is adjusted to carbohydrate content of diet
- Understand what a 'hypo' is and how to treat it
- Be aware they can access their own diabetes health records
- Understand what to expect from the diabetes team, how to make contact and the date/time/mode of their next interaction
- Understand that notifying the DVLA* about the diagnosis of type 1 diabetes is a legal requirement and the precautions to be taken before driving
- Understand that suboptimal glycaemic control increases risks to both mother and baby
- Understand that their employer should know they have been diagnosed with type 1 diabetes

*Or equivalent in other countries.
(DVLA = United Kingdom Driver and Vehicle Licensing Agency)

motivation and meticulous attention in terms of dietary factors, glucose monitoring and decision-making around insulin dosing.

Some individuals with type 1 diabetes have long-term suboptimal glycaemic control. The reasons for this are complex, but in many cases relate to difficulty finding time to devote the effort required to self-manage the condition in the context of other events and demands within their personal, family and work lives. Such factors vary across the lifespan with major differences among individuals. Other individuals have more serious psychological problems in accepting or adjusting to the diagnosis. These factors can lead to behaviours that have a negative impact on glycaemic control, such as omission of insulin injections (either deliberate or accidental), taking insulin injections after (instead of before) meals, taking fixed doses of insulin or doses based on symptoms (e.g. taking extra insulin when person feels thirsty), under-dosing with insulin to reduce risk of hypoglycaemia, consumption of foods high in unrefined carbohydrate, non-adherence to carbohydrate counting, over-treatment of episodes of hypoglycaemia and avoidance of glucose monitoring. Attempts to improve glycaemic control may involve enhanced input and support from diabetes specialist nurses and dietitians, more regular review in out-patient clinics, referral into structured education programmes and (increasingly) provision or recommendation of technologies like CGM, CSII and HCL therapy (where resources permit).

Type 1 diabetes is associated with other immune-mediated disorders (see Ch. 4), including thyroid disease, coeliac disease, Addison disease, pernicious anaemia and vitiligo. Awareness of these is important so that they can be diagnosed promptly and managed appropriately. Approximately 30% of women and 15% of men with type 1 diabetes have at least one related immune-mediated condition. The association with hypothyroidism is strongest (present in ~20% overall); coeliac disease is the second most common (present in 4%) and is particularly associated with childhood-onset diabetes. Thyroid function should be checked annually in all people with type 1 diabetes and systematic screening for coeliac disease is recommended in many countries.

Self-assessment of glycaemic control

Type 2 diabetes People with type 2 diabetes usually only need to self-test capillary blood glucose regularly if they require insulin or sulphonylurea therapy. For those on insulin, blood glucose testing 1–4 times daily (depending on the intensity of the prescribed regimen) helps guide insulin dosing and to manage diet, exercise and illness. It also helps to detect and protect against hypoglycaemia. This is also the case for sulphonylurea therapy. People with type 2 diabetes who are on neither of these therapies do not have an absolute need to test blood glucose, but it can be useful, e.g. for self-education on the effects of food and exercise on glycaemia. Fasting or pre-meal blood glucose target is usually 5.0–7.0 mmol/L (90–126 mg/dL). Those who require to test should be taught how to monitor their own blood glucose using an electronic meter and prescribed adequate supplies of blood glucose testing strips. CGM systems may be recommended for some patients, especially those on multiple daily doses of insulin.

Type 1 diabetes People with type 1 diabetes usually require intensive insulin regimens. Those who are not using CGM are advised to test capillary blood glucose four or more times per day. Blood glucose meters with dual functionality for ketone testing are particularly useful to provide early warning of ketosis and help prevent ketoacidosis when blood glucose is high and/or during intercurrent illness.

CGM systems are increasingly becoming a standard of care in type 1 diabetes. Specific devices are funded by the NHS in the UK, as their use is associated with improved glycaemic control and is cost-effective. CGM widens the lens through which day-to-day glycaemia can be monitored by people with diabetes and provides a more holistic view of the lived experience of diabetes. CGM data can be displayed in different formats depending on the manufacturer of the device, but most provide a standardised summary as an Ambulatory Glucose Profile (AGP). This display provides a graphical representation of interstitial glucose over time, allowing trends to be readily identified (Fig. 21.18). Summary metrics include: mean glucose, time in range, time above range and time below range (see below). Glucose variability over time is reported as standard deviation and percentage coefficient of variation. A ‘Glucose Management Indicator’ or other metric corresponding to ‘estimated HbA1c’ (eA1c) is provided by most CGM devices: the accuracy of this statistic increases with the volume of CGM data available (minimum 10 days and preferably > 14 days).

The proportion of time spent within an optimal glycaemic range is increasingly recognised as a clinically meaningful tool. Time in range (TIR) denotes the average percentage of time each day spent within agreed

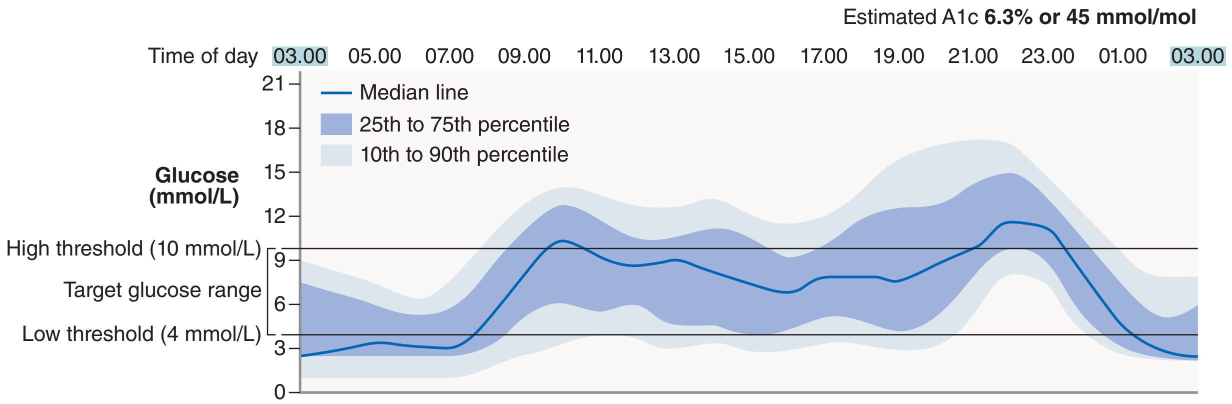


Fig. 21.18 Ambulatory blood glucose profile. The Ambulatory Glucose Profile (AGP) is generated by combining continuous glucose monitor (CGM) data over a prolonged period (usually 14 days). It provides an example of a ‘typical day’ allowing the person with diabetes and health-care professionals to make more rational adjustments to insulin therapy. An estimated HbA can also be derived from these data. Black/blue solid line (median line) – the average (middle) point of all glucose levels. Ideally this should be in the target glucose range with minimal variability. Inner blue-shaded band (25th to 75th percentile) – most common glucose levels and how they vary from day to day. Outer light blue–shaded band (10th to 90th percentile) – less common glucose levels and how they vary from day to day. *Adapted from DPC Toolkits, The Ambulatory Glucose Profile (AGP) in 4 steps. cdn.asp. events/CLIENT_CloserSt_D86EA381_5056_B739_5482D50A1A831DDD/sites/DPC2020/media/toolkits-2018/The-Ambulatory-Glucose-Profile-AGP-in-4-steps.pdf.*

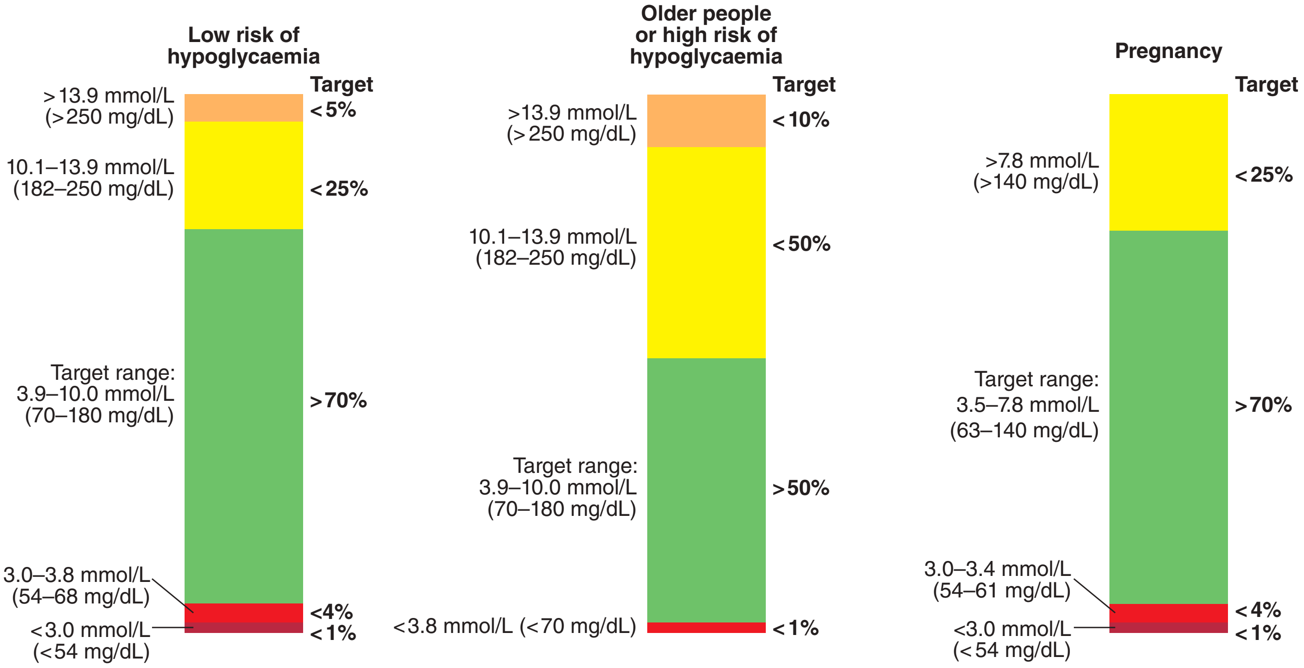

Fig. 21.19 Target time in range for different groups of people with type 1 diabetes. The different coloured sections represent the proportion of time spent within a glucose range: green = proportion of time spent within range; yellow = time above range; orange = time significantly above range; red = time below range; brown = time significantly below range. ‘In range’ glucose levels are much lower for women who are pregnant. A lower ‘time in range’ is accepted for people at higher risk of hypoglycaemia and in older people. Note: as the percentages are targets, they do not add up to 100%. *Adapted from Battelino T, et al. Clinical targets for continuous glucose monitoring data interpretation: recommendations from the international consensus on time in range. Diabetes Care 2019;42(8):1593–1603.*

glucose targets (Fig. 21.19). The international consensus for 'in range' glucose values is between 3.9 and 10 mmol/L (70–180 mg/dL) inclusive, with lower and higher levels termed time below range (TBR) and time above range (TAR). TIR of > 70% is considered the optimum target for most people living with diabetes on the basis of extrapolation from the Diabetes Control and Complications Trial. In people at higher risk of hypoglycaemia, 50% TIR is accepted, with an understanding that this means more TAR. In pregnancy, stricter glucose targets are specified (3.5–7.8 mmol/L (63–140 mg/dL)), but still with a target of 70% TIR (see Ch. 30).

Therapeutic goals

HbA1c targets

Type 1 diabetes The first evidence that improved glycaemic control decreases the risk of microvascular complications in diabetes came in 1993 from the Diabetes Control and Complications Trial (DCCT). The DCCT randomised adolescents and young adults with type 1 diabetes in the United States and Canada to intensive treatment (mean HbA1c 53 mmol/mol) or conventional treatment (mean HbA1c 75 mmol/mol) for 6.5 years. There was a 60% overall reduction in the risk of developing microvascular complications with an intensive therapy strategy, although severe hypoglycaemia was increased up to threefold in those in whom HbA1c was most reduced. Thirty-year follow-up of both groups of DCCT participants demonstrated that macrovascular complications were also reduced even many years after a period of intensive control – this has been described as 'metabolic memory'.

Type 2 diabetes In the UK Prospective Diabetes Study (UKPDS), published in 1998, adults with type 2 diabetes were randomised to intensive blood glucose control mainly with sulphonylureas and insulin (mean HbA1c 53 mmol/mol) versus conventional glucose control mainly with dietary treatment (mean HbA1c 64 mmol/mol) for 10 years. Rates of microvascular complications were reduced in those who received intensive therapy, but a beneficial effect on macrovascular complications was observed only in overweight participants randomised to metformin therapy in whom there was a reduction in the rate of diabetes-related death. Follow-up of UKPDS participants over further decades reinforced the microvascular benefits of glucose lowering and the specific macrovascular benefits of metformin.

With use of CGM and HCL systems in type 1 diabetes, as well as the use of newer glucose-lowering therapies in type 2 diabetes, it is now possible to intensify glycaemic control to achieve HbA1c levels below that achieved in the DCCT and UKPDS, without significantly increasing risk of hypoglycaemia. Therefore, the target HbA1c is ≤ 48 mmol/mol for type 1 diabetes and for type 2 diabetes treated with agents that do not cause hypoglycaemia; an HbA1c target of ≤ 53 mmol/mol is recommended for type 2 diabetes treated with agents that may cause hypoglycaemia (insulin and sulphonylureas). However, an individualised target is appropriate depending on the needs of the person in question. For example, a target of 57 mmol/mol may be more acceptable for older people with a shorter duration of diabetes (i.e. at lower lifetime risk of complications), individuals with a high risk of level 3 hypoglycaemia (e.g. those with impaired awareness of hypoglycaemia) or those in whom hypoglycaemia could have a particularly adverse consequence (e.g. individuals at high falls risk). Even higher HbA1c targets may be appropriate in frail individuals (Box 21.20). As always in type 1 diabetes, the benefits of lower target HbA1c (primarily a lower risk of microvascular disease) need to be weighed against the increased risk of hypoglycaemia. The risk of hypoglycaemia is higher in individuals with absent or minimal endogenous insulin (e.g. childhood-onset type 1 diabetes or following total pancreatectomy), in whom there is more marked glycaemic variability (see Fig. 21.11). Achieving strict glycaemic targets in such individuals can be particularly challenging, unless advanced technologies are used. Type 2 diabetes is associated with much lower glycaemic variability (due to retained endogenous insulin production), but unless significant weight loss is achieved, it is usually a progressive condition and so there is a need to increase diabetes medication over time to achieve the individualised target HbA1c.

21.20 Diabetes in old age

- **Incidence:** type 2 diabetes becomes more common with increasing age.
- **Aetiology:** almost any form of diabetes can present in older people; do not presume that a new diagnosis of diabetes in an older person is automatically due to type 2 diabetes.
- **Hypoglycaemia:** older people may not recognise hypoglycaemia, increasing their risk of level 3 (severe) hypoglycaemia.
- **Glycaemic targets:** need moderated in frail older people, especially if using agents that cause hypoglycaemia (insulin and sulphonylureas).
- **Dementia:** both Alzheimer disease and vascular dementia are more common in people with diabetes, which can significantly affect ability to manage diabetes safely. Input from family, carers and community nurses may be essential.

Control of other risk factors

Type 2 diabetes Due to underlying insulin resistance, most people with type 2 diabetes have hypertension and dyslipidaemia, in addition to hyperglycaemia. Targeting of these cardiovascular risk factors is crucial in reducing the risk of macrovascular complications. UKPDS participants were also randomised to tight (< 150/85 mmHg) or less tight (< 180/105 mmHg) blood pressure control: the former was associated with a reduction in the risk of death as well as fewer complications overall (including retinopathy). The target for blood pressure is now usually below 140/80 mmHg, although some guidelines suggest below 130/80 mmHg (e.g. in those with renal disease). As a rule, anyone with type 2 diabetes over the age of 40 years (unless a woman of childbearing potential not using an effective method of contraception) should be prescribed a statin, irrespective of their blood cholesterol level. Some guidelines do not propose a target level once a statin has been started, but others suggest a total cholesterol of less than 4.0 mmol/L (approximately 150 mg/dL) and an LDL cholesterol of less than 2.0 mmol/L (36 mg/dL) or non-HDL cholesterol levels of 2.6 mmol/L (47 mg/dL) or less.

Type 1 diabetes Elevation of the same cardiovascular risk factors also commonly occurs over time in type 1 diabetes, but is thought, at least in the early years, to be of secondary importance to hyperglycaemia. Guidelines suggest targeting risk factors in those with a duration of type 1 diabetes of over 15–20 years, or aged over 35–40 years (whichever comes first). Similar BP and cholesterol treatment targets are recommended as for people with type 2 diabetes. As with statin treatment, angiotensin-converting enzyme (ACE) inhibitors should not be prescribed for women of childbearing potential unless using effective contraception.

Education, diet and lifestyle

Broadly, people with diabetes should follow similar dietary recommendations as appropriate for non-diabetic people, but if overweight or obese should be supported to lose weight. However, this can be difficult as 'healthy' diet recommendations are rarely followed by the general population, particularly in countries in which cheap calorie-rich foods are widely available and heavily advertised. Labelling of foods as 'suitable for diabetics' was prohibited in the UK in 2016, but some products labelled 'diabetic' are still available. These should be avoided as they are often expensive, sweet-tasting foods (jam, biscuits, chocolate, ice-cream) that can contain synthetic sugars that raise blood glucose. People with diabetes may be misled into believing these products are essential or especially suitable. Diabetes prevention programmes are in place in many countries, essentially supporting low-fat healthy eating, weight reduction and increased physical activity (often referred to as 'non-pharmacological intervention').

Principles of healthy eating

Type 1 diabetes Soon after diagnosis there should be access to a dietitian for education on 'carbohydrate counting', as this is essential for rational insulin dose adjustment. Books and smartphone apps are available that show carbohydrate content next to pictures of commonly consumed foodstuffs in varying portion sizes. These can assist individuals in making an educated estimate of the carbohydrate content of a meal (Fig. 21.20). Highly accurate information on the carbohydrate content of pre-prepared foods and basic ingredients is provided on package labels; some people with type 1 diabetes weigh food portions to get as precise information as possible. Carbohydrate counting requires patience and diligence, but becomes more routine with lived experience. In theory, people with type 1 diabetes with a normal weight should be able to eat unrestricted types and amounts of carbohydrate while maintaining blood glucose control, as they can simply take an appropriate amount of insulin to 'cover' the carbohydrate content of the meal. However, in practice, because the time action profiles of available exogenous insulins do not exactly match physiological variations in endogenous insulin, consumption of refined carbohydrate (such as sweets and sugar-rich drinks) and large portions of carbohydrate (>60 g) usually results in 'spikes' in blood glucose. Therefore, the best glycaemic control is generally seen in

The macronutrient and calorie content is provided for each portion. *From Cheyette C, Balolia Y. Carbs and Cals. Carb & Calorie Counter. 6th ed. Chello Publishing Limited; 2016.*

individuals who avoid too much unrefined carbohydrate and limit carbohydrate portion size.

Education on advanced carbohydrate counting and how to manage diet and insulin therapy during daily life (e.g. in the context of exercise, alcohol and intercurrent illness) is provided in formal structured and cost-effective programmes, such as 'Dose Adjustment for Normal Eating' (DAFNE). This involves one week of small group learning with other individuals with the condition supported by a diabetes specialist nurse and a dietician. Web-based educational modules are also available, as are remote 'flipped classroom' models of education supported by videotelephony platforms.

Type 2 diabetes There is no 'one size fits all' way of eating for people with type 2 diabetes, beyond making healthy choices more often and in smaller portions, as recommended by the Food Standards Agency (Box 21.21). There is no fixed formula for the balance of carbohydrate, fat and protein ('macronutrient composition'); neither is there a universal 'diet sheet' or list of 'banned' foods. Current advice is loosely based on the principles of a 'Mediterranean' diet (for which there is evidence of protection against cardiovascular disease in the general population) combined with a focus on choosing unrefined (e.g. brown rice, brown pasta, brown noodles, porridge, granary bread, beans, lentils) rather than refined carbohydrates (fruit juices, pastries, white bread, white pasta, white rice). Nutritional advice should be tailored to individuals and take account of age, lifestyle, culture and personal circumstances. A variety of structured education programmes, which focus on dietary and lifestyle factors, are available for type 2 diabetes, including DESMOND (Diabetes Education and Self Management for Ongoing and Newly Diagnosed).

Inducing remission of type 2 diabetes Over 80% of people with type 2 diabetes are overweight or obese. Central obesity with increased waist circumference is particularly associated with insulin resistance and increased cardiovascular risk. Ectopic fat deposited in the pancreas can directly exacerbate β-cell dysfunction (lipotoxicity). Following a diagnosis of type 2 diabetes, there should be an intense focus on reversing any unhealthy habits and behaviours with the aim, where appropriate, of radical weight loss. Weight loss in obese people of around 15 kg (usually about 15% of initial body weight) can put type 2 diabetes into remission for several years. In the UK, programmes are increasingly being provided by the NHS to help people achieve this using, for example, an 800 kcal/day liquid 'meal replacement' diet with gradual and supported meal re-introduction at 3 months (see p. 98). Trained supervision is essential. It should be recognised that it is challenging for most overweight people (with or without type 2 diabetes) to lose body weight and avoid weight regain. However, it is important to emphasise as sensitively as possible that if weight loss can be achieved, it markedly improves glycaemic control, slows diabetes progression and improves long-term outcomes.

21.21 Dietary management of diabetes

Food Standards Agency Eatwell recommendations 2020

- Eat at least 5 portions of a variety of fruit and vegetables every day
- Base meals on potatoes, bread, rice, pasta or other starchy carbohydrates, choosing wholegrain versions where possible
- Have some dairy or dairy alternatives (such as soya drinks), choosing lower fat and lower sugar options
- Eat some beans, pulses, fish, eggs, meat and other proteins (including 2 portions of fish every week, one of which should be oily)
- Choose unsaturated oils and spreads and eat in small amounts
- Drink 6–8 cups/glasses of fluid a day
- If consuming foods and drinks high in fat, salt or sugar, have these less often and in small amounts
- Eat <6.0 g salt per day

Available from: www.food.gov.uk/sites/default/files/media/document/eatwell-guide-master-digital.pdf.

Weight management in established diabetes

Some health professionals and people with type 2 diabetes are strong advocates of low-carbohydrate, high-fat ('ketogenic') diets to promote weight loss, or alternatively intermittent reduction in caloric intake 2 days out of every 7 ('5:2' diet). Perhaps because they help to provide and sustain motivation, these approaches are successful in achieving and sustaining weight loss in some individuals, but to date it has not been possible to predict in advance who will respond or to demonstrate general efficacy of these diets in controlled trials. Such diets are not appropriate in type 1 diabetes due to the risks of hypoglycaemia, ketosis (causing acute insulin resistance), and even DKA.

Bariatric surgery (see p. 99) can induce marked weight loss in obese individuals with type 2 diabetes and this is often associated with significant improvements in HbA1c and withdrawal of or reduction in requirement for glucose-lowering medications. Shared decision-making is important as surgery carries small but appreciable risks of both short- and long-term complications.

Over 50% of adults with type 1 diabetes are now also obese, at least in the United States and the UK. Insulin is an anabolic hormone, so if insulin dosing is imperfectly matched to carbohydrate intake, calorie ingestion in excess of nutritional requirements may at times be required to prevent hypoglycaemia. Some individuals appear to be more susceptible to insulin-induced weight gain than others. Increasing use of technology (CGM, CSII and HCL) may help with this problem.

Exercise

People with diabetes should be advised to follow advice on physical activity as for the general population. Supervised and structured exercise programmes may be of particular benefit in type 2 diabetes. The American Diabetes Association recommends that all adults with diabetes reduce sedentary time (avoiding periods >90 minutes) and do either 150 minutes per week of moderate-intensity exercise or 75 minutes per week of vigorous-intensity exercise. Muscle-strengthening (resistance) exercise is recommended on two or more days of the week. Of course, older individuals, those with disabilities and those with foot complications may not be able to follow these recommendations in full.

People with type 1 diabetes (and people with insulin-treated type 2 diabetes) face additional challenges in relation to exercise compared with the general population due to the risk of exercise-induced hypoglycaemia (see p. 768). However, with support to plan reduction of insulin dosing (and in some cases increased carbohydrate ingestion) prior to exercise, many can participate in high-level competitive sports including golf, rowing, American Football and even marathon running.

Alcohol and smoking

In type 2 diabetes, recommendations on alcohol are as for the general population (i.e. no more than 14 units per week for adults) to prevent liver cirrhosis and weight gain. In type 1 diabetes (and for people with insulin-treated type 2 diabetes) alcohol can also reduce hypoglycaemia awareness and suppress gluconeogenesis, increasing risk of level 3 hypoglycaemia. In addition, the signs of hypoglycaemia can be mistaken for alcohol intoxication by observers. People with insulin-treated diabetes are therefore advised during ingestion of alcohol to: (i) let a companion know that they have diabetes and how to treat them if they develop hypoglycaemia; (ii) continue to monitor and correct blood glucose by eating while drinking; and (iii) measure and ensure glucose is not low before retiring to bed.

Given the risk of cardiovascular complications associated with diabetes and despite increasing access to smoking cessation support, around 20% of people with type 1 and type 2 diabetes are current cigarette smokers (rates similar or higher to that in the general population). Research is required into better methods of achieving behaviour modification.

Driving

Legislation on driving has a major impact on people with diabetes. It varies from country to country so individuals should discuss with their diabetes health-care professional if their treatment necessitates reporting to the licensing authority (Box 21.22). To drive a car or ride a motorcycle in the UK, people with diabetes who take insulin therapy must notify the Driver and Vehicle Licensing Agency (DVLA). They must have adequate awareness of hypoglycaemia, have had no more than one episode of level 3 hypoglycaemia in the preceding 12 months, meet the standards for visual acuity and visual fields, and not be regarded as a likely risk to the public while driving. In addition, glucose testing is required to be performed no more than 2 hours before the start of a journey and every 2 hours while driving. Blood glucose levels should be over 4.0 mmol/L (72 mg/dL) before driving; if below 4.0 mmol/L (72 mg/dL) or there are symptoms of hypoglycaemia, the person should not drive. CGM has been approved for monitoring glucose at times relevant for driving in the UK, provided: (i) the glucose level is above 4.0 mmol/L; (ii) there are no symptoms of hypoglycaemia; (iii) the CGM device reading is consistent with the symptoms experienced. Legislative requirements in the UK for people on insulin therapy who have Group 2 licences to drive larger vehicles such as buses or lorries require, in addition, an annual examination by a diabetes specialist, along with review of three months of glucose readings.

21.22 Diabetes and driving

The main risk is hypoglycaemia due to insulin treatment. Health professionals should be proactive in supporting people with diabetes on insulin therapy to drive safely within the regulations while following legislation designed to protect road-users.

- Licensing regulations vary considerably between countries.
- In the UK, it is a legal requirement for people with diabetes requiring insulin therapy to notify the Driver and Vehicle Licensing Agency (DVLA)
- Group 1 licences (car, motorcycle, van) are 'period-restricted' for insulin-treated drivers, i.e. usually renewable every 3 years but with specific criteria: particularly no more than one episode of level 3 hypoglycaemia while awake in the preceding 12 months (the most recent episode more than 3 months ago)
- Group 2 licences (bus and lorry) may be granted for insulin-treated drivers: stricter criteria to be met – in particular no episode of level 3 hypoglycaemia (see Box 21.14) within the last 12 months and full awareness of hypoglycaemia regardless of whether this occurred when asleep. The licence is renewable annually.
- Blood glucose must be monitored appropriately. Continuous glucose monitoring systems may be used, but must confirm the reading using a capillary blood glucose meter if symptoms do not match the CGM level.
- Insulin-treated drivers should:
    Check glucose before driving and 2-hourly during long journeys
    Keep an accessible supply of fast-acting carbohydrate in the vehicle
    Take regular snacks or meals during long journeys
    Stop driving if hypoglycaemia develops
    Pull over and sit in the passenger seat
    Wait 45 mins after correction of hypoglycaemia before resuming driving (delayed recovery of cognitive function)
    Carry identification in case of injury

Note: Intermittently scanned monitoring (isCGM) is now approved in the UK for Group 1 licences provided the driver has the facility to check capillary blood glucose if symptoms of hypoglycaemia or hyperglycaemia are experienced.
See: Assessing fitness to drive: a guide for medical professionals (Ch. 3). assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/866655/assessing-fitness-to-drive-a-guide-for-medical-professionals.pdf.

Ramadan

The Quran requires Muslims to fast from sunrise to sunset during the 29 or 30 days of Ramadan, the ninth month of the Muslim calendar. People with diabetes are a recognised exception to this and are not required to fast, but many choose to do so. In this context, they are advised to seek advice from a diabetes health-care professional 6–12 weeks before Ramadan. Prior to fasting, the person should be counselled on their personal risk of fasting and an individualised management plan should be developed. This should include: structured education around fluids and meal planning, when to exercise, the role of increased frequency and/or timing of glucose monitoring (which does not invalidate the fast) and adjustment to the dose time and/or frequency of glucose-lowering agents. The majority of people with type 2 diabetes can be supported to fast during Ramadan provided they are prepared to stop the fast in the case of frequent hypo- or hyperglycaemia or worsening of other related medical conditions. The highest risk of hypoglycaemia is in people who are managed with sulphonylureas and insulin (especially if they are of older age, or have renal failure or advanced macrovascular complications); such individuals need careful glucose monitoring and, if necessary, their treatment regimens may need to be adjusted. Glucose-lowering therapies that do not cause hypoglycaemia are safest during Ramadan, if glycaemic control permits. It also recommended that people with diabetes imbibe extra clear fluids during the fasting period and that drug administration should be with the evening meal (*iftar*). Published guidance is available to help guide dose and timing adjustments from the International Diabetes Federation and the Diabetes and Ramadan International Alliance (IDF-DAR).

Glucose-lowering agents

Type 1 diabetes is managed with insulin from the time of diagnosis. When glucose levels are above target in type 2 diabetes despite appropriate lifestyle advice, drug therapy will usually be initiated and subsequently increased ('intensified') with the aim of establishing or re-establishing adequate glucose control, abolishing osmotic symptoms and preventing microvascular complications. Some individuals require pharmacological therapy from the time of (or very soon after) diagnosis. Over the following years and decades, the majority will require to take combinations of glucose-lowering drugs, oral or injectable, and some will also require insulin.

Seven main classes of glucose-lowering drugs are generally used to manage type 2 diabetes (Box 21.23). Four are oral agents: metformin (the only available biguanide), sulphonylureas, dipeptidyl peptidase-4 (DPP-4) inhibitors and sodium-glucose co-transporter 2 (SGLT2) inhibitors. GLP-1 receptor agonists are usually given by subcutaneous

21.23 Glucose-lowering agents in type 2 diabetes: additional information (see also Fig. 21.21)

	Insulin	Sulphonylureas	Metformin	Thiazolidinediones ('glitazones')	DPP-4 inhibitors ('gliptins')	GLP-1 receptor agonists	SGLT2 inhibitors
Introduced	1922	1956	1957	1999	2006	2007	2013
Route of administration	SC injection	Oral	Oral	Oral	Oral	SC injection (oral)	Oral
Cost	High	Low	Very low	Low	Moderate	Very high	High

(DPP-4 = dipeptidyl peptidase 4; GLP-1 = glucagon-like peptide 1; SC = subcutaneous; SGLT2 = sodium-glucose co-transporter 2) injection, but an oral preparation of semaglutide is also available. There is also a combined GLP-1 and GIP agonist (tirzepatide), administered by weekly subcutaneous injection. Insulin is given by subcutaneous injection. The effects of these drugs are compared in Box 21.23. Acarbose (an intestinal disaccharidase inhibitor that prevents dietary glucose absorption), pioglitazone (a thiazolidinedione that reduces insulin resistance) and meglitinides (oral agents that stimulate endogenous insulin) are also available, but little used due to either relatively low efficacy (meglitinides and acarbose) and/or adverse effects (acarbose causes frequent gastrointestinal upset, while pioglitazone has been linked with heart failure, small bone fractures and bladder cancer). Other agents are in development.

To date, the totality of evidence confirms that any agent that reduces blood glucose will also reduce the long-term risk of microvascular complications. Factors that determine which of these drugs should be prescribed first – and then which should subsequently be added in – include:

- individual profile (severity of initial symptoms, degree of obesity)
- glucose-lowering efficacy
- protective properties in relation to cardiovascular and renal complications (see below)
- adverse effect profile (hypoglycaemia, weight gain)
- renal function
- drug factors (mechanism of clearance/metabolism)
- ability or willingness to self-inject
- occupation (e.g. driving, working at heights)
- cost: whether covered by a national health-care system, reimbursed by an insurance company, or paid for 'out-of-pocket'.

Algorithms to guide prescribing decisions are available, e.g. consensus documents from the American Diabetes Association and the European Association for the Study of Diabetes (ADA/EASD; Fig. 21.21). These are frequently updated.

Metformin is often positioned as first-line, with second-line treatment personalised for each patient according to the above factors. A third or even fourth oral agent may be added in over time, but injectable therapy (GLP-1 receptor agonists or insulin) should not be delayed while levels of glycaemia above target are sustained for months or years; this will almost inevitably result in severe complications years later.

Unlike microvascular complications, it cannot be assumed that all agents that lower glucose also reduce rates of macrovascular complications, i.e. myocardial infarction and stroke. Some agents clearly protect against cardiovascular disease (GLP-1 receptor agonists and SGLT2 inhibitors), although they are more expensive. SGLT2 inhibitors have additional benefits in heart failure and chronic kidney disease. Metformin provides some cardiovascular protection (and is considerably cheaper), while others do not (sulphonlyureas, DPP-4 inhibitors and insulin). It is therefore likely that the protective (and adverse) effects of these different classes of glucose-lowering agents are mediated by 'off-target' mechanisms, i.e. unrelated to glucose-lowering.

Where resources allow, SGLT2 inhibitor and/or GLP-1 agonist therapy should be offered (as an adjunct to metformin) to patients with cardiovascular disease and/or chronic kidney disease even if HbA1c targets have been attained. For those without cardiorenal disease, additional therapies are generally added on the basis of failure to reach the individualised HbA1c target. The adverse risk profile of each agent plays an important role in personalisation of second- and third-line therapy. For example, agents that cause hypoglycaemia should be avoided in those who drive for a living (particularly those holding a Group 2 licence in the UK) or who work at heights. In general, drugs that promote significant weight loss (SGLT2 inhibitors and GLP-1 agonists) are favoured in overweight individuals. Sulphonylureas may be preferred in lower resource settings and in slim individuals (who may have a degree of insulin insufficiency). It is hoped that biomarkers will in the future help predict who will respond better and/or experience fewer side-effects with one drug rather than another.

Biguanides

Metformin is the only biguanide available. Its long-term benefits include not just reduction in rates of microvascular complications, but also reducing the risk of myocardial infarction, as shown in the UKPDS. It is widely used as first-line therapy for type 2 diabetes. Approximately 15% of individuals experience significant gastrointestinal side-effects, including bloating, nausea, diarrhoea and abdominal pain, such that they are unable to tolerate metformin. Metformin monotherapy may not be sufficient to provide rapid relief from symptoms in individuals with marked osmotic symptoms and weight loss at diagnosis (see Sulphonylureas, below).

Mechanism of action

The mechanism of action of metformin has not been precisely defined. It is classically considered an 'insulin sensitiser' because in lowering fasting glucose it tends to lower (rather than raise) insulin levels. Metformin reduces hepatic glucose production, may also increase insulin-mediated glucose uptake, and has effects on gut glucose uptake and utilisation. At the molecular level, metformin acts as a weak inhibitor of mitochondrial respiration, which increases intracellular adenosine monophosphate (AMP) and reduces adenosine triphosphate (ATP). This has direct effects on the flux through gluconeogenesis and activates the intracellular energy sensor, AMP-activated protein kinase (AMPK), leading to multiple beneficial effects. However, although metformin has been available for more than 60 years, it is not yet clear whether other AMPK-independent mechanisms may be just as important.

Clinical use

Metformin causes modest sustained weight loss (on average 1–2 kg), does not cause hypoglycaemia and has established benefits in microvascular disease. It is prescribed first-line therapy for the majority of people unless they do not tolerate it, and it is usually maintained when additional agents are required (see Fig. 21.21). Metformin is usually introduced at low dose (500 mg twice daily) to minimise the risk of gastrointestinal side-effects. The usual maintenance dose is 1000 mg twice daily (maximum licensed dose 1000 mg three times daily). Modified-release formulations of metformin are better tolerated by some individuals with gastrointestinal side-effects on the standard formulation.

Due to inhibition of mitochondrial respiration, metformin can cause asymptomatic hyperlactataemia, which during acute illness can present as lactic acidosis. However, this is much less common than previously thought and most instances of lactic acidosis that occur in the context of metformin prescription are due to other factors. As metformin is cleared by the kidneys, it can accumulate in renal impairment, so the dose should be halved when estimated glomerular filtration rate (eGFR) is below 45 mL/min/1.73 m^2, and it should not be used when eGFR is below 30 mL/min/1.73 m^2. It should be omitted temporarily during any acute illness potentially involving dehydration, as acute kidney injury greatly increases the risk of lactic acidosis. Metformin is contraindicated in the presence of significantly impaired hepatic function and in those who drink alcohol to excess as they are more vulnerable to lactic acidosis.

Sulphonylureas

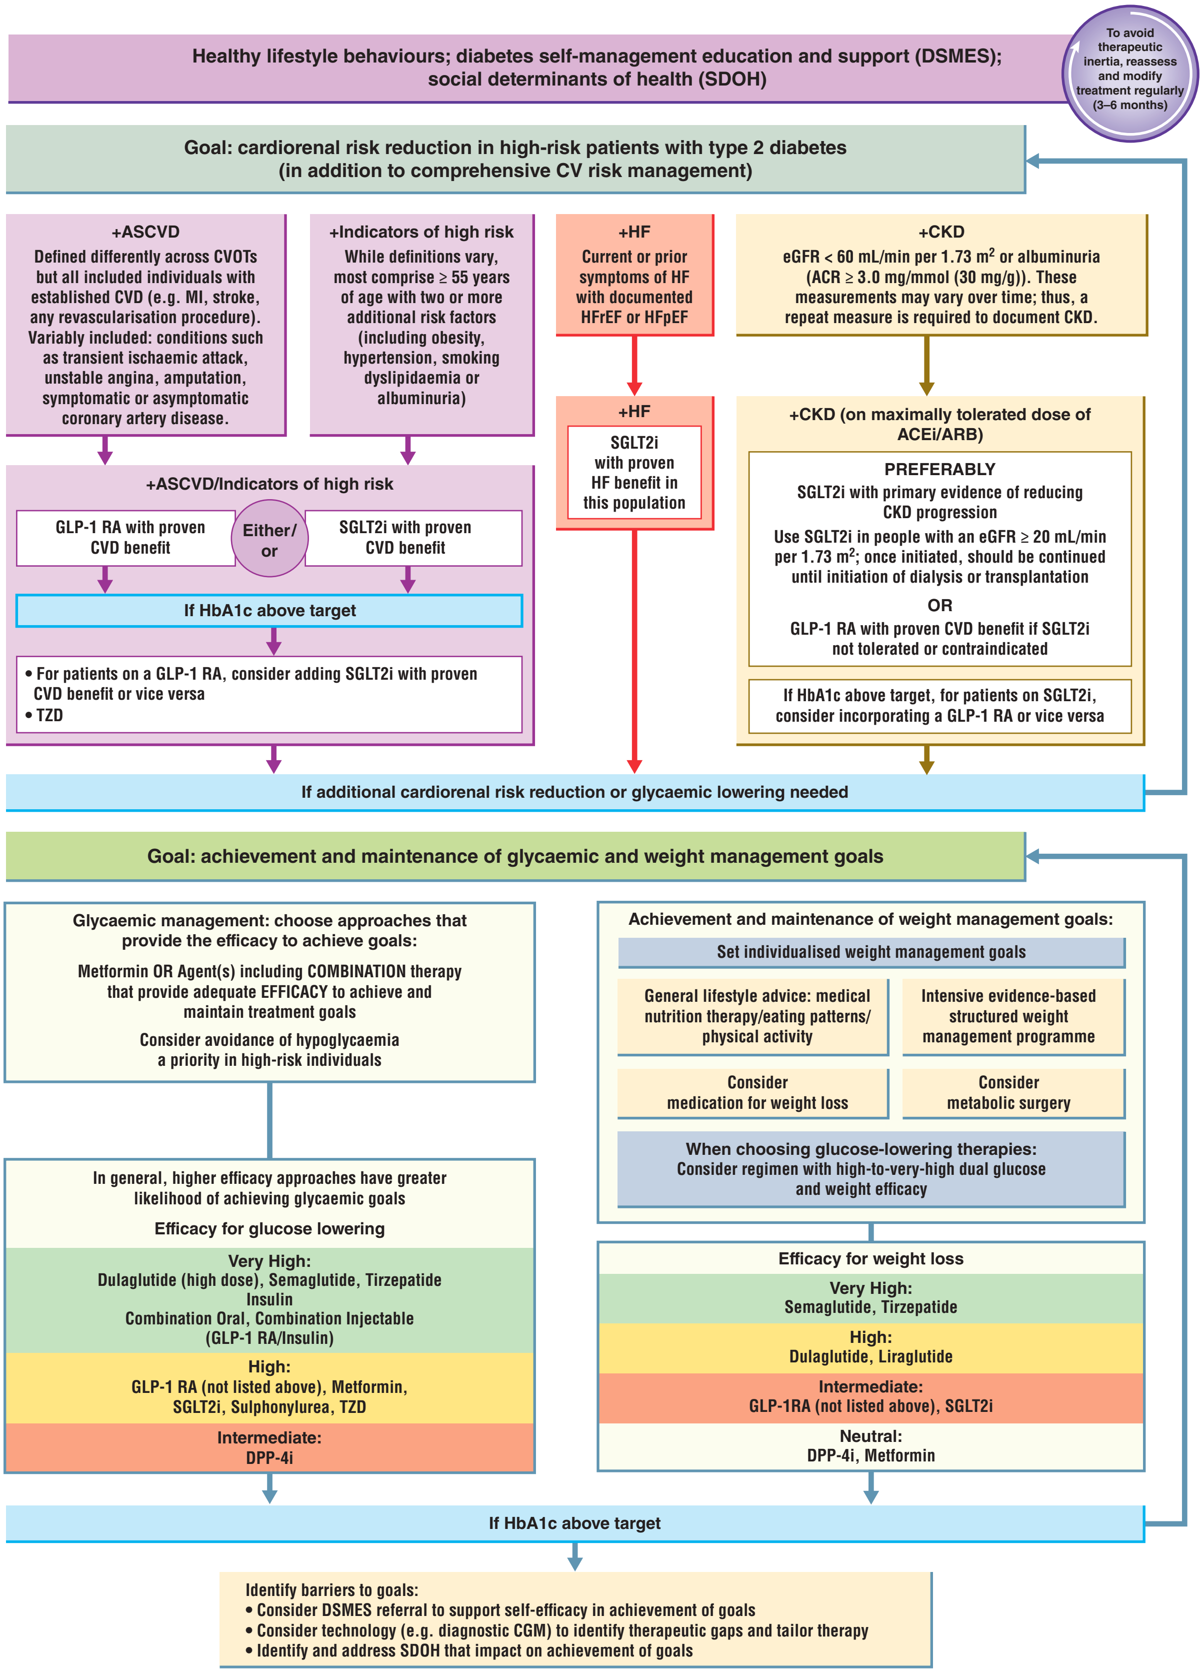
Sulphonylureas are 'insulin secretagogues', i.e. they promote pancreatic β-cell insulin secretion. Similar to metformin, the long-term benefit of sulphonylureas in reducing rates of microvascular complications was established in the UKPDS.

Mechanism of action

Sulphonylureas act by closing pancreatic β-cell ATP-sensitive potassium (K_{ATP}) channels, decreasing K^+ efflux, and triggering insulin secretion by a series of molecular events (see Fig. 21.3C).

Clinical use

Sulphonylureas are an effective therapy for lowering blood glucose. They may be used to relieve osmotic symptoms in individuals with newly



Healthy lifestyle behaviours; diabetes self-management education and support (DSMES); social determinants of health (SDOH)

To avoid therapeutic inertia, reassess and modify treatment regularly (3–6 months)

Goal: cardiorenal risk reduction in high-risk patients with type 2 diabetes (in addition to comprehensive CV risk management)

+ASCVD
Defined differently across CVOTs but all included individuals with established CVD (e.g. MI, stroke, any revascularisation procedure). Variably included: conditions such as transient ischaemic attack, unstable angina, amputation, symptomatic or asymptomatic coronary artery disease.

+Indicators of high risk
While definitions vary, most comprise ≥ 55 years of age with two or more additional risk factors (including obesity, hypertension, smoking dyslipidaemia or albuminuria)

+HF
Current or prior symptoms of HF with documented HFrEF or HFpEF

+CKD
eGFR < 60 mL/min per 1.73 m^2 or albuminuria (ACR ≥ 3.0 mg/mmol (30 mg/g)). These measurements may vary over time; thus, a repeat measure is required to document CKD.

+ASCVD/Indicators of high risk

GLP-1 RA with proven CVD benefit

Either/or

SGLT2i with proven CVD benefit

If HbA1c above target

- For patients on a GLP-1 RA, consider adding SGLT2i with proven CVD benefit or vice versa
- TZD

+HF
SGLT2i with proven HF benefit in this population

+CKD (on maximally tolerated dose of ACEi/ARB)

PREFERABLY
SGLT2i with primary evidence of reducing CKD progression

Use SGLT2i in people with an eGFR ≥ 20 mL/min per 1.73 m^2; once initiated, should be continued until initiation of dialysis or transplantation

OR

GLP-1 RA with proven CVD benefit if SGLT2i not tolerated or contraindicated

If HbA1c above target, for patients on SGLT2i, consider incorporating a GLP-1 RA or vice versa

If additional cardiorenal risk reduction or glycaemic lowering needed

Goal: achievement and maintenance of glycaemic and weight management goals

Glycaemic management: choose approaches that provide the efficacy to achieve goals:

Metformin OR Agent(s) including COMBINATION therapy that provide adequate EFFICACY to achieve and maintain treatment goals

Consider avoidance of hypoglycaemia a priority in high-risk individuals

In general, higher efficacy approaches have greater likelihood of achieving glycaemic goals

Efficacy for glucose lowering

Very High:
Dulaglutide (high dose), Semaglutide, Tirzepatide
Insulin
Combination Oral, Combination Injectable (GLP-1 RA/Insulin)

High:
GLP-1 RA (not listed above), Metformin, SGLT2i, Sulphonylurea, TZD

Intermediate:
DPP-4i

Achievement and maintenance of weight management goals:

Set individualised weight management goals

General lifestyle advice: medical nutrition therapy/eating patterns/physical activity

Intensive evidence-based structured weight management programme

Consider medication for weight loss

Consider metabolic surgery

When choosing glucose-lowering therapies: Consider regimen with high-to-very-high dual glucose and weight efficacy

Efficacy for weight loss

Very High:
Semaglutide, Tirzepatide

High:
Dulaglutide, Liraglutide

Intermediate:
GLP-1RA (not listed above), SGLT2i

Neutral:
DPP-4i, Metformin

If HbA1c above target

Identify barriers to goals:
- Consider DSMES referral to support self-efficacy in achievement of goals
- Consider technology (e.g. diagnostic CGM) to identify therapeutic gaps and tailor therapy
- Identify and address SDOH that impact on achievement of goals

Fig. 21.21 Guidelines for glucose-lowering treatment in type 2 diabetes: adapted from ADA-EASD 2022. This pathway is illustrative – for treatment decisions please refer to the figure provided in the full guideline (link.springer.com/article/10.1007/s00125-022-05787-2) and region-specific drug licensing information. (ACEi = angiotensin-converting enzyme inhibitor; ACR = albumin/creatinine ratio; ARB = angiotensin receptor blocker; ASCVD = atherosclerotic cardiovascular disease; CGM = continuous glucose monitoring; CKD = chronic kidney disease; CV = cardiovascular; CVD = cardiovascular disease; CVOT = cardiovascular outcomes trial; DPP-4i = dipeptidyl peptidase-4 inhibitor; DSMES = diabetes self-management education and support; GLP-1 RA = glucagon-like peptide-1 receptor agonist; HF = heart failure; HFpEF = heart failure with preserved ejection fraction; HFrEF = heart failure with reduced ejection fraction; HHF = hospitalisation for heart failure; MACE = major adverse cardiovascular events; MI = myocardial infarction; SDOH = social determinants of health; SGLT2i = sodium-glucose co-transporter 2 inhibitor; TZD = thiazolidinedione; T2D = type 2 diabetes) *Adapted from Davies MJ, Aroda VR, Collins BS, et al. 2022 Management of hyperglycaemia in type 2 diabetes, 2022. A consensus report by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD). Diabetologia 2022;65:1925–1966.*

diagnosed diabetes who have very high blood glucose, although insulin should also be considered in this context, particularly if a diagnosis of new-onset type 1 diabetes remains possible (as in this context they are dangerous because they are ineffective). They are more often used as an add-on to other glucose-lowering therapy when glycaemia is inadequately controlled (see Fig. 21.21), in non-obese people with type 2 diabetes (who likely have significant β-cell dysfunction) and in glucocorticoid-induced diabetes. Sulphonylureas are also particularly effective in some forms of monogenic and neonatal diabetes (see p. 762). The main adverse effects of sulphonylureas are weight gain and hypoglycaemia (as insulin secretion occurs irrespective of the prevailing blood glucose). A number of sulphonylureas are available: gliclazide is most commonly used in the UK and glibenclamide (known as glyburide) in the United States. Glibenclamide, however, is long-acting and prone to inducing hypoglycaemia, so should be avoided in older people. Other sulphonylureas include glimepiride and glipizide. The dose–response of all sulphonylureas is steepest at low doses, i.e. little additional benefit is obtained when the dose is increased above half-maximal doses.

Thiazolidinediones

Mechanism of action

These drugs (also called TZDs, 'glitazones' or PPARγ agonists) bind and activate peroxisome proliferator-activated receptor-γ, nuclear receptors present mainly in adipose tissue (similar to steroid and thyroid nuclear receptors), which regulate the expression of several genes involved in adipocyte differentiation. By promoting adipogenesis in subcutaneous depots, TZDs decrease circulating concentrations of free fatty acids, enhancing the actions of endogenous insulin. Therefore, they tend to increase body weight. They also alter release of 'adipokines', e.g. increasing levels of adiponectin, which improves insulin sensitivity in the liver. TZDs appear to be particularly effective at improving glycaemic control in women and people who are obese.

Clinical use

TZDs were widely prescribed in the late 1990s and 2000s, but their use has declined dramatically with the advent of other agents with fewer adverse effects and greater efficacy. One popular TZD, rosiglitazone, was withdrawn from the market in 2010 due to a subsequently disproven concern that it might increase rates of myocardial infarction. Pioglitazone, the other drug in this class, remains in use and may reduce hepatic steatosis and metabolic dysfunction–associated steatohepatitis (MASH) (see p. 895) as well as providing protection from stroke. However, it exacerbates cardiac failure by causing fluid retention and increases the risk of bone fracture (and possibly bladder cancer) with long-term use.

DPP-4 inhibitors

Mechanism of action

The incretin hormones (see Fig. 21.4) GLP-1 and GIP are gut hormones that potentiate post-prandial insulin secretion (see Fig. 21.3). GLP-1 and GIP are rapidly broken down by dipeptidyl peptidase-4 (DPP-4). The 'gliptins', or DPP-4 inhibitors, prevent physiological breakdown of endogenous GLP-1 and GIP and so enhance their circulating concentrations. Incretin-based therapies (DPP-4 inhibitors and GLP-1 agonists) are 'glucose-dependent', i.e. promote insulin secretion only when glucose is high (Fig. 21.22). Thus, insulin secretion is not augmented when blood glucose is normal, i.e. there is minimal risk of hypoglycaemia when these therapies are used as monotherapy or in combination with other drugs that do not cause hypoglycaemia.

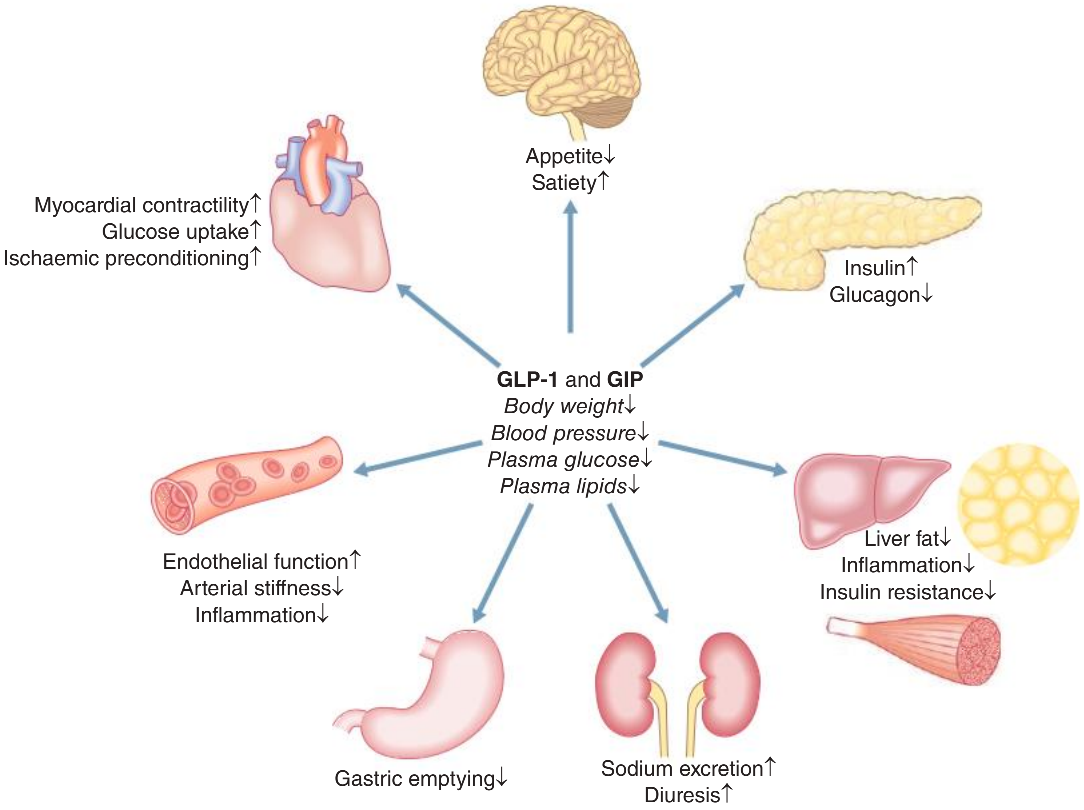


Fig. 21.22 Actions of incretin-based therapies. GLP-1 receptor agonists (GLP-RAs) and dual agonists including glucose-dependent insulinotropic polypeptide (GIP-RAs) mediate all of the actions shown and have potent effects on blood glucose and weight. Many GLP-RAs have been shown to reduce rates of cardiovascular events. Dipeptidyl peptidase-4 (DPP-4) inhibitors have less potent glucose-lowering ability and have a neutral effect on weight and cardiovascular disease. DPP-4 inhibitors do not mediate all of the actions shown, e.g. do not reduce gastric emptying or have significant effects on appetite. (GLP-1 = glucagon-like peptide-1; GIP = glucose-dependent insulinotropic polypeptide)

Clinical use

DPP-4 inhibitors include sitagliptin, linagliptin, alogliptin, vildagliptin and saxagliptin. All are well tolerated and have a neutral effect on weight, but are less potent than GLP-1 receptor agonists and provide only moderate glucose-lowering activity (see Box 21.23). They are safe but do not improve cardiovascular outcomes. The DPP-4 inhibitors are useful in combination with other drugs to get HbA1c to target when it is only modestly elevated and are commonly used in older people as they have few adverse effects. Linagliptin is the only DPP-4 inhibitor that does not require dose reduction in renal impairment.

GLP-1 receptor agonists and other incretin mimetics

Mechanism of action

The GLP-1 receptor agonists are peptide hormones that mimic the action of GLP-1; all but one to date require to be given by subcutaneous injection. Some have a high degree of structural homology to native GLP-1, but are modified at the sites usually cleaved by DPP-4 to prevent breakdown (liraglutide, semaglutide, dulaglutide). Others are synthetic forms of exendin-4, a 39 amino acid peptide originally isolated from the salivary secretions of the Gila monster, native to the Arizona desert (exenatide, lixisenatide). As incretin-based therapies, they potentiate release of insulin, but with greater potency than DPP-4 inhibitors. However, they also have important central actions, acting on receptors in specific areas of the hypothalamus (including the arcuate nucleus); in addition they delay gastric emptying, giving a feeling of satiety after eating (see Fig. 21.22). GLP-1 receptor agonists therefore decrease appetite and feeding behaviour, resulting in weight loss of on average 3–6 kg. Modifications of either the molecule or the formulation allow some agents within the class to be injected once weekly (semaglutide, dulaglutide, extended-release exenatide), rather than once daily (liraglutide) or twice daily (exenatide). An orally administered GLP-1 receptor agonist is also available consisting of encapsulated semaglutide with an advanced gastrointestinal delivery system: this must be taken once daily on an empty stomach with up to half a glass of water and nothing consumed for 30 minutes afterwards.

Tirzepatide, a more potent 'dual agonist' once-weekly injectable agent (with both GIP and GLP-1 agonist activity) is now available, while 'triple agonists' (with additional glucagon agonist activity, e.g. retatrutide) are also in late-phase clinical development. These drugs have the potential to cause significant weight loss (10–15 kg), with some individuals losing more than 20% of their total body weight.

Clinical use

These drugs have the potential to reduce HbA1c by 10–20 mmol/mol. Their main side-effect is nausea (and even vomiting) in the first few days of use; this is prevented in many individuals by slowly uptitrating from a low starting dose to a therapeutic dose. Several of the GLP-1 receptor agonist class, particularly those with high structural homology to native GLP-1 (liraglutide, semaglutide and dulaglutide), have been shown in large cardiovascular outcome trials to reduce rates of major cardiovascular adverse events. These are now the most frequently prescribed drugs in the class. As GLP-1 agonists are more expensive than other glucose-lowering agents, in the early years after their launch they were restricted to use 'third-line' and only in those with a BMI of > 30 kg/m^2 and this remains the case for some UK guidelines (including NICE). However, international guidelines (e.g. American Diabetes Association/European Association for the Study of Diabetes/European Society for Cardiology) now recommend that they should be started much earlier in individuals at high risk of a cardiovascular event.

GLP-1 receptor agonists have contributed to a revolution in the treatment of type 2 diabetes. They are associated with some serious adverse effects, including pancreatitis and non-arteritic anterior ischaemic optic neuropathy. However, these are rare. The high efficacy of GLP-1 receptor agonists and their increasing use to support weight loss in people without diabetes has led to supply issues for people with diabetes. Restrictions on prescribing and supply issues may ease with the expected eventual launch of biosimilar versions.

SGLT2 inhibitors

Mechanism of action

Sodium-glucose co-transporter 2 (SGLT2) inhibitors are derived from apple tree bark and were first licensed for type 2 diabetes in 2013. The best-known drugs in the class are dapagliflozin and empagliflozin. They act on glucose handling in the kidneys: glucose is normally filtered freely in the glomerulus and then completely reabsorbed in the proximal tubules with sodium (mainly via SGLT2) (Fig. 21.23). During hyperglycaemia, this response reaches saturation and glucose is lost in the urine. Glycosuria is a hallmark feature of type 2 diabetes, but in many cases there is a paradoxical increase in reabsorption of glucose such that the threshold blood glucose value at which glucose is lost in the urine is higher than the usual physiological level; this may be due to increased expression of SGLT2.

SGLT2 inhibitors act by lowering the renal threshold for glucose excretion, such that typically 25% of filtered glucose is not reabsorbed. As well as lowering blood glucose, a negative energy balance is created with 200–300 kcal being lost each day (as glucose in the urine), resulting in significant weight loss. As sodium is also lost in the urine (also known as natriuresis), blood pressure is also reduced.

SGLT2 inhibitors reduce rates of major adverse cardiovascular outcomes, particularly heart failure, and also have a reno-protective effect, i.e. reducing rates of death, dialysis and transplantation. These beneficial effects are at least in part due to blood pressure and weight lowering but other more complex mechanisms are also of clinical relevance. Compensatory glucagon release from pancreatic α cells (in response to urinary loss of glucose) decreases the circulating ratio of insulin to glucagon, promoting lipolysis and even mild ketosis; however, because of weight loss this is not sufficient to exacerbate insulin resistance. The work of the myocardium is more efficient when it utilises free fatty acids (and ketones) for fuel than it is when metabolising glucose (as it does in heart failure). Renal benefits of SGLT2 inhibitors are due to constriction of the afferent arteriole (as a reflex response to increased renal tubular loss of sodium, termed 'tubuloglomerular feedback'). This decreases intraglomerular pressure in a complementary manner to ACE inhibitors (p. 661), which cause relaxation of the efferent arteriole by opposing the action of angiotensin II.

Clinical use

SGLT2 inhibitors have also contributed to a revolution in the treatment of type 2 diabetes. They are effective oral glucose-lowering agents (can reduce HbA1c by approximately 10 mmol/mol) that are usually added in with other agents second-line after metformin. They help with body weight reduction (3–5 kg) and are associated with improvements in renal and cardiovascular (particularly heart failure) outcomes that have substantially advanced the treatment of type 2 diabetes. They should be prescribed for all individuals with type 2 diabetes and heart failure, prior myocardial infarction, coronary artery disease, stroke, unstable angina, and occlusive peripheral arterial disease. They should be considered for all those with chronic kidney disease and albuminuria provided eGFR has not fallen below 15 mL/min/1.73 m^2 (Ch. 18).

The main adverse effect (in 5%–10% of those who take these agents) is genital mycotic (fungal) infections, usually with *Candida albicans*, i.e. vaginal 'thrush' and balanitis. Urine infection is also more common and, very rarely, severe genital infection (Fournier gangrene, see Ch. 14) can occur. It is essential for prescribers to mention these side-effects, to ensure that prompt measures can be taken to treat any infection; good genital hygiene is also necessary. Once blood glucose is under control, genital infections are much less likely to occur. Euglycaemic diabetic ketoacidosis (i.e. DKA not associated with marked hyperglycaemia) is a rare complication of this class of drugs, presumably driven by reduced insulin:glucagon ratio and consequent increased levels of circulating

SGLT2 inhibitors reduce net reabsorbed glucose by 25%. For a mean plasma glucose of 8 mmol/L (144 mg/dL), this results in a glucose loss of approximately 80 g per day in the urine, which in turn reduces plasma glucose. This equates to 320 kcal per day and promotes weight loss. **B** SGLT2 inhibition leads to glycosuria and is associated with improved glycaemia, blood pressure reduction and weight loss.

ketones. It can be minimised by education about ‘sick day rules’, i.e. interrupting therapy during acute illness (e.g. gastrointestinal or respiratory), avoiding dehydration and seeking medical attention. The provision of a glucose meter with additional functionality for blood ketone monitoring can also be useful as an early warning of DKA for individuals considered to be at higher risk.

Insulin therapy

Manufacture and formulations

Insulin was first isolated in Toronto in 1921, transforming the previously short life expectancy of children and young adults with type 1 diabetes. It was obtained for therapeutic use by extraction and purification from pancreases of cows and pigs (bovine and porcine insulins), until the emergence of recombinant DNA technology enabled large-scale production of human sequence insulin from the early 1980s. From the mid-1990s, ‘analogue insulins’ gradually gained ground; these contain alterations to the native human insulin amino acid sequence and/or additional molecules covalently added to confer desirable pharmacological profiles. They have now largely replaced human sequence insulin.

The underlying principles of insulin pharmacology are simple, but the naming of the various available insulin preparations is complicated by trade names conferred on similar or equivalent products by different manufacturers. The time-action profile of an insulin describes its pharmacodynamic properties as time to onset and time to peak action as well as its overall duration of action after subcutaneous injection. These properties are depicted using simplified graphs (see Fig. 21.25) as an educational tool for insulin users and health-care professionals. With a few exceptions, insulin concentration is standardised internationally at 100 U/mL (U100), using a system based on the one developed by the team in Toronto. Expert advice should be sought before prescribing more concentrated insulins: for safety, these are now provided via dedicated pen devices to avoid confusion and prevent prescribing errors.

Unmodified ('soluble' or 'regular') short-acting insulin is clear in appearance and has an onset of action within 30 minutes of injection, wearing off by 6–8 hours. Extending this duration of action was initially achieved in the 1930s by adding protamine and zinc at neutral pH to create Neutral Protamine Hagedorn insulin (known as 'isophane' or NPH insulin) – this has a cloudy appearance (and requires to be resuspended by shaking before use). It is now referred to as 'intermediate-acting' with onset of action at 60–90 minutes, peaking at 6 hours and wearing off by 12–16 hours.

When insulin is injected into subcutaneous tissues, it aggregates into hexamers; these polymers of six insulin molecules must dissociate before systemic absorption can occur. The speed of dissociation can be altered by making small changes to the amino acid sequence (insulin analogues). For example, in insulin lispro, the penultimate lysine and proline residues on the C-terminal end of the B-chain are reversed (Fig. 21.24). This prevents hexamer formation leading to a more rapid onset and shorter duration of action than soluble insulin (Box 21.24). Short-acting insulin analogues allow greater flexibility as they can be injected closer to mealtimes (ideally 15–30 minutes before). Onset of action may be further hastened by the addition of excipients to the formulation (e.g. nicotinamide and L-arginine to insulin aspart to create 'faster insulin aspart').

Other changes to the insulin molecule have been engineered to produce long-acting analogue insulins. An example is insulin glargine, in which a substitution of glycine for asparagine in the A-chain and the addition of two additional arginine residues to the C-terminal end of the B-chain prolongs its duration of action to nearly 24 hours by increasing its isoelectric point from pH 5.4 to 6.7, i.e. making it less soluble at a physiological pH (see Fig. 21.24). Other long-acting insulins include insulin detemir and degludec; their duration of action is extended by adding fatty acid side chains to the C-terminal end of the B-chain (see Fig. 21.24). Following subcutaneous injection, insulin detemir and degludec bind to albumin in the blood, from which insulin molecules slowly disassociate. The duration of action of insulin degludec is almost 48 hours as the fatty acid moiety also promotes subcutaneous formation of multi-hexamers of insulin (see Box 21.24). It is termed a second generation long-acting insulin. However, a comparable pharmacological profile can be achieved by using a triple concentrated form of insulin glargine ('U300 glargine'); this can also be useful to decrease injection volume for individuals who require high doses to achieve glycaemic control. Modern long-acting insulins provide more consistent basal insulin levels during the day and night and are associated with lower rates of hypoglycaemia, particularly

i 21.24 Duration of action (in hours) of insulin preparations

Insulin	Onset	Peak	Duration
Rapid-acting insulin analogues: lispro, aspart, glulisine, Fiasp	< 0.5	0.5–2.5	3–4.5
Short-acting soluble (regular)	0.5–1	1–4	4–8
Intermediate-acting isophane (NPH), lente	1–3	3–8	7–14
Long-acting insulin analogues: glargine, detemir, degludec	1–2	None	18–26

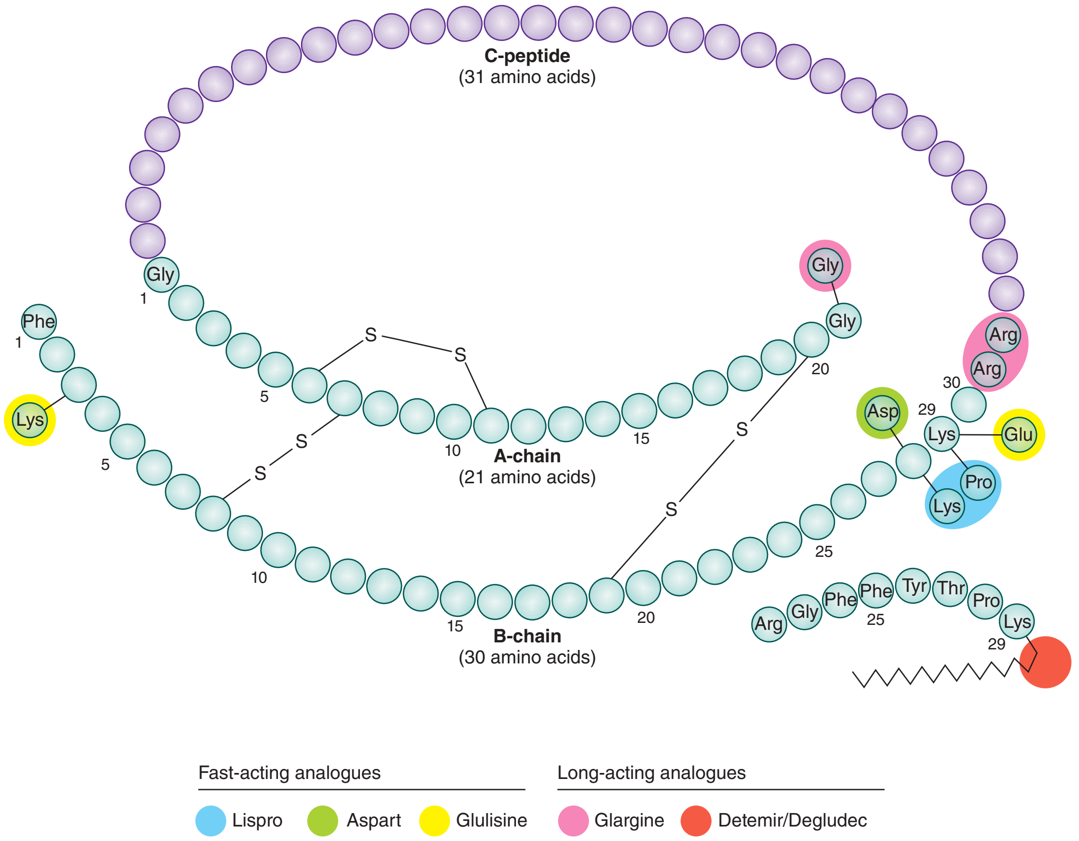

Fig. 21.24 Schematic structure of insulin and insulin analogues. Insulin is created when C-peptide is cleaved from the A- and B-chains of proinsulin. The areas in the shaded colours show the modifications made to the normal structure of insulin to create analogues. These are important in altering the pharmacokinetic properties of the analogues. Long-acting insulin analogues detemir and degludec are synthesised by adding specific fatty acid chains (shown) at position 29 (lysine) on the B-chain.

overnight. Long-acting insulins that only require injection once weekly were approved in some countries in 2024.

Pre-mixed formulations containing short-acting and isophane insulins in various proportions ('biphasic', see below) are also available and widely prescribed in some countries, particularly for individuals with type 2 diabetes with regular mealtimes who wish to avoid injecting more than twice a day (see below).

Intermittent subcutaneous insulin injection therapy

Insulin is most commonly administered several times a day as an injection into the subcutaneous adipose tissue of the anterior abdominal wall, upper arms or outer thighs with the needle sited at a right-angle to the skin. Even with careful technique, the rate of absorption of insulin is influenced by the site, depth and volume of injection, skin temperature (warming) and exercise. Accidental intramuscular injection results in more rapid absorption and hypoglycaemia; it is more likely to occur in children and slim adults (with little subcutaneous adipose tissue) and can be minimised by using shorter needles (e.g. 4 mm rather than 8 mm). A clinically important reason for delayed absorption is lipohypertrophy, which can develop at over-used injection sites (see p. 783). This is due to the local trophic (growth factor) action of insulin and results in greater variability in blood glucose. It can be avoided by not injecting into the same place and instead 'rotating' injections around (and within) the recommended sites.

Following absorption into blood, circulating insulin has a half-life of just a few minutes as it is cleared by the liver and kidneys. The total daily dose required may therefore diminish in individuals who develop liver disease or renal failure.

Traditional insulin syringes have largely been replaced by unobtrusive portable 'pen' devices, sufficient for multiple dosing and either disposable or designed to accept insulin in cartridges. Insulin users are advised to keep their stock in a refrigerator (approximately 4°C), but to keep their current pen at room temperature (as cold insulin is more painful to inject). Insulin will denature and become inactive if accidentally frozen and thawed. The complications of insulin therapy include hypoglycaemia (p. 763), weight gain, peripheral oedema, insulin antibodies, local allergy (rare) and lipohypertrophy or lipoatrophy at injection sites. Fasting hyperglycaemia in the morning has traditionally been attributable to a rebound from undetected overnight hypoglycaemia driven by counter-regulatory hormones (cortisol, growth hormone and catecholamines) – the 'Somogyi effect'. However, systematic investigation in the era of CGM has detected little supporting evidence for this, as high blood glucose on rising is more often due to a combination of the circadian cycle (or 'dawn phenomenon') and inadequate overnight basal insulin dosing.

Intermittent subcutaneous insulin injection regimens

The choice of insulin injection regimen depends on the agreed target for glycaemic control (set using the principle of 'shared decision-making'), need for flexibility in lifestyle and whether an individual can safely and reliably learn to adjust insulin doses in response to counting the carbohydrate content of planned meals. Time–action profiles for different insulin regimens are shown in Figure 21.25.

In general, people with type 1 diabetes should be prescribed either multiple daily insulin injections (MDI) or continuous subcutaneous insulin infusion therapy (CSII). MDI or 'basal-bolus' therapy consists of four or five daily injections: one or two 'basal' injections (with a long-acting or intermediate insulin, respectively) and an injection of 'bolus' insulin (usually with a rapid-acting analogue) 15–30 minutes before each of three main meals. The purpose of bolus insulin is to limit the magnitude of the rise in blood glucose following a meal. The purpose of basal ('background') insulin is to keep blood glucose stable between meals by reducing hepatic glucose output, both overnight and during periods of the daytime when there is little bolus insulin activity (i.e. if there is a long time-gap between bolus injections). An MDI regimen allows greater freedom of meal timing than one based on a premixed insulin formulation as bolus insulin is simply administered before each meal, whenever it occurs.

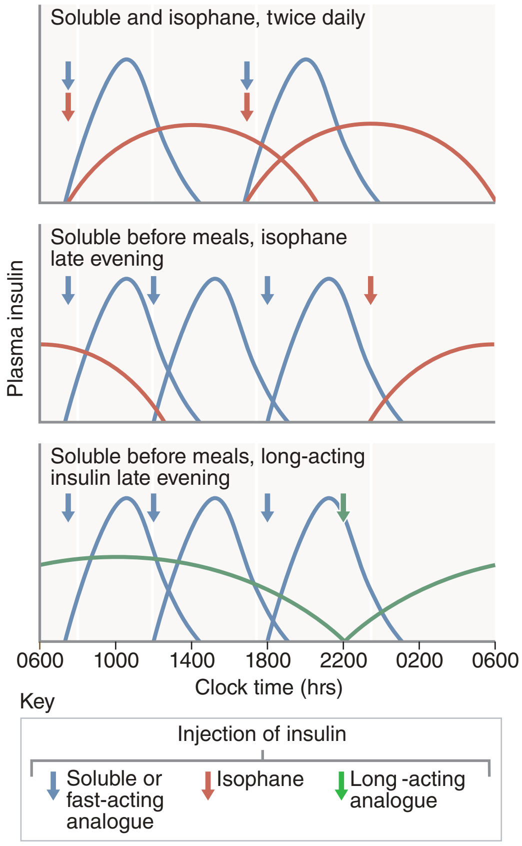

Fig. 21.25 Profiles of plasma insulin associated with different insulin regimens. These are theoretical patterns of plasma insulin and may differ considerably in magnitude and duration of action between individuals.

The dose of bolus insulin administered at any one meal is primarily determined by the carbohydrate content of the meal, the prevailing glucose level and the target glucose for the individual. Each patient is advised by health-care professionals of their 'insulin to carbohydrate ratio', i.e. the amount of insulin to take for each carbohydrate portion. In most people, this ratio is around 1:10 (i.e. 1 unit of insulin is taken for each 10 g carbohydrate portion in the meal to be consumed), but may be higher or lower depending on the individual's insulin sensitivity. It may also vary between meals (e.g. breakfast vs evening meal). Individuals are also advised of their 'insulin sensitivity factor' (or 'correction factor'), i.e. the amount that 1 unit of insulin lowers their blood glucose. In most people, 1 unit of insulin lowers glucose by 3 or 4 mmol/L, although this again varies according to insulin sensitivity. Box 21.25 shows a worked example of how a person with diabetes may use this information to determine the dose of insulin to be administered with a meal. Additional adjustments to the final dose may also need to take into account other variables, including exercise and alcohol consumption. Thus, bolus insulin may need to be reduced to cover a meal taken 2 hours prior to vigorous exercise or if consuming large amounts of alcohol (see p. 775).

Basal insulin doses are determined with reference to fasting glucose levels and overnight profiles. Thus, the dose may be decreased if there is overnight or fasting hypoglycaemia and increased if there is overnight hyperglycaemia. Further refinement of daytime basal insulin can be made with reference to daytime glucose profiles following a series of carbohydrate-free meals (which do not require injection of bolus insulin) as the glucose levels in this context are mainly dependent on basal insulin.

The foregoing shows how the therapeutic use of insulin demands considerable attention to detail, with respect to a whole variety of factors, as well as significant numeracy skills. Many people understandably struggle to maintain the motivation required to monitor glucose regularly, count carbohydrate accurately, remember to take all their insulin injections and

21.25 Example of bolus insulin dose calculation

You are about to eat a meal with 60 g carbohydrate

Your pre-meal blood glucose is 13.0 mmol/L

Your personalised diabetes data:

Insulin to carbohydrate ratio = 1:10
Insulin sensitivity factor = 3, i.e. 1 unit of insulin lowers blood glucose by 3 mmol/L
Target blood glucose = 7 mmol/L

Bolus dose calculation

1. Bolus dose of insulin to cover meal = 60 g ÷ 10 g
   = 6 units
2. Blood glucose correction = Actual glucose − target glucose
   = 13.0 − 7.0 mmol/L
   = 6.0 mmol/L
3. Correction dose of insulin = Blood glucose correction ÷ insulin sensitivity factor
   = 6.0 ÷ 3
   = 2 units
4. Total bolus dose of insulin = Meal dose + correction dose
   = 6 + 2 units
   = 8 units

to leave an adequate gap between the bolus injection and the start of a meal.

In type 2 diabetes, insulin is usually initiated as a once-daily long-acting insulin, either alone or in combination with oral glucose-lowering agents. However, in time, more frequent insulin injections may be required, including MDI. Another option is a fixed ratio of long-acting insulin analogue and GLP-1 receptor agonist combined in a single pen injector device, enabling co-administration of insulin and GLP-1 receptor agonists in a single daily (or soon weekly) injection.

Twice-daily administration of a short-acting and intermediate-acting insulin (usually soluble and isophane insulins), given as a premixed formulation before breakfast and the evening meal, is still commonly used in many countries. Initially, two-thirds of the total daily requirement of insulin is given in the morning and the remaining third is given in the evening. Pre-mixed formulations are available that contain different proportions of soluble and isophane insulins (e.g. 30:70 and 50:50). These offer convenience in that only two injections per day are required (before breakfast and before the evening meal), but are inflexible as the individual components cannot be adjusted independently, i.e. a late meal or unexpected physical exercise can result in hypoglycaemia. Such regimens usually only allow adequate glycaemic control to be achieved without hypoglycaemia in individuals who prefer set meal times with little dietary flexibility and who take part in little moderate or vigorous physical exercise.

Continuous subcutaneous insulin infusion therapy (insulin pump)

Continuous subcutaneous insulin infusion (CSII), commonly known as insulin pump therapy, is a system of insulin delivery that uses a battery-operated medical device to deliver insulin continuously to people with type 1 diabetes. A variety of insulin pumps are available and the choice is often framed by cost, compatibility with CGM systems and the personal preference or circumstances of the person with diabetes. When using a traditional pump, rapid-acting insulin is infused from a disposable insulin cartridge/reservoir within the pump (which has controls, a processing module and batteries). The disposable insulin cartridge/reservoir is attached to a tubing system that connects to a cannula, which is inserted subcutaneously (disposable infusion set) and secured by an adhesive dressing. The insulin infusion set and site should be changed every 3 days to avoid superficial infection of the site and compromise to the subcutaneous infusion of insulin. Patch pumps eliminate tubing from the insulin infusion set as the cannula, cartridge/reservoir and batteries are located in a wearable disposable 'pod'. The controls and processing module are located in a handheld 'personal diabetes manager' that communicates wirelessly to the pod, which is changed every 3 days, as with the traditional pump. Examples of a traditional pump and patch pump are shown in Figure 21.26.

Fig. 21.26 Insulin pumps. An insulin pump is an alternative means of delivering insulin in type 1 diabetes. **A** Different types are available and include the pump device itself (with controls, processing module and batteries), a disposable reservoir for insulin (inside the pump) and a disposable infusion set (with tubing and a cannula for subcutaneous insertion). **B** Alternative configurations include disposable or semi-disposable pumps without infusion tubing. Insulin pumps deliver rapid-acting insulin continuously and can be adjusted by the user, based on regular glucose monitoring and carbohydrate counting. (IOB = insulin on board)

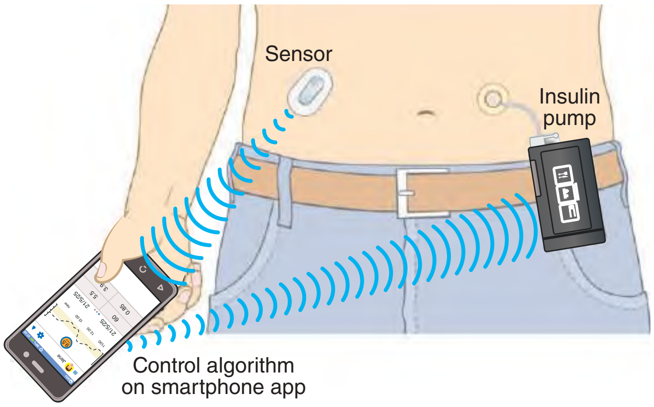
Basal insulin is delivered in the form of continuous infusion of rapid-acting insulin, usually 40%–50% of total daily dose (TDD). The proportion of basal insulin to TDD can vary, particularly in people who consume low or high carbohydrate diets. The number of units per hour can be calculated simply by dividing the TDD by 24. The basal rate is adjusted by fasting for periods of at least 4 hours while periodically evaluating the blood glucose levels and adjusting the pump infusion rate to maintain glucose in the normal range. Adjustments are made by approximately 10% at a time, 2 hours before a change in blood glucose is required, because of the kinetics of insulin absorption and time to reach steady state. One of the key advantages of CSII is that basal rates can be varied *within* a 24-hour period (this is in contrast to basal insulin in an MDI regimen, for which the dose can be altered, but the basal levels then remain relatively constant for the duration of action of that injection). This flexibility to pre-program adjustments is especially useful overnight, e.g. when basal rates can be reduced to prevent low glucose and then increased pre-dawn to prevent high morning (fasting) glucose. In addition, temporary basal rates can be used to lessen the risk of hypoglycaemia with daily activity (e.g. commuting, grocery shopping) or aerobic exercise (e.g. running, cycling).

Pre-meal boluses are administered 15–30 minutes before food via the insulin pump to limit post-prandial glucose excursions. As with MDI, bolus dosing is determined by the carbohydrate content of the meal, a personalised insulin to carbohydrate ratio and pre-meal glucose levels. Insulin pumps allow more flexibility with bolus insulin infusions in both timing and shape (e.g. using an extended or dual-wave bolus when covering high-fat/protein meals such as pizza or steak, or when diabetes is complicated by gastroparesis). Additionally, insulin pumps have calculators or 'bolus wizards' that calculate the 'active insulin on board', for precise calculation of pre-meal boluses and to allow safer 'correction' doses during periods of hyperglycaemia. This helps reduce the risk of hypoglycaemia from boluses given close together in time, an effect known as 'insulin stacking'.

Overall, CSII reduces blood glucose variability in type 1 diabetes and in some people can help improve HbA1c. However, the benefits of insulin pump therapy can only be fully realised with meticulous and attentive carbohydrate counting and glucose monitoring, and proactive adjustment of bolus and basal insulin in response to glucose levels. There are also risks to pump therapy that limit its suitability for some people. Pump failure leading to an interruption of the subcutaneous insulin infusion can occur for a variety of reasons. Causes include detachment or kinking of the insulin infusion set cannula or malfunction due to expiry of the battery. As the pump delivers rapid-acting insulin and there is no depot of intermediate or long-acting insulin, pump failure can very quickly (within a matter of hours) lead to insulin deficiency and DKA. Therefore, insulin pump users must regularly monitor glucose and promptly check for ketones and change the infusion set and cannula site if they have concerns about pump failure. 'Back-up' unexpired insulin pens should always be available. Individuals who are not prepared or able to monitor glucose regularly are not suitable for CSII because of the risks of DKA. Cannula site infection is another recognised complication of pump therapy; this risk can be reduced by good hygiene and by ensuring the cannula is changed every 3 days.

Sensor-augmented CSII therapy

A further iteration in insulin pump therapy in recent years is communication with certain CGM devices via computerised algorithms (Fig. 21.27).



Sensor
Insulin pump
Control algorithm on smartphone app

Fig. 21.27 Sensor-augmented insulin pump system. The artificial pancreas (AP) can vary in its set-up, but core to an AP system are: (1) a continuous glucose monitor (CGM) measuring interstitial glucose levels every 5–15 minutes; (2) a smartphone (or personal diabetes manager) with an app that uses the glucose information from the CGM, along with modifications inserted by the user, to calculate how much insulin should be delivered. This is communicated wirelessly to (3) the insulin pump that delivers insulin subcutaneously as directed.

Sensor-augmented insulin pumps can use data from CGM, and with knowledge of the amount of 'active insulin on board', to adjust basal rates towards a target glucose. Rather than preset basal rate infusions, such hybrid closed-loop (HCL) systems (also known as the 'artificial pancreas') automatically decide whether to infuse a small amount of basal insulin every 5 minutes, with decisions about pre-meal boluses still determined by the person with diabetes (Fig. 21.28). Features also include 'low-glucose suspend' or 'suspend before low' functions, such that detection of hypoglycaemia or a glucose level falling below a pre-set threshold (e.g. 5.0 mmol/L (90 mg/dL)), respectively, signal the pump to stop infusing insulin temporarily, leading to a substantial reduction in hypoglycaemia without rebound hyperglycaemia. Fully closed-loop (FCL) systems, where the user is not required to enter meal-time carboyhdrate counts, are in development. The current systems are not perfect (e.g. recurrent low glucose sensor alarms can be irritating), but sensor-augmented CSII technologies are rapidly improving and offer the real prospect of a 'technological cure' for type 1 diabetes, i.e. delivering near normal blood glucose, with little or no hypoglycaemia and with minimal input required from the user. However, these technologies are expensive, and widespread use may be limited by cost for some time to come. Some patients use do-it-yourself artificial pancreas systems (DIY-APS), also known as 'looping'. DIY-APS are by definition not approved by regulatory bodies, but use existing insulin pumps and CGM devices with free open resource software to link the systems and provide much of the functionality described above.

Intravenous insulin therapy

Circulating insulin has a half-life of approximately 2.5 minutes (the longer duration of action of subcutaneous insulin is because of the time taken for insulin to be absorbed from subcutaneous sites to the blood). Therefore, direct infusion of insulin via the intravenous route gives maximum flexibility in regulating blood glucose concentrations: an increase in the infusion rate will rapidly correct hyperglycaemia, while cessation of intravenous insulin will arrest a rapidly declining blood glucose. This inherent flexibility makes intravenous insulin a powerful tool in the management of hyperglycaemic emergencies and in stabilising blood glucose in a peri-operative situation or in individuals who are unwell, e.g. with poor oral intake or delayed gastric emptying. Subcutaneous insulin does not lower blood glucose quickly enough for hyperglycaemic emergencies, particularly if skin perfusion is reduced during sepsis, while its duration of action may also be too long (i.e. result in hypoglycaemia) if given to an unwell patient who subsequently cannot eat or vomits. Intravenous insulin is, however, a dangerous therapy if not properly supervised and monitored. There are substantial risks of hypoglycaemia, hypokalaemia and hyperglycaemia (including DKA) and so it must only be used in a setting where medical and nursing staff have the necessary experience and time to safely prescribe, prepare and administer the therapy. Standardised

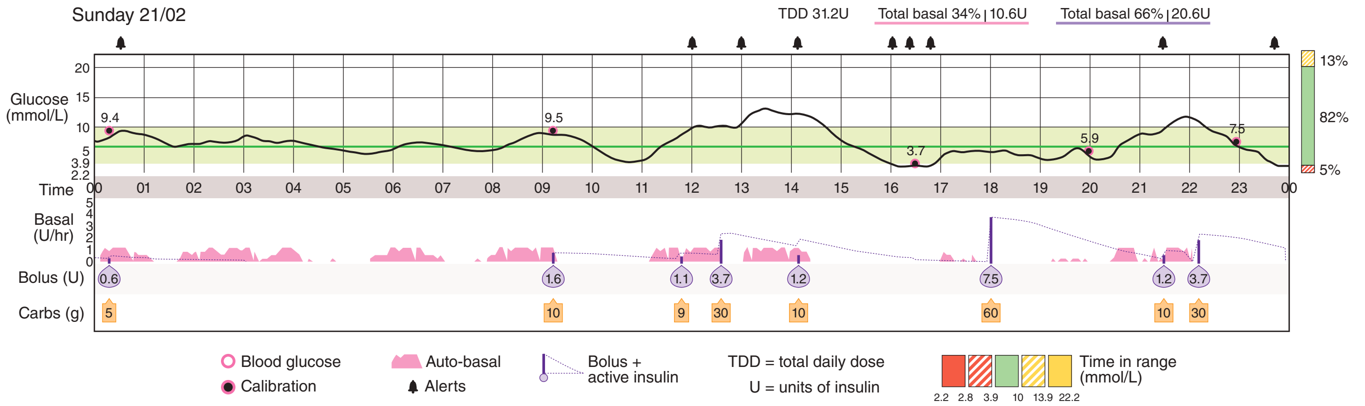


Fig. 21.28 Download from a sensor-augmented insulin pump system. The user is required to enter the carbohydrate content of meals and snacks. Bolus doses of insulin are determined in part on this information (purple). Basal insulin administration is determined by an algorithm using glucose data and 'active insulin'. Note how the basal insulin infused (pink) varies substantially with time, such that basal insulin ceases when glucose levels are falling (especially if there is still active insulin present from a previous bolus dose). The user is also alerted when there are impending low or high glucose events. These functions facilitate excellent glycaemic control (especially overnight when there is no impact on glucose from food ingestion and exercise) and prevent or minimise low glucose events.

ward-level documentation and protocols are essential to support the clinical team.

Intravenous insulin is most commonly given via an electronic syringe driver (insulin injected directly into a bag of intravenous glucose and potassium is now rarely used). Usually, 50 units of soluble insulin (Actrapid or Humulin S) is diluted in 50 mL 0.9% sodium chloride, to provide an infusion of 1 unit insulin/mL. In hyperglycaemic emergencies (especially DKA), it is usually given as a fixed rate insulin infusion (FRII). This avoids the possibility of the infusion rate reducing to zero, as can occur with a variable rate insulin infusion (VRII), which might cause a worsening of acidosis and ketosis.

In peri-operative and medically unwell patients, insulin is usually given as a VRII (formerly called an 'insulin sliding scale'). Indications and principles of using VRII in the hospital setting are outlined in Box 21.26. An example of a VRII prescription chart is shown in Figure 21.29. Bedside capillary blood glucose monitoring should be performed on an hourly basis. Due to the short half-life of intravenous insulin, the insulin infusion must be monitored regularly to ensure it is continuously running; if there is interruption to the infusion even for a relatively short period of time (e.g. a 'tissued' intravenous cannula, a kink in the infusion tube, a mechanical failure in the pump or the syringe simply running out), significant hyperglycaemia can quickly ensue. With a VRII, intravenous glucose (e.g. 0.45% sodium chloride + 5% glucose + 0.15% potassium chloride infused at 100 mL/hr) should be prescribed to provide some energy substrate and to reduce the risk of hypoglycaemia and hypokalaemia. Where possible, the glucose and insulin infusions should be given through a volumetric infusion device via the same intravenous catheter with a Y-connector, so that if the cannula blocks or 'tissues', then both infusions simultaneously cease, reducing the risk of hypoglycaemia from unopposed insulin. If additional fluids or potassium replacement are required, depending on the volume and potassium status of the individual, they should be given via a separate infusion. Unused insulin should be discarded every 24 hours and a new infusion prepared. VRIIs should be reviewed at least every 24 hours to ensure that the infusion rates prescribed for a given blood sugar level have resulted in stable glucose levels. If blood sugar levels have been very variable, with frequent adjustments to the infusion rate, this is usually a sign that the prescription needs to be modified (or that it is time for the VRII to be discontinued as the patient has begun to eat).

i 21.26 Variable rate insulin infusion (VRII)

Principles

- Desired glucose targets are achieved and maintained
- Avoidance of hypoglycaemia
- Avoidance of ketonaemia by providing adequate carbohydrate and insulin
- Maintenance of fluid and electrolyte balance

Indications

- People with diabetes undergoing operations, e.g. fasting > 24 hours, emergency surgery
- People with diabetes who have uncontrolled hyperglycaemia or who are unable to eat and drink due to prolonged fasting, nausea, vomiting or reduced consciousness

Do not use

- Diabetic ketoacidosis (DKA)
- Hyperglycaemic hyperosmolar state (HHS)

Additional requirements

- Capillary blood glucose should be checked at least hourly
- The standard regimen for intravenous fluid prescription is 0.45% sodium chloride + 5% glucose + 0.15% potassium chloride (pre-prepared infusion bags) run at 100 mL/hr through a volumetric pump only
- Potassium monitoring is required to maintain serum level between 4 and 5 mmol/L
- Specialty input is required to guide fluid replacement in special situations, such as cardiac failure, renal failure, following head injury and after neurosurgery

Considerations when stopping

- Continue long-acting insulin at usual time while on VRII to allow stopping at any time
- Pre-mixed insulin should not be administered on VRII – if stopping VRII, give usual dose at breakfast/dinner and stop VRII after 2 hours (due to short half-life of intravenous insulin and risk of rebound hyperglycaemia)

Transplantation

The goal of transplantation is to facilitate independence from insulin, reduce complications and improve quality of life.

The American Diabetes Association (ADA) criteria for transplantation include three main types of pancreas transplantation:

- Simultaneous pancreas–kidney (SPK) transplant, when pancreas and kidney are transplanted simultaneously from the same deceased donor, or pancreas-after-kidney (PAK) transplant, when a cadaveric donor pancreas transplant is performed after a previous, and different, living or deceased donor kidney transplant
- Pancreas transplant alone (PTA)
- Islet transplantation

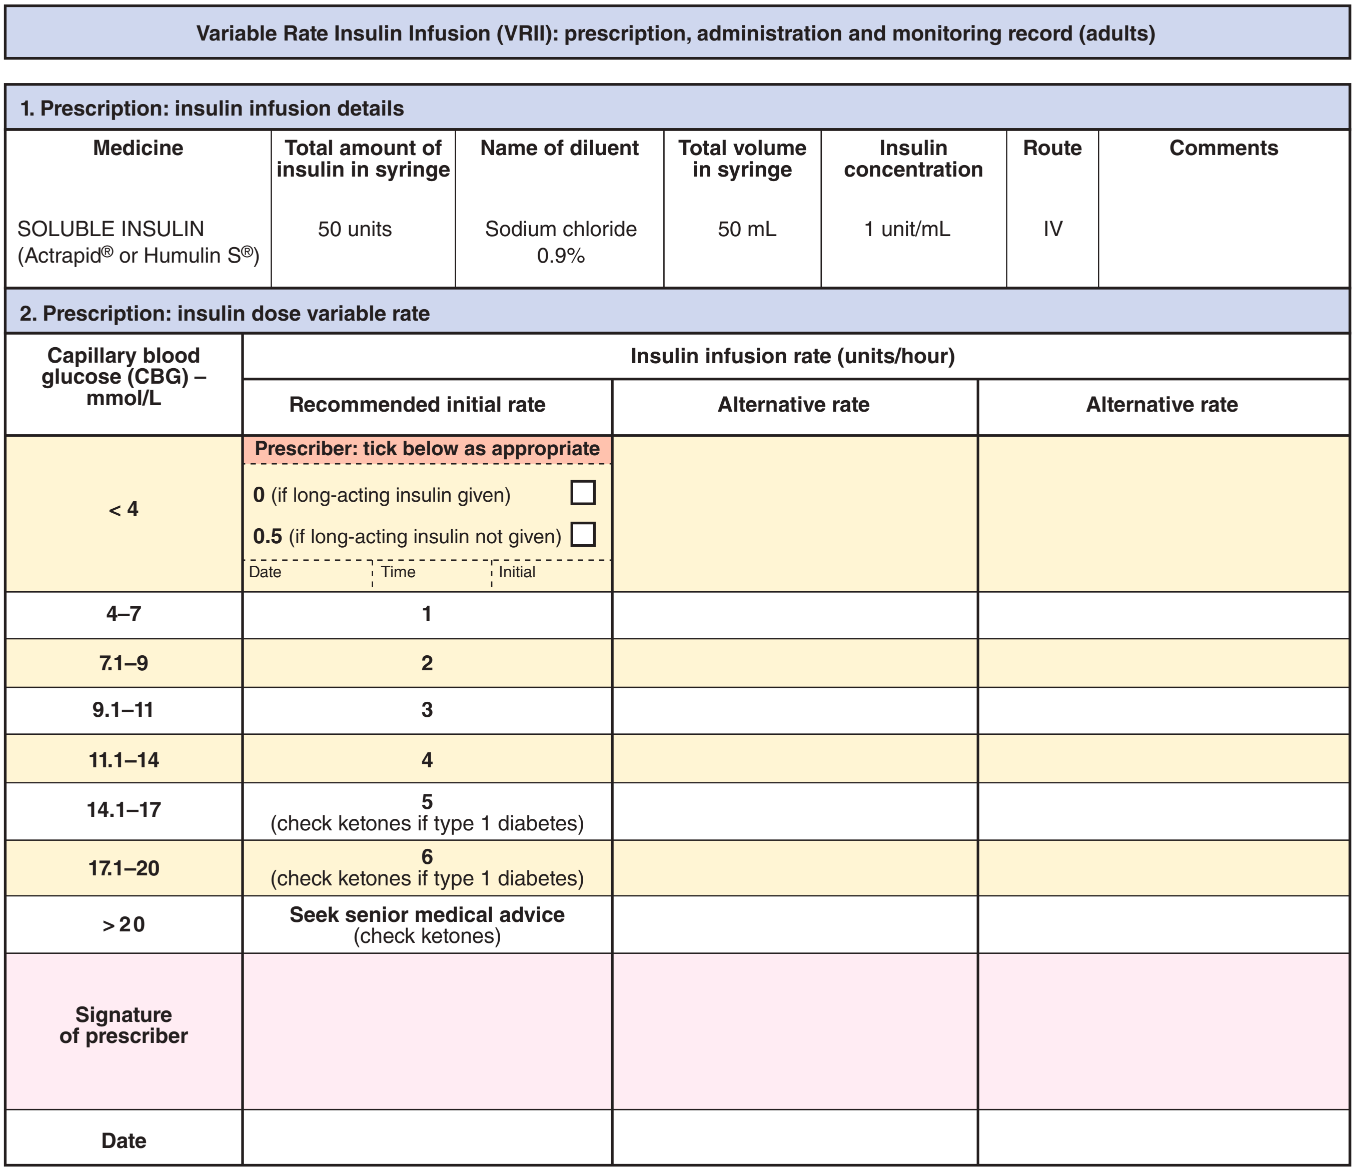
Whole pancreas transplantation is carried out in a relatively small number of people each year. SPK is the most commonly performed procedure. Most SPK and PAK are undertaken in people with diabetes and end-stage kidney disease, in whom successful transplantation will improve glycaemia and may improve kidney survival. PTA is generally considered for people with progressive complications leading to significant loss of quality of life (for example recurrent level 3 hypoglycaemia). The principal complications occurring immediately after surgery include thrombosis, pancreatitis, infection, bleeding and rejection. Prognosis is improving: 1 year after transplantation > 95% of all patients are still alive and 80%–85% of all pancreases are still functional. After transplantation, people will need life-long immunosuppression, which carries with it an increased risk of infection and skin cancer.

Islet transplantation involves the transplantation of islets from a donor pancreas into a person with type 1 diabetes. The isolated pancreatic islets are usually infused into the patient's liver via the portal vein. This approach has now been successfully adopted in a number of centres around the world (Fig. 21.30). At present, islet transplantation is usually suitable only for people with unstable glycaemic control characterised by severe intractable hypoglycaemia that cannot be corrected by structured education, modern insulin regimens and technology. Progress is being made towards meeting the needs of supply, purification and storage of islets, but problems remain relating to transplant rejection and destruction by the immune-mediated process against β cells that caused type 1 diabetes in the first place. Nevertheless, the development of methods of inducing tolerance to transplanted islets and the potential use of stem cells mean that this may still prove a promising approach in the long term. Adoption of newer immunosuppressive protocols has resulted in far better outcomes and now nearly 50% of people with diabetes transplanted will be insulin-independent at 3 years post transplantation. This is an evolving therapy area with many new experimental techniques under development. There are no direct comparisons between whole pancreas and islet transplantation, but it appears that whole pancreas transplantation results in higher rates of insulin independence albeit with the greater morbidity of surgery.

Management of diabetes in special situations

Diabetes in pregnancy and gestational diabetes

As elevated maternal blood glucose in pregnancy is associated with significant maternal and fetal morbidity, pregnancy in women with diabetes should always be planned: effective contraception should be used at all other times in those who are sexually active. It is important that pregnancy is raised as a matter of course in general diabetes consultations



Variable Rate Insulin Infusion (VRII): prescription, administration and monitoring record (adults)

1. Prescription: insulin infusion details

Medicine	Total amount of insulin in syringe	Name of diluent	Total volume in syringe	Insulin concentration	Route	Comments
SOLUBLE INSULIN (Actrapid® or Humulin S®)	50 units	Sodium chloride 0.9%	50 mL	1 unit/mL	IV	

2. Prescription: insulin dose variable rate

Capillary blood glucose (CBG) – mmol/L	Insulin infusion rate (units/hour)		
	Recommended initial rate	Alternative rate	Alternative rate
< 4	**Prescriber: tick below as appropriate** **0** (if long-acting insulin given) ☐ **0.5** (if long-acting insulin not given) ☐ Date Time Initial		
4–7	1		
7.1–9	2		
9.1–11	3

Date			

Fig. 21.29 Example of a prescription document for a variable rate insulin infusion (VRII). The insulin infusion has a standard concentration of 1 unit/mL. The rate of insulin infusion is adjusted according to the prevailing blood glucose level. Adjustments are made to the infusion rates as capillary blood glucose falls and rises.

with women of child-bearing potential and that prescribing decisions of potentially teratogenic drugs (e.g. ACE inhibitors and statins) take into account potential effects on the fetus in the event of an unplanned pregnancy. Women who are planning a pregnancy should be referred prior to conception to a dedicated diabetes pre-pregnancy clinic focused on achieving glycaemic targets prior to conception and with extra focus on nutrition (including supplementation with high-dose folic acid), diabetes education, and screening for diabetes comorbidities and complications. Combined obstetric and diabetes specialist management of women with diabetes who are pregnant or who have developed diabetes during pregnancy (gestational diabetes) is discussed in detail in Chapter 30.

Children, adolescents and young adults with diabetes

Most type 1 diabetes is diagnosed in children below 18 years of age, with peak incidence rates between 5 and 7 years of age and at puberty. The management of diabetes in children and adolescents has important differences to adults (also discussed in Chapter 31), which should be addressed in specialised clinics with multidisciplinary input (Box 21.27). Some of the unique aspects of childhood type 1 diabetes management include changing insulin sensitivity related to sexual maturity and physical growth, unique vulnerability to hypoglycaemia (especially in children below 6 years of age) and DKA. Family dynamics, childcare and schooling, developmental stages and ability to self-care all have to be considered in the personalised management plan. In older children and adolescents, there may be issues of body image, eating disorders and recreational drug and alcohol use. Innovative models of education such as digital comics and gamification are emerging. It is also notable that there is very limited clinical research in children with diabetes and so most recommendations are based on expert opinion. The prevalence of type 2 diabetes in those below 20 years of age is increasing and is estimated to increase fourfold in the next 40 years.

Diabetes in hospital

People with diabetes account for around 20% of all hospital inpatients in the UK. The vast majority (around 9 out of 10) are admitted to hospital for a cause unrelated to diabetes or for a condition where diabetes may be a contributory factor (e.g. an acute cardiovascular event or elective surgery

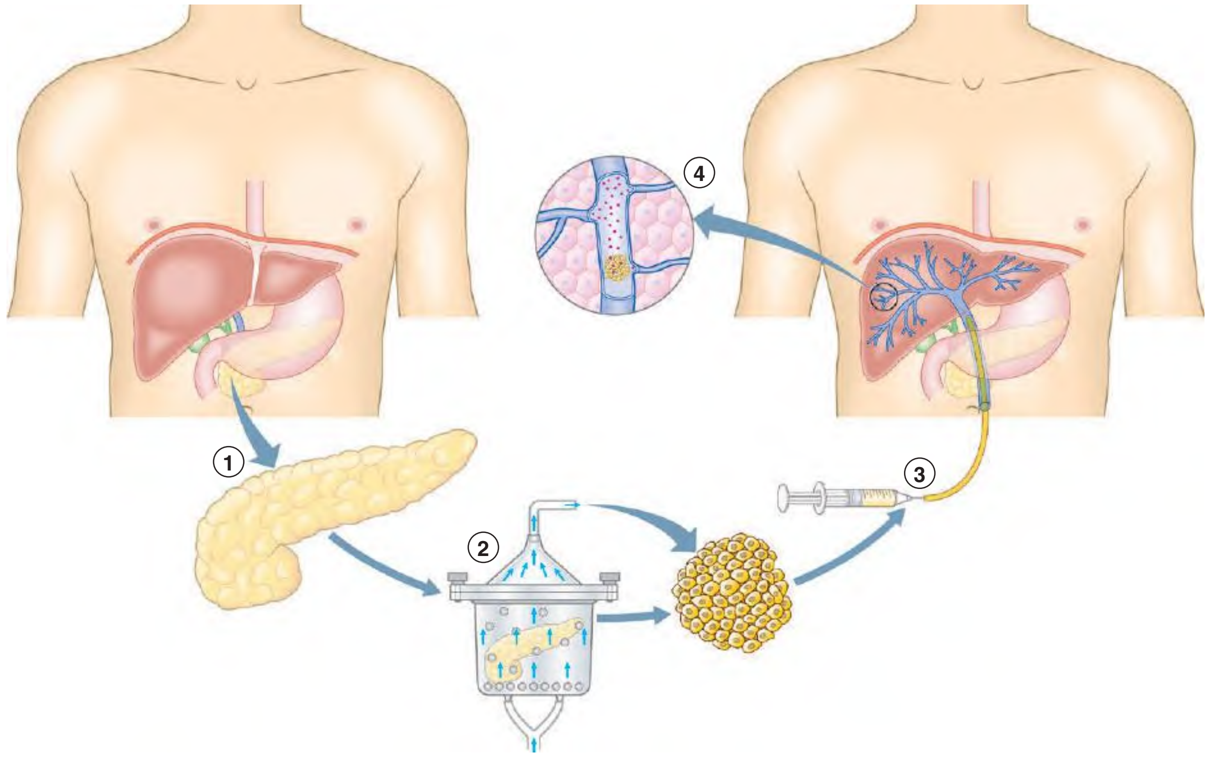

Fig. 21.30 Transplanting islet cells. (1) Pancreas obtained from suitable human donor. (2) Pancreatic islets containing insulin-producing β cells are isolated first in a Ricordi chamber. (3) Islets, once separated and purified, are infused into the hepatic portal vein. (4) Once embedded in the liver, pancreatic islets secrete insulin in response to changes in portal vein glucose.

21.27 Diabetes in adolescence

- **Type of diabetes**: type 1 diabetes is predominant in children and adolescents, but type 2 diabetes is now presenting in unprecedented numbers of obese, inactive teenagers. Monogenic diabetes (MODY) should also be considered (see Box 21.8).
- **Physiological changes**: hormonal, physical and lifestyle changes in puberty affect dietary intake, exercise patterns and sensitivity to insulin, necessitating alterations in insulin regimen.
- **Emotional changes**: adolescence is a phase of transition into independence (principally from parental care). Periods of rebellion against parental control, experimentation (e.g. with alcohol and recreational drugs) and a more chaotic lifestyle are common, and often impact adversely on control of diabetes.
- **Glycaemic control**: a temporary deterioration in control is common, although not universal. It is sometimes more important to maintain contact and engagement with a young person than to insist on tight glycaemic control.
- **Diabetic ketoacidosis**: a few adolescents and young adults present with frequent episodes of DKA, often because of suboptimal adherence to insulin therapy. This is more common in females. Precipitating factors include desire for weight loss, personality and even manipulation of family or schooling circumstances.
- **Adolescent diabetes clinics**: these challenges are best tackled with support from a specialised multidisciplinary team, including paediatricians, physicians, nurses and psychologists. Support is required for the patient and parents.

for cataract). Common causes for diabetes-specific admission include foot ulceration, DKA, HHS, newly diagnosed diabetes and hyperglycaemia. Any person with diabetes presenting to hospital acutely unwell should have a blood glucose measurement.

People with diabetes often report unhappiness with how their diabetes was managed during a hospital admission. Clearly admission to hospital disturbs an individual's usual daily routine, including the timings and types of meal being offered, and the amount of physical activity. Acute illness and surgery can cause blood glucose levels to rise and the individual may not be able to eat or drink for extended periods. Insulin and other glucose-lowering medication may be prescribed by relatively inexperienced residents or non-specialists and some people with diabetes report a feeling of 'loss of control' in the management of their condition. When the prescribed dose of insulin is different from what is considered appropriate by the person with diabetes, this should be discussed and handled sensitively with clear explanations for the rationale behind prescribing decisions. Through lived experience, the person with diabetes may well know more about their condition than the doctor.

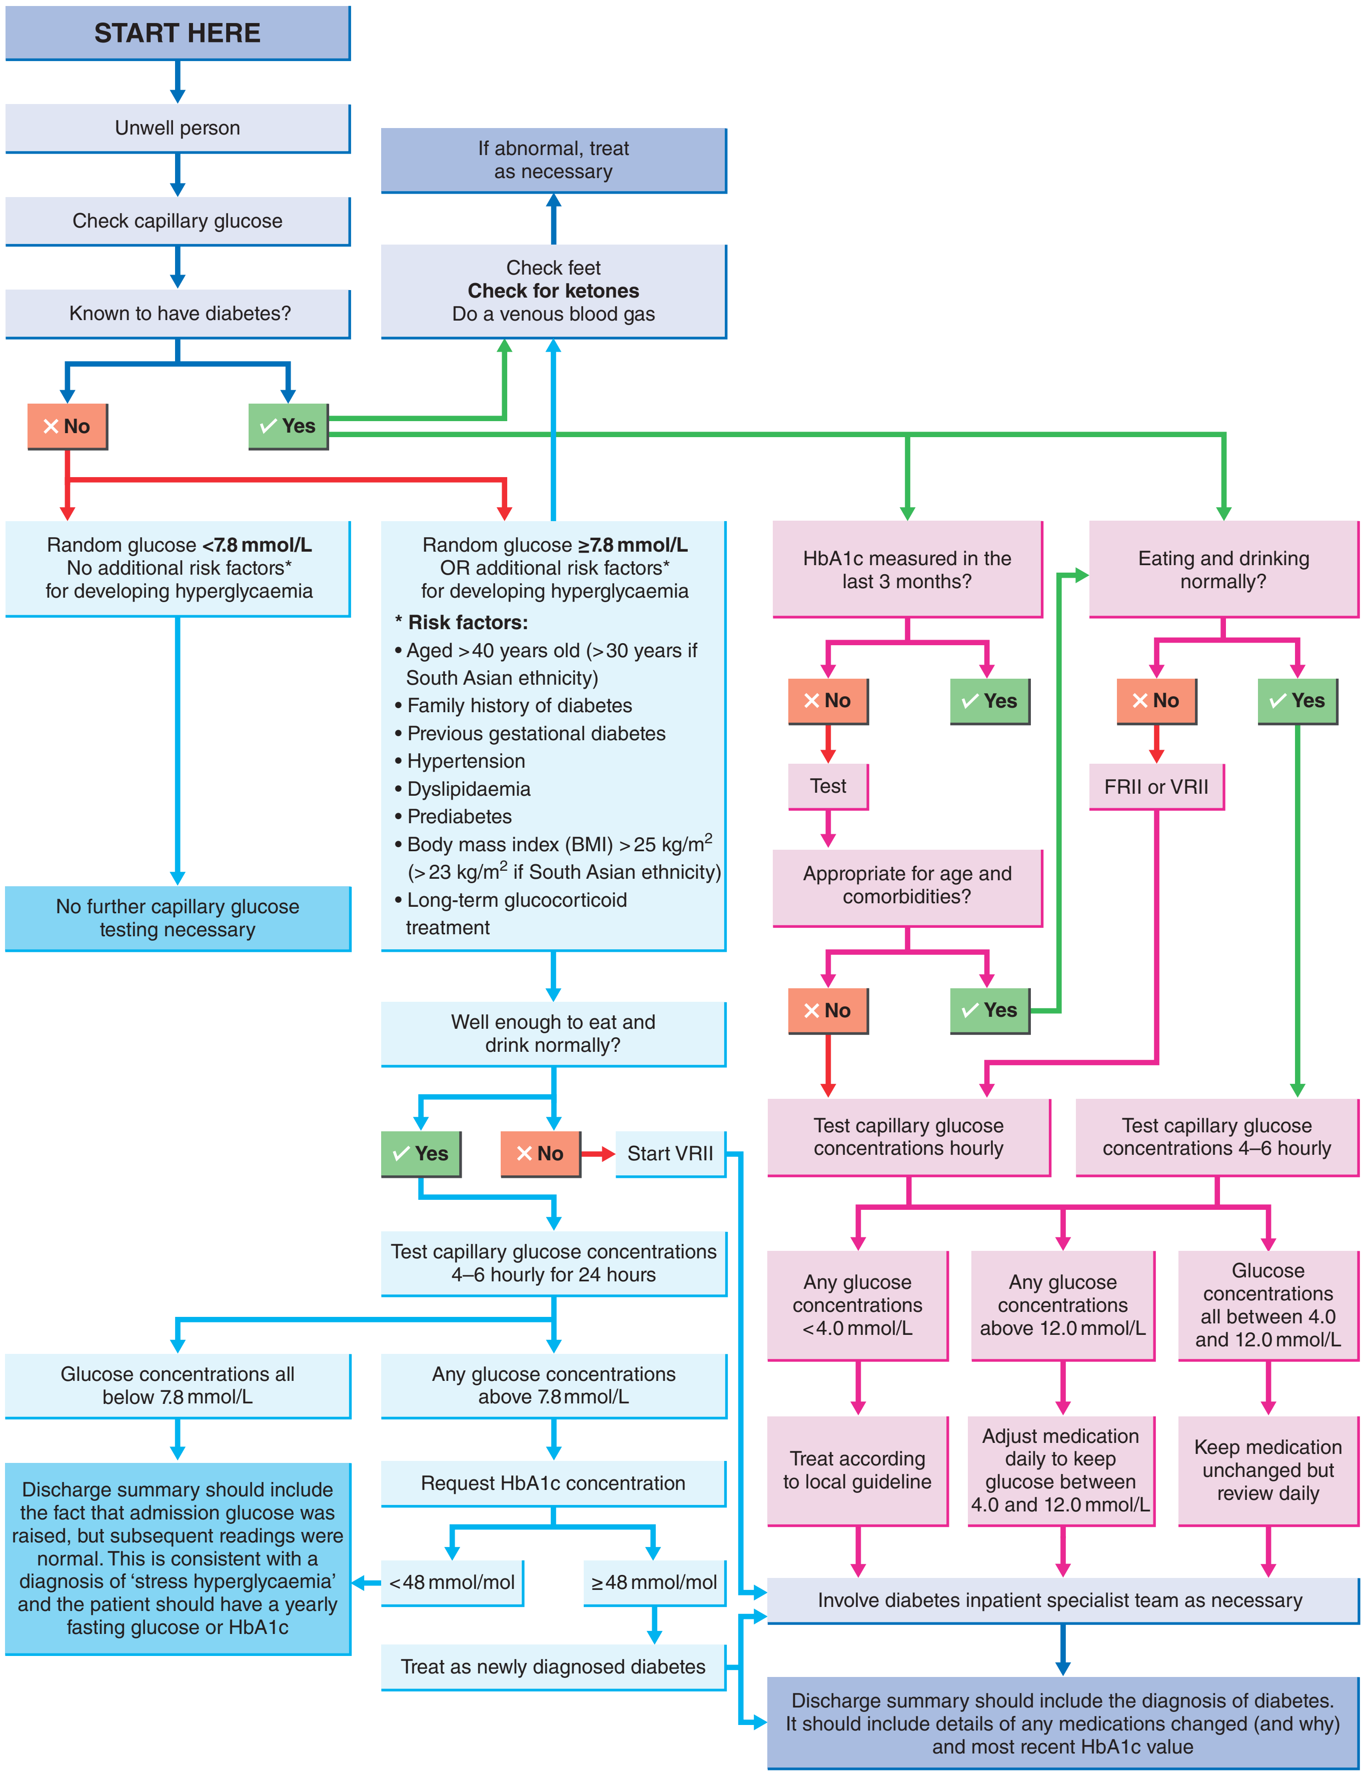
Errors in prescriptions of glucose-lowering therapies (especially insulin) are unfortunately common and may be due to lack of knowledge on the part of medical staff, inadvertent error due to time pressures or other human or system factors (see Ch. 1). It is important that medical staff are proactive in adjusting glucose-lowering therapy to avoid extreme glucose excursions. Hyperglycaemia and hypoglycaemia are not only unpleasant and potentially harmful but also associated with increased length of stay.

Hyperglycaemia in acute admissions to hospital

Hyperglycaemia is often found in patients who are admitted to hospital as an emergency. In most instances, this occurs in people with known diabetes, but it may also be due to undiagnosed diabetes or stress hyperglycaemia (see p. 763). An example of decision-making support around the management of hyperglycaemia on admission to hospital can be found in Figure 21.31.

Acute intercurrent illness causes catabolic stress and secretion of counter-regulatory hormones (including catecholamines and cortisol) in both normal and diabetic individuals. This results in increased glycogenolysis, gluconeogenesis, lipolysis, proteolysis and insulin resistance. Starvation exacerbates this process by increasing lipolysis. In a person without diabetes, these metabolic effects lead to a secondary increase in the secretion of insulin, which exerts a controlling influence. In people with untreated or poorly controlled diabetes, the uptake of metabolic substrate into tissues is significantly reduced because of insulin deficiency (relative or absolute), catabolism is increased and, ultimately, metabolic decompensation in the form of DKA or HHS may develop.

Hyperglycaemia on admission to hospital is associated with increased length of stay and increased mortality in a wide variety of acute medical



START HERE
Unwell person
Check capillary glucose
Known to have diabetes?
✗ No
✓ Yes
If abnormal, treat as necessary
Check feet
Check for ketones
Do a venous blood gas
Random glucose <7.8 mmol/L
No additional risk factors*
for developing hyperglycaemia
No further capillary glucose testing necessary
Random glucose ≥7.8 mmol/L
OR additional risk factors*
for developing hyperglycaemia
* Risk factors:
• Aged >40 years old (>30 years if South Asian ethnicity)
• Family history of diabetes
• Previous gestational diabetes
• Hypertension
• Dyslipidaemia
• Prediabetes
• Body mass index (BMI) >25 kg/m² (>23 kg/m² if South Asian ethnicity)
• Long-term glucocorticoid treatment
Well enough to eat and drink normally?
✓ Yes
✗ No
Start VRII
Test capillary glucose concentrations 4–6 hourly for 24 hours
Glucose concentrations all below 7.8 mmol/L
Any glucose concentrations above 7.8 mmol/L
Discharge summary should include the fact that admission glucose was raised, but subsequent readings were normal. This is consistent with a diagnosis of 'stress hyperglycaemia' and the patient should have a yearly fasting glucose or HbA1c
Request HbA1c concentration
<48 mmol/mol
≥48 mmol/mol
Treat as newly diagnosed diabetes
HbA1c measured in the last 3 months?
✗ No
✓ Yes
Test
Appropriate for age and comorbidities?
✗ No
✓ Yes
Eating and drinking normally?
✗ No
✓ Yes
FRII or VRII
Test capillary glucose concentrations hourly
Test capillary glucose concentrations 4–6 hourly
Any glucose concentrations <4.0 mmol/L
Any glucose concentrations above 12.0 mmol/L
Glucose concentrations all between 4.0 and 12.0 mmol/L
Treat according to local guideline
Adjust medication daily to keep glucose between 4.0 and 12.0 mmol/L
Keep medication unchanged but review daily
Involve diabetes inpatient specialist team as necessary
Discharge summary should include the diagnosis of diabetes. It should include details of any medications changed (and why) and most recent HbA1c value

Fig. 21.31 **Decision-making algorithm for an individual presenting to hospital with hyperglycaemia.** The target glucose of individuals with established diabetes is 6–10 mmol/L, but a range of 4–12 mmol/L is acceptable. (BMI = body mass index; FRII = fixed rate insulin infusion; VRII = variable rate insulin infusion) *Adapted from Joint British Diabetes Societies for Inpatient Care. Diabetes at the Front Door; 2023 abcd.care/sites/default/files/site_uploads/JBDS_Guidelines_Current/JBDS_16_Diabetes_at_the_Front_Door_Guideline_with_QR_code_May_2023.pdf.*

emergencies, including acute myocardial infarction and acute stroke. This may be a direct consequence of hyperglycaemia (perhaps through volume depletion from osmotic diuresis, electrolyte imbalance, a secondary pro-coagulant state and/or negative effects on the immune system) or simply a consequence that more severe illness (with a worse prognosis) causes greater degrees of hyperglycaemia. Intuitively, intensive glycaemic control with intravenous insulin should improve outcomes during acute illness. However, studies to date have shown that strategies aiming for near-normal blood glucose levels in acutely ill patients are associated with either increased mortality or no overall benefit. The reasons for the adverse outcomes are not established, but intensive glycaemic control is inevitably associated with an increased risk of hypoglycaemia, because of the inherent limitations even of modern insulins, the limited frequency of glucose monitoring in a ward environment and the relative imprecision of near-patient blood glucose meters. Activation of the sympathetic nervous system and release of counter-regulatory hormones during acute hypoglycaemia likely has deleterious consequences for the acutely ill patient. Therefore, a target blood glucose of between 6 and 10 mmol/L (105 and 180 mg/dL) with an acceptable range of 4–12 mmol/L (72–220 mg/dL) is recommended for inpatients with diabetes. Higher targets may be considered in frail individuals. VRII is sometimes used for uncontrolled hyperglycaemia in hospital.

Surgery and diabetes

People with diabetes are reported to have up to 50% higher peri-operative mortality than people without diabetes. Surgery has the same metabolic consequences, described above, as acute intercurrent illness. In addition, hyperglycaemia impairs wound healing and innate immunity, leading to increased risk of infection. People with diabetes are also more likely to have underlying pre-operative morbidity, especially cardiovascular disease. Finally, glycaemic management errors may cause dangerous hyperglycaemia or hypoglycaemia. Careful pre-operative assessment and peri-operative management are therefore essential, ideally with support from the diabetes specialist team.

Pre-operative assessment

Unless a surgical intervention is an emergency, people with diabetes should be assessed well in advance of surgery so that glycaemic control can be achieved and other risk factors can be addressed (Box 21.28). There is good evidence that a higher HbA1c is associated with adverse peri-operative outcome. In general, the upper limit for an acceptable HbA1c in this context is 69 mmol/mol (8.5%). However, since optimisation of care may take weeks or months to achieve, the potential benefits of improved glycaemia need to be weighed against the potential benefits for early surgical intervention.

Peri-operative management

Figure 21.32 outlines a general approach to peri-operative management of diabetes, although this may need to be adapted according to the individual, the surgical procedure and local guidelines, i.e. there is no ‘one size fits all' approach. Each individual should have a personalised diabetes management plan for their admission. People with diabetes who are considered low risk can attend as day cases or be admitted on the day of surgery. Occasionally, they may be admitted the night before surgery to ensure optimal management.

Post-operative management

People with diabetes who need to continue fasting after surgery should be maintained on a VRII until they are able to eat and drink. During this time, care must be taken with fluid balance and electrolyte levels; the ideal glucose range is 6–10 mmol/L (105–180 mg/dL), with an acceptable range of 4–12 mmol/L (72–220 mg/dL). Once usual glucose-lowering

21.28 Pre-operative assessment

- Consider delaying surgery and refer to the diabetes team if HbA1c > 69 mmol/mol; this should be weighed against the need for surgery
- Establish an **individualised diabetes management plan** for the pre-admission period (including optimisation if required) and peri-operative period (this will be determined by pre-operative glucose-lowering regimens – non-insulin and insulin therapies, glycaemic control and period of starvation (i.e. will the patient miss more than one meal?)
- Patients with high-risk feet (p. 796) should have suitable pressure relief provided during post-operative nursing
- Plan for the patient to be first on the list. This minimises the starvation period and thereby the need for VRII and length of inpatient stay

	Day before	Day of surgery
Once daily evening	↓dose 20%	No dose change
Once daily morning	↓dose 20%	↓dose 20%
Twice daily mixed insulin	No dose change	↓morning dose 50%
Multiple daily insulin	No dose change	Omit short-acting insulin ↓long-acting insulin 20%

Fig. 21.32 A suggested approach to the peri-operative management of diabetes. (DPP-4 = dipeptidyl peptidase 4; GLP-1 = glucagon-like peptide-1; SGLT2 = sodium-glucose co-transporter 2) *Adapted from Joint British Diabetes Societies for Inpatient Care. Management of adults with diabetes undergoing surgery and elective procedures: Improving standards. March 2016.*

treatment has been reinstated, good blood glucose control should be maintained to optimise wound healing and recovery.

Diabetes foot care in hospital

Diabetes foot disease is discussed in detail on p. 796. Between 2% and 3% of people with diabetes admitted to hospital develop a foot ulcer during the admission: many of these are avoidable. Pressure ulceration (due to prolonged contact between part of the foot, such as the heel, and a firm surface, such as a mattress) can occur due to prolonged immobility in a hospital bed and is associated with peripheral vascular disease, poor glycaemic control, malnourishment and dehydration. Delirium, dementia and peripheral neuropathy all increase the risk of developing pressure ulceration, because the individual does not recognise the sensation of abnormal heel pressure. The feet of all people with diabetes should be examined on admission to hospital. Those with feet 'vulnerable' for ulceration must be given protection for their feet. Individuals who are bed-bound should wear special 'foot protectors' – moulded plastic boots with padding that specifically redistribute pressure and off-load the heel areas as these are particularly susceptible to pressure ulceration. Pressure relief pads are also available that can be fitted to the end of a bed and are indicated for people with 'at risk' feet who are ambulant. If ulceration is identified on the initial foot assessment or occurs during admission (something that should be a 'never event'), then the patient should be immediately referred to the multidisciplinary diabetes foot team.

Complications of diabetes

Chronic hyperglycaemia causes irreversible damage over time to a number of tissues: particularly the small blood vessels of the retina (retinopathy), the glomerulus (nephropathy) and peripheral nerves (peripheral neuropathy) (Box 21.29). These so-called microvascular complications are amongst the commonest causes of visual loss, end-stage renal failure (dialysis) and foot ulceration (amputation) in most global populations and have a major adverse impact on quality of life. They are strongly linked to hyperglycaemia and increased duration of diabetes. Hyperglycaemia causes tissue damage via four main biochemical pathways: the polyol pathway, the hexosamine pathway, accumulation of advanced glycation end products and activation of protein kinase C. Each of these leads to overproduction of reactive oxygen species by the mitochondrial electron transport chain, giving rise to oxidative stress and tissue damage. The histopathological hallmark of diabetic microangiopathy is thickening of the capillary basement membrane, with associated increased vascular permeability. This occurs throughout the body resulting in the characteristic microvascular complications and accelerated atherosclerosis.

21.29 Complications of diabetes

Microvascular/neuropathic

Retinopathy, cataract
- Common cause of visual loss

Nephropathy
- Renal failure, requirement for dialysis

Peripheral neuropathy (foot disease)
- Sensory loss
- Pain
- Ulceration
- Charcot neuroarthropathy

Autonomic neuropathy
- Postural hypotension
- Gastroparesis
- Sexual dysfunction

Macrovascular

Coronary circulation
- Angina
- Acute coronary syndrome/myocardial infarction

Cerebral circulation
- Transient ischaemic attack
- Stroke

Peripheral circulation (foot disease)
- Claudication
- Ischaemia
- Ulceration

Infection
- Increased risk of certain infections, e.g. *Candida* spp., urine infection, fungal nail disease
- Increased risk of severe forms of infection, e.g. COVID-19, influenza, tuberculosis
- Increased risk of opportunistic infections, e.g. emphysematous pyelonephritis

Rheumatological complications
- Cheiroarthropathy, limited joint movement
- Dupuytren contracture
- Adhesive capsulitis
- Trigger finger

Skin complications
- Diabetic dermopathy
- Necrobiosis lipoidica
- Xerosis

In the 1990s over 20% of people with type 2 diabetes in the UK had evidence of microvascular complications at the time of diagnosis, but this rate has fallen dramatically in many countries (e.g. to as low as 1% in parts of Germany) with better awareness and screening in the community and consequently earlier diagnosis. Microvascular complications are strongly linked to long-term elevated blood glucose and individuals with long-term glycaemic control to target have a much lower risk of developing these complications.

Macrovascular complications are less closely linked to blood glucose, particularly in type 2 diabetes. In type 2 diabetes, insulin resistance is also directly and pathophysiologically linked with hypertension and dyslipidaemia (as part of the metabolic syndrome, each of which is also a risk factor for atherosclerosis). Thus, even individuals with impaired glucose tolerance (i.e. who do not have high enough blood glucose to be diagnosed with diabetes) already have an elevated risk of cardiovascular disease. Management of blood pressure and dyslipidaemia in diabetes are discussed briefly on p. 773), while the investigation and management of cardiovascular disease are discussed in detail in Chapters 16 and 27.

In addition to vascular complications, glycation of soft tissues and periarticular structures can cause a variety of rheumatological disorders, including diabetic cheiroarthropathy and adhesive capsulitis. Glycation and subsequent osmotic changes in the lens of the eye can cause reversibly reduced visual acuity at presentation of diabetes and can predispose to cataracts. Type 2 diabetes is associated with a twofold increased risk of dementia, with increased risk of both Alzheimer disease and vascular dementia. The mechanisms underpinning this association are complex and may involve factors such as micro- and macrovascular disease, abnormalities in insulin action in the brain and glycosylation of neuronal tissue.

Life expectancy/mortality

The life expectancy of people with type 2 diabetes in the UK is similar to that of the general population for those of higher socioeconomic status. However, those who are subject to social deprivation lose on average 4–5 years of life, even in countries where there is universal access to health care and free prescriptions. This gradient of life expectancy according to factors that are not classically 'biomedical' is more difficult to measure in countries that do not have universal health-care coverage, but is likely even steeper in those countries with an 'uninsured' section of the population.

Excess mortality in type 2 diabetes is caused mainly by cardiovascular disease, particularly myocardial infarction, stroke and cardiac failure. These and other manifestations of macrovascular disease (e.g. angina and intermittent claudication) also cause substantial morbidity. The pathological changes of atherosclerosis in type 2 diabetes are similar to those in non-diabetic individuals, but occur earlier in life and are more extensive and severe with the effects of associated major cardiovascular risk factors (smoking, hypertension and dyslipidaemia) amplified. Rates of mortality adjusted for age and socio-economic status are 38% higher in men and 49% higher in women with type 2 diabetes, mainly driven by cardiovascular disease. In the United States, hospitalisation rates for stroke are 1.5 times higher in adults with type 2 diabetes while 60% of non-traumatic amputations are in people with diabetes.

In type 1 diabetes, life expectancy is reduced on average by 11 years in men and 13 years in women. Under the age of 30 years, most deaths occur due to severe acute metabolic complications (DKA and hypoglycaemia). Cardiovascular disease accounts for almost as many deaths aged 30–39 years and predominates after the age of 40 years. Death may also be a consequence of renal failure caused by diabetic nephropathy. In addition, microvascular complications are responsible for substantial morbidity and disability: for example, blindness from diabetic retinopathy, lifestyle restrictions associated with renal dialysis, difficulty in walking and chronic ulceration of the feet from peripheral neuropathy, and bowel and bladder dysfunction from autonomic neuropathy.

Infections and diabetes

People with diabetes are at increased risk of infection and when such infections occur they may be more severe. Hyperglycaemia affects the function of key aspects of the cellular innate immune system, notably the function of neutrophils and monocytes/macrophages, with reduced chemotaxis, phagocytosis and killing of pathogens. Abnormalities in humoral immunity are also seen, such as reduced levels of complement proteins and cytokines, but the significance of this is less clear. Therefore, diabetes is in effect an immunocompromised state and, as a consequence, infections are more common and more likely to be caused by opportunistic pathogens, such as anaerobic organisms and fungi. In addition, microbes grow better in a high glucose environment and this may contribute to increased virulence. Finally, peripheral vascular disease and neuropathy, especially in the feet, predispose to skin ulceration. Breaks in the skin act as a portal for bacteria to enter the body and, if there is associated vascular disease, the reduced blood supply to the injured tissue impairs wound healing so there is reduced access for neutrophils and other components of the immune system to the damaged tissues. Individuals with glycaemic control above target (raised HbA1c) are at higher risk of infection and its consequences, although risk remains increased in all people with diabetes.

Urogenital, skin and soft tissue infections

As already noted, one of the commonest sites of infection in people with diabetes is the urogenital system. Genital infections, especially from yeasts such as *Candida* species, causing balanitis in men and vulvovaginitis in women, are common at diagnosis of diabetes, in those taking SGLT2 inhibitors and in individuals with poor glycaemic control. Urine infections, including pyelonephritis, are also more common in people with diabetes and may progress to sepsis and acute kidney injury; rarely, even more serious forms of pyelonephritis can occur in which gas is formed in the renal parenchyma (emphysematous pyelonephritis).

Fungal nail infections and infections of skin and soft tissues are also more prevalent in people with diabetes. Skin and soft tissue infections, e.g. cellulitis, abscesses and boils, are usually caused by *Staphylococcus aureus* or β-haemolytic streptococci, as in non-diabetic patients. However, people with diabetes are more likely to experience polymicrobial and anaerobic infections, such as necrotising fasciitis, gas gangrene and synergistic gangrene (including Fournier gangrene of genital and perineal skin), presumably because of the combination of relative immunosuppression and poor tissue perfusion (p. 306).

Bone and joint infection

Approximately 30% of all cases of osteomyelitis are associated with diabetes (see Ch. 25). The most commonly affected sites are the bones of the feet, because of the strong association with peripheral neuropathy, peripheral vascular disease and foot ulceration. Osteomyelitis may occur as a primary consequence of a puncture injury (which has introduced microbes into the wound) or secondary to a long-term skin ulcer or other breach in the skin. Approximately 90% of cases of diabetic foot osteomyelitis occur in the forefoot, with approximately 5% of cases in the mid- and hindfoot, respectively. Osteomyelitis results in destruction of the bone and potentially adjacent joints. It can present as an acute infection, but more commonly is a chronic, insidious infection that progressively worsens.

The clinical features of osteomyelitis in people with diabetes often appear non-severe and may be more suggestive of a soft tissue infection than bone infection. The diagnosis may, therefore, be delayed unless clinicians have a low threshold for suspecting osteomyelitis and carrying out appropriate investigations. Larger ulcers (> 2 cm) and deeper ulcers (> 3 mm) are associated with an increased risk of osteomyelitis, as is the presence of visible bone in the wound or bone that can be probed. However, none of these signs are diagnostic for osteomyelitis. Plain X-rays are insensitive, especially in milder infections, only showing features of osteomyelitis if more than 30%–50% of bone is lost. MRI and bone scintigraphy have higher sensitivity. Although *Staphylococcus aureus* is most commonly involved, gram-negative and anaerobic organisms can also be detected. Wound swabs are usually unhelpful, because of contamination from organisms on the skin that are not involved in the bone infection; the most useful microbiological data comes if a bone fragment can be obtained for culture. Osteomyelitis is particularly difficult to treat because many antibiotics do not reach adequate concentrations in bone. Primary antibiotic therapy can be used in milder infections, though often a prolonged course of antibiotics (of many weeks and months) is required. Surgical débridement of infected soft tissue and bone is often required and can reduce the need for amputation. However, osteomyelitis, particularly in the hindfoot, is associated with a poor prognosis and a very high risk of below-knee amputation (~50%).

Septic arthritis and discitis are also more common in people with diabetes, either as a consequence of a direct puncture injury, haematogenous spread from an infection elsewhere or direct spread from an adjacent area of osteomyelitis. *Staphylococcus aureus* is the most commonly implicated organism in both instances: investigation and management are discussed on pages 1050 and 1051.

COVID-19

Severe infection with SARS-CoV-2, i.e. that resulting in death and/or admission to a critical care unit, is much more common in people with diabetes. Precise estimates of the increased risk vary, but people with type 1 diabetes are at approximately 2.5–3.5 times increased risk, while people with type 2 diabetes are at 1.5–2.0 times increased risk. There is a strong association with glycaemic control, such that those individuals with chronically elevated blood glucose are at the highest risk.

Diabetic eye disease

Diabetic retinopathy and diabetic maculopathy are together the most common causes of visual impairment and loss in many countries. The pathogenesis, clinical features and management of diabetic retinopathy and other eye conditions (including cataract) relevant to diabetes are described in Chapter 28.

Diabetic kidney disease

Diabetes is the most common cause of end-stage renal disease globally, and approximately 40% of people requiring renal replacement therapy (i.e. dialysis or transplantation) have diabetes. Kidney disease in types 1 and

2 diabetes can be caused by diabetic nephropathy. The pathophysiology underlying diabetic nephropathy is not fully understood, but is strongly related to hyperglycaemia. A key molecule is transforming growth factor β, which upregulates flux of glucose into renal cells and activates the renin–angiotensin system leading to renal inflammation and fibrosis.

The classical pattern of progression of diabetic nephropathy is shown schematically in Figure 21.33. Initially there is hyperfiltration in the glomeruli, then onset of microalbuminuria due to damage (and thickening) of the glomerular basement membrane causing leaking of protein, which can then progress to frank (dipstick-positive) proteinuria. Matrix material also accumulates in the mesangium and, as disease advances, nodular deposits form in the glomeruli ('focal' glomerulosclerosis; Fig. 21.34). As glomeruli are progressively lost, renal function deteriorates, which manifests as a declining glomerular filtration rate and chronic kidney disease (CKD).

About 30% of individuals with type 1 diabetes develop diabetic nephropathy from 10–20 years after diagnosis but the incidence after this time falls to less than 1% per year. Some individuals with long-standing hyperglycaemia do not develop nephropathy, suggesting the presence of as-yet-undiscovered protective (potentially genetic) factors. The risk of nephropathy in populations of European descent with type 2 diabetes is similar to that with type 1 diabetes, but is much higher in some ethnic groups (e.g. African Caribbeans, South Asians and Japanese).

It should be noted that CKD in people with diabetes is often caused (or exacerbated) by other coexisting conditions (comorbidities) to which people with diabetes are predisposed (Box 21.30); hence, not all will have evidence of albuminuria or proteinuria.

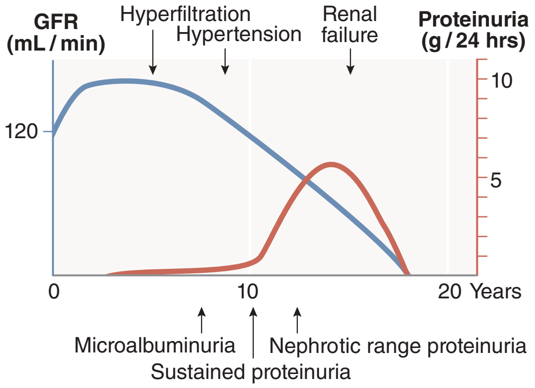


Fig. 21.33 Natural history of diabetic nephropathy. In the first few years of type 1 diabetes mellitus, there is hyperfiltration; thereafter, glomerular filtration rate declines fairly steadily to return to a normal value at approximately 10 years (blue line). In susceptible patients (about 30%), there is sustained proteinuria after about 10 years and by approximately 14 years this has reached the nephrotic range (red line).

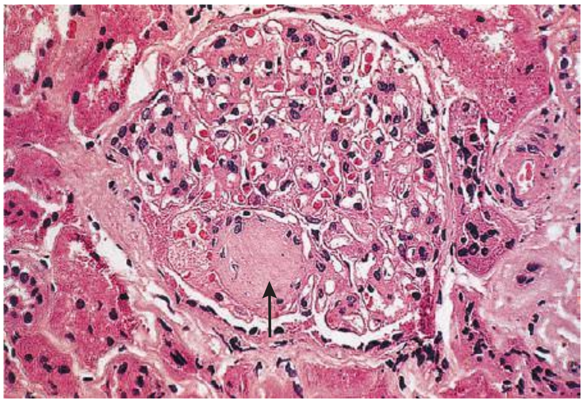

Fig. 21.34 Nodular diabetic glomerulosclerosis. There is thickening of basement membranes, mesangial expansion and a Kimmelstiel–Wilson nodule (arrow), which is pathognomonic of diabetic kidney disease.

With improved standards of care focusing on glycaemic control and more widespread use of blood pressure–lowering medication targeting the renin–angiotensin system, the proportion of people with diabetes and CKD is reducing. However, due to the global rise in the incidence of type 2 diabetes, the absolute number of people with diabetes and end-stage renal failure continues to rise.

Diagnosis and screening

Urine should be tested for microalbuminuria and a blood test sent for estimated glomerular filtration rate (eGFR) on an annual basis in all adults with diabetes. CKD in diabetes is defined using criteria listed in Box 18.3. Microalbuminuria is the presence in the urine of small amounts of albumin at a concentration below that detectable using a standard urine dipstick. As the measurement is physiologically variable, a single measurement is not considered informative: it should be confirmed as present in at least two of three 'first-morning' specimens taken on separate days (Box 21.31). Microalbuminuria is usually reported as a proportion of the concentration or weight of creatinine present in the sample (mg/mmol or mg/g) to reduce variability, with the threshold for diagnosis higher in women (see Box 18.9). Overt nephropathy is the presence of macroalbuminuria equivalent to the level of protein detectable on a standard urine dipstick. Microalbuminuria is a good predictor of progression to nephropathy in type 1 diabetes and an indication for ACE inhibitor or angiotensin II receptor blocker (ARB) therapy to protect the kidneys. It is also a risk marker for macrovascular disease, especially in type 2 diabetes.

Management

Establishing the presence of microalbuminuria should prompt vigorous efforts to reduce the risk of progression to nephropathy (and to protect against cardiovascular disease) by:

- control of blood pressure
- reduction of cardiovascular risk factors
- optimisation of glycaemic control.

Blockade of the renin–angiotensin system using either ACE inhibitors or ARBs has been shown to have an additional benefit over similar levels of blood pressure control achieved with other antihypertensive agents and is recommended as first-line therapy. This relieves angiotensin II–mediated vasoconstriction of efferent arterioles downstream from the glomerular capillary tuft (see Fig. 18.1D), decreasing glomerular filtration pressure and, therefore, hyperfiltration and protein leak. Electrolytes and renal function should be checked after initiation or dose increase of these agents as they can cause a marked deterioration in renal function if there is occult stenosis of the main renal artery, i.e. when adequate intraglomerular pressure is critically dependent on efferent arteriolar tone. There is no additional benefit of combining agents from these two classes. However, addition of other antihypertensive agents is required to achieve target BP control in many cases, e.g. calcium channel blockers, diuretics and α-adrenoceptor antagonists (α-blockers).

Halving the amount of albuminuria with an ACE inhibitor or ARB results in a nearly 50% reduction in long-term risk of progression to end-stage renal disease and requirement for renal replacement therapy, often in the form of haemodialysis (p. 634). SGLT2 inhibitor therapy in people with type 2 diabetes, overt proteinuria (>300 mg/day) and eGFR >30 mL/min/1.73 m^2 reduces the risk of progression to end-stage kidney disease by approximately 30%. SGLT2 inhibitor therapy also reduces cardiovascular events in people with CKD and is rapidly becoming a standard of care as an add-on to ACE inhibitor or ARB therapy.

Renal transplantation is indicated for people with end-stage kidney disease, who are fit enough to undergo the procedure; it dramatically improves lives of organ recipients (see Ch. 18). Simultaneous pancreas transplantation should be performed, where possible, in people with type 1 diabetes. Anti-rejection immunosuppression carries risks and

21.30 Causes of CKD in diabetes

	Cause	Mechanism/Description
Diabetes-related	Hyperglycaemia	Diabetic nephropathy – chronic high blood glucose damages renal blood vessels, glomeruli and tubular structures
	Glomerular hyperfiltration	Early over-filtration causes glomerular damage and accelerates CKD progression
	Advanced glycation end products (AGEs)	AGEs promote oxidative stress, inflammation and fibrosis, contributing to renal damage
	Activation of renin–angiotensin–aldosterone system (RAAS)	Over-activation of RAAS promotes inflammation, vasoconstriction and fibrosis
Comorbidity-related		
• **Acute**	Acute kidney injury	Episodes increase the risk of CKD in people with diabetes
	Urinary tract infections or sepsis	As above, particularly in context of hyperglycaemia
• **Long-term (atherosclerosis related)**	Hypertension	Increased pressure damages kidney blood vessels leading to renal vascular disease with worsening of CKD progression
	Obesity	Increases renal workload and worsens insulin resistance and inflammation
	Dyslipidaemia	Elevated LDL and triglycerides cause glomerular injury and promote atherosclerosis, inflammation and fibrosis
	Chronic inflammation	Leads to fibrosis and scarring of kidney structures
Medication/Iatrogenic	NSAIDS, aspirin	Inhibition of prostaglandin production reduces blood flow
	ACE inhibitors	Inhibition of angiotensin II production can decrease glomerular blood flow in the presence of atherosclerotic renal vascular disease (by causing vasodilation of efferent arteriole)
	Radiological contrast agents	Idiosyncratic reaction
Lifestyle factors	High sodium diet	Aggravates hypertension and fluid overload
	Sedentary	Increases risk of obesity, hypertension and dyslipidaemia
	Smoking	Causes oxidative stress, endothelial dysfunction and reduced renal blood flow

(ACE = angiotensin-converting enzyme; AGE = advanced glycation end product; CKD = chronic kidney disease; LDL = low-density lipoprotein; NSAIDs = non-steroidal anti-inflammatory drugs; RAAS = renin-angiotensin-aldosterone system)

21.31 Screening for microalbuminuria

- Early morning urine is measured for the albumin:creatinine ratio (ACR)
- Microalbuminuria is present if:
  Male: ACR 2.5–30 mg/mmol creatinine or 25–300 mg/g
  Female: ACR 3.5–30 mg/mmol creatinine or 35–300 mg/g
- An elevated ACR should be followed by a repeat test:
  There is established microalbuminuria if 2 out of 3 tests are positive
- Proteinuria (overt or dipstick-positive nephropathy) is likely to be present if ACR > 30 mg/mmol
  This is confirmed by a protein:creatinine ratio (PCR) of > 45 mg/mmol
  Nephrotic range proteinuria is present when PCR > 300 mg/mmol

requires careful monitoring. Recurrence of diabetic nephropathy in the transplanted organ (allograft) is usually too slow to be a serious problem, although other complications may continue to progress.

Metabolic dysfunction–associated steatotic liver disease (MASLD)

Central obesity is common in people with type 2 diabetes and has a potent effect on hepatic insulin sensitivity due to venous drainage of visceral adipose tissue into the portal vein. Fat accumulation in the liver (steatosis) has adverse effects on hepatic glucose and lipid metabolism and can progress in a proportion of cases (about 20%) to inflammation, fibrosis and cirrhosis, termed ‘metabolic dysfunction–associated steatohepatitis (MASH)’. Due to the increasing prevalence of obesity and diabetes, metabolic liver disease is now more common than alcoholic liver disease, with an estimated worldwide prevalence of 20%. There is, therefore, an increasing focus on monitoring liver function tests in people with type 2 diabetes and referral on for liver imaging for diagnosis (see Ch. 23).

Diabetic neuropathy

Diabetic neuropathy causes substantial morbidity, particularly due to foot ulceration. It is diagnosed on the basis of symptoms and signs after the exclusion of other causes of neuropathy (see Ch. 27). It is more common with increased duration of either type 1 or 2 diabetes. The most common type is a ‘polyneuropathy’ (i.e. evidence that more than one type of nerve fibre is affected). About 25%–30% of adults have evidence of neuropathy 10–15 years on from diagnosis and about half of these have painful diabetic neuropathy (PDN). Like retinopathy, neuropathy occurs secondary to hyperglycaemia and is related to duration of diabetes. Motor, sensory and autonomic nerves may be involved in varying combinations.

Pathological features can occur in any peripheral nerves. They include axonal degeneration of both myelinated and unmyelinated fibres, with thickening of the Schwann cell basal lamina, patchy segmental demyelination and abnormal intraneural capillaries (with basement membrane thickening and microthrombi).

Clinical features

Symmetrical sensory polyneuropathy

This is the commonest type of diabetic neuropathy and is a diffuse, small-fibre neuropathy that is, at least initially, frequently asymptomatic. There is impairment, in a ‘glove and stocking’ distribution, of all modalities of sensation including diminished vibration sensation (Fig. 21.35). Symptoms may include paraesthesiae in the feet, sharp pain in the lower limbs (worse at night and felt mainly on the anterior aspect of the legs), burning sensations in the soles of the feet and cutaneous hyperaesthesia. As the condition advances, weakness and atrophy of the interosseous muscles may develop leading to structural changes in the foot with loss of lateral and transverse arches, clawing of the toes and exposure of the metatarsal heads. This results in increased pressure on the plantar aspects of the metatarsal heads, with hard ‘callus’ skin at these and other pressure points, leading to ulceration and even Charcot neuroarthropathy (see below).

In practice, loss of sensation to a 10 g monofilament provides evidence of increased risk and requirement for increased foot care (e.g. regular foot inspection, care from podiatry, attention to appropriate footwear). When diagnosis is uncertain, formal electrophysiological tests (p. 1161) may be performed demonstrating slowing of both motor and sensory conduction as well as abnormal vibration sensitivity and thermal thresholds.

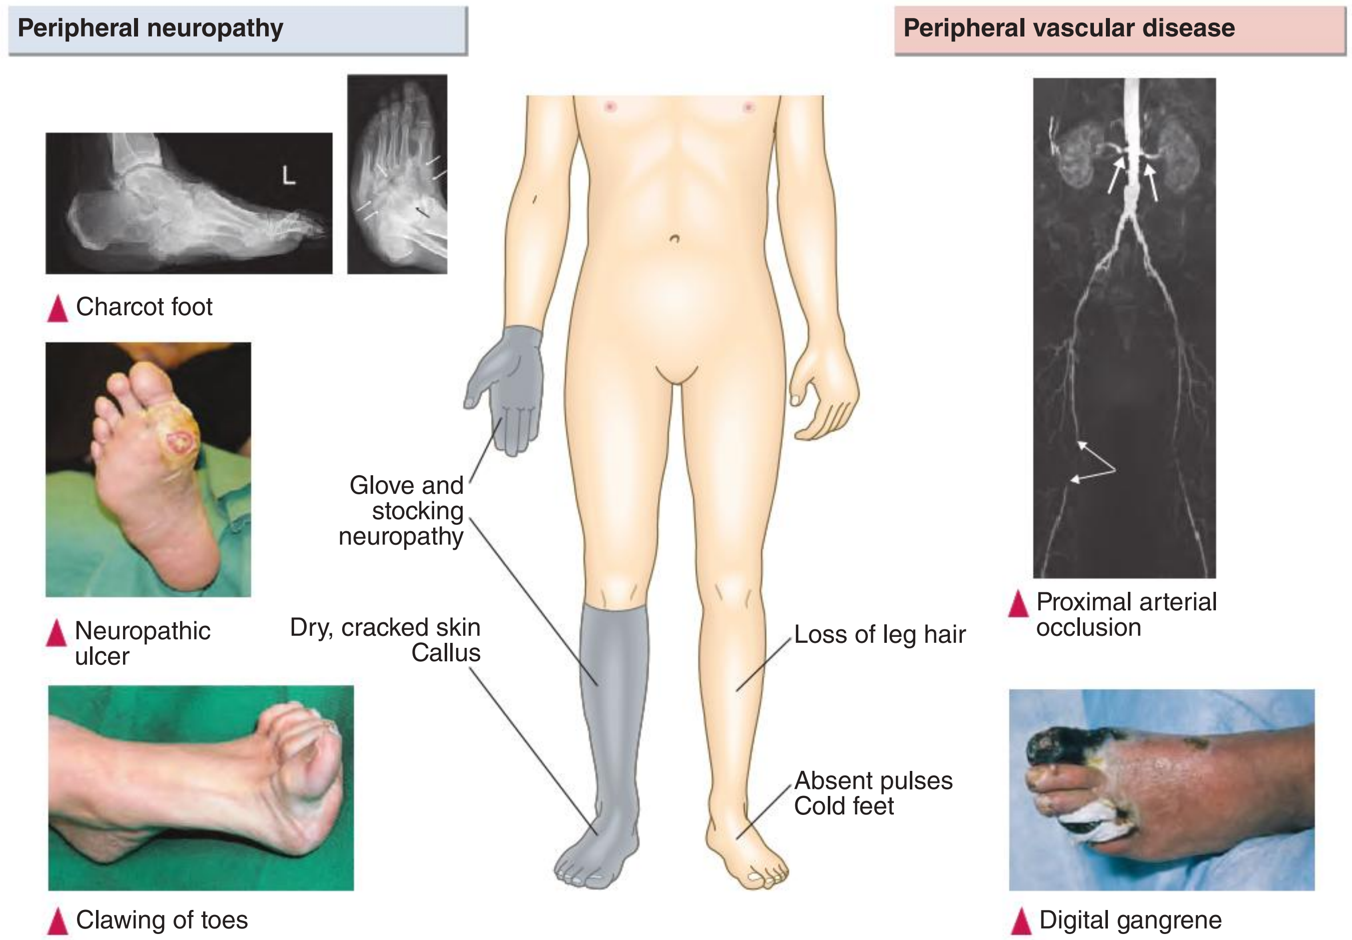

Fig. 21.35 Diabetic foot disease. Patients with diabetes can have neuropathy, peripheral vascular disease or both. Clawing of the toes is thought to be caused by intrinsic muscle atrophy and subsequent imbalance of muscle function, and causes greater pressure on the metatarsal heads and pressure on flexed toes, leading to increased callus and risk of ulceration. A Charcot foot occurs only in the presence of neuropathy, and results in bony destruction and ultimately deformity (the anteroposterior and lateral X-rays show destruction and disorganisation of the tarsal bones (arrows)). The MRI angiogram demonstrates diffuse arterial atherosclerotic disease including bilateral renal artery stenosis (thick white arrows) and short segment right distal superficial femoral artery occlusion (thin white arrows).

Asymmetrical motor diabetic neuropathy (diabetic amyotrophy)

This is much less common; it presents as severe, progressive weakness and wasting of the proximal muscles of the lower limbs. It is accompanied by severe pain, felt mainly on the anterior aspect of the leg, hyperaesthesia and paraesthesiae. This condition is thought to involve acute infarction of the lower motor neurons of the lumbosacral plexus. Partial recovery usually occurs within 12 months; management is supportive.

Mononeuropathy

Mononeuropathies of a single sensory or motor, peripheral or cranial nerve are rare, but more often affect people with diabetes. The nerves most likely to be affected are the 6th and 3rd cranial nerves (resulting in diplopia), the 7th cranial nerve (resulting in Bell palsy) and the femoral and sciatic nerves. The mononeuropathy is usually severe and of rapid onset, but eventually recovers. Nerve compression palsies are more common in diabetes, e.g. the median nerve, resulting in carpal tunnel syndrome, and less commonly, the ulnar nerve. Compression palsies may be a consequence of glycation and thickening of connective tissue and/or diabetic microangiopathy.

Autonomic neuropathy

This may occur independently of other types of neuropathy. It is less clearly associated with glycaemic control and improving control does not usually relieve the symptoms. Parasympathetic or sympathetic nerves may be predominantly affected. Common symptoms include dizziness, nausea and vomiting, post-gustatory sweating, difficulty with micturition, and diarrhoea/faecal incontinence. A postural drop may be detected on lying and standing BP measurement with a resting tachycardia. Pupils may be pinpoint.

Formal testing is rarely performed but involves the Ewing tests, which screen for evidence of lack of heart rate variability in response to manoeuvres designed to alter the activity of the autonomic nerve system (Valsalva manoeuvre, deep breathing, sustained handgrip).

Support stockings and fludrocortisone therapy may be helpful for symptoms of postural hypotension. Due to the risk of sudden cardiorespiratory arrest, there is only 50%–70% survival within 10 years of developing overt autonomic neuropathy. Fortunately, severe cases are infrequent.

Gastroparesis This is one of the most disabling complications of diabetes. It usually affects people with type 1 diabetes. Following exclusion of mechanical forms of obstruction (by upper gastrointestinal endoscopy), delayed gastric emptying is demonstrated using scintigraphy following a technetium-99m (^{99m}Tc)-labelled standard meal. Gastroparesis is a prominent feature of severe autonomic neuropathy, but can also occur secondary to a coexistent primary eating disorder. The main symptoms (the severity of which tend to wax and wane) are nausea and vomiting (especially of undigested food), abdominal pain and a feeling of fullness/early satiety. It can contribute to increased variability in blood glucose, as there can be a mismatch between the delayed rise in post-prandial glucose and the time–action profile of injected insulin.

Improving quality of life and achieving glycaemic control is difficult. Low-fibre and low-residue diets may be tried, as well as eating smaller amounts more frequently. Prokinetic dopamine antagonist antiemetics (metoclopramide, domperidone) are often prescribed in an effort to accelerate gastric emptying, but are not recommended for long-term use due to adverse effects. For individuals on MDI, rapid-acting insulin may be better taken after rather than before a meal and CSII is beneficial for some. There may be frequent hospital admissions during ‘flare-ups.’ A ‘gastric pacemaker’ device is of benefit in some cases; others may benefit from endoscopic injection of botulinum toxin into the gastric pylorus (to increase gastric emptying). Enteral nutrition is rarely required unless gastroparesis is very severe.

Sexual dysfunction Men with type 2 diabetes are 30% more likely than non-diabetic men to have erectile dysfunction, rising to 70% with more than 20 years’ duration of diabetes. In type 1 diabetes, the risk of erectile dysfunction is elevated threefold. This is mainly due to autonomic neuropathy and vascular disease (cavernosal microangiopathy). The approach to treatment options is as for non-diabetic men (for further information, see p. 653). Women with diabetes also have higher rates of sexual dysfunction, including vaginal dryness, dyspareunia and increased susceptibility to urinary tract infections.

Management

Tricyclic antidepressants (low-dose amitriptyline, duloxetine) and anticonvulsants (pregabalin, gabapentin) – combined if necessary with opiate analgesia (tramadol, oxycodone) – can improve quality of life in PDN. Management of other forms of neuropathy is shown in Box 21.32.

Diabetic foot disease

The feet are especially vulnerable in diabetes as there may be loss of protective sensation (due to neuropathy), inadequate blood supply (due to small and large blood vessel disease) or both. For this reason foot care is particularly important. Foot ulceration and associated complications are the most common reasons for prolonged hospital admission for people with diabetes. Risk factors include age, male sex, smoking, higher systolic BP, HbA1c, socio-economic deprivation and the presence of multiple long-term conditions.

i 21.32 Management options for peripheral sensorimotor and autonomic neuropathies

Pain and paraesthesiae from peripheral somatic neuropathies

- Insulin therapy (intensive glycaemic control)
- Anticonvulsants (gabapentin, pregabalin)
- Tricyclic antidepressants (low-dose amitriptyline, imipramine)
- Other antidepressants (duloxetine)
- Substance P depleter (capsaicin – topical)
- Opiates (tramadol, oxycodone)
- Antioxidant α-lipoic acid

Postural hypotension

- Support stockings
- Fludrocortisone
- Midodrine

Gastroparesis

- Dopamine antagonists (metoclopramide, domperidone)*
- Erythromycin
- Botulinum toxin (endoscopic injection into pylorus)
- Gastric pacemaker; percutaneous enteral (jejunal) feeding (see Fig. 5.11)

Diarrhoea (Ch. 22)

- Loperamide
- Rifaximin (for suspected bacterial overgrowth)

Constipation

- Stimulant laxatives (senna)

Excessive sweating

- Anticholinergic drugs (propantheline, poldine, oxybutynin)
- Clonidine
- Topical antimuscarinic agent (glycopyrrolate cream)

Erectile dysfunction (p. 653)

- Phosphodiesterase type 5 inhibitors (sildenafil, vardenafil, tadalafil) – oral
- Dopamine agonist (apomorphine) – sublingual
- Prostaglandin E_1 (alprostadil) – injected into corpus cavernosum or intra-urethral administration of pellets
- Vacuum tumescence devices
- Implanted penile prosthesis
- Psychological counselling; psychosexual therapy

*Not licensed for long-term use due to risk of dystonia.

Aetiology

In a vulnerable foot, ulceration is initiated by (often minor) trauma (Fig. 21.35). Disruption of the protective epidermis then permits infection, particularly in the presence of hyperglycaemia. Most ulcers develop at the site of a plaque of callus skin, which has developed on a ‘pressure point’ typically on the plantar aspect of the foot, on the metatarsal heads or the tips of clawed toes. The majority of foot ulcers are neuropathic or neuroischaemic. Neuroischaemic ulcers classically occur on the margins of the foot as they are often precipitated by compression of the foot by ill-fitting shoes. Hence, they are seen over the medial aspect of the first metatarsophalangeal joint, the styloid process of the 5th metatarsal and the tips of the toes.

Management

Systematic annual screening to estimate and record risk of foot ulceration in order to ensure appropriate access to podiatry has been shown to reduce rates of ulceration and amputation. Two simple tests are required to grade risk according to a ‘traffic light’ system (Fig. 21.36): a 10 g monofilament should be used to assess sensation at five points on each foot and foot pulses should be palpated (dorsalis pedis and/or posterior tibial).

- Green: People with normal protective sensation and palpable pulses are at ‘low risk’ and can be educated and reassured regarding foot care until next screening (Box 21.33).
- Amber: Those who have reduction or loss of sensation to monofilament, or in whom no pulse can be palpated in at least one foot, are at ‘moderate’ risk. Assessment and development of a care plan by a trained podiatrist is recommended when first identified, and annual screening thereafter. Regular support with foot care may be offered. Well-fitting footwear is essential.
- Red: As for amber, but there is both reduced sensation and absent pulses in at least one foot or callus/structural foot deformity in the presence of either reduced sensation or absent pulses. Assessment and treatment by a specialist podiatrist is required. Orthotic footwear may be recommended.

People with diabetes and their relatives or carers can easily learn to use the Ipswich Touch Test to screen for neuropathy: this involves lightly and briefly (for 1–2 seconds) touching the tips of the first, third and fifth toes of both feet with the index finger: an abnormal result is when touch cannot be felt on two or more toes.

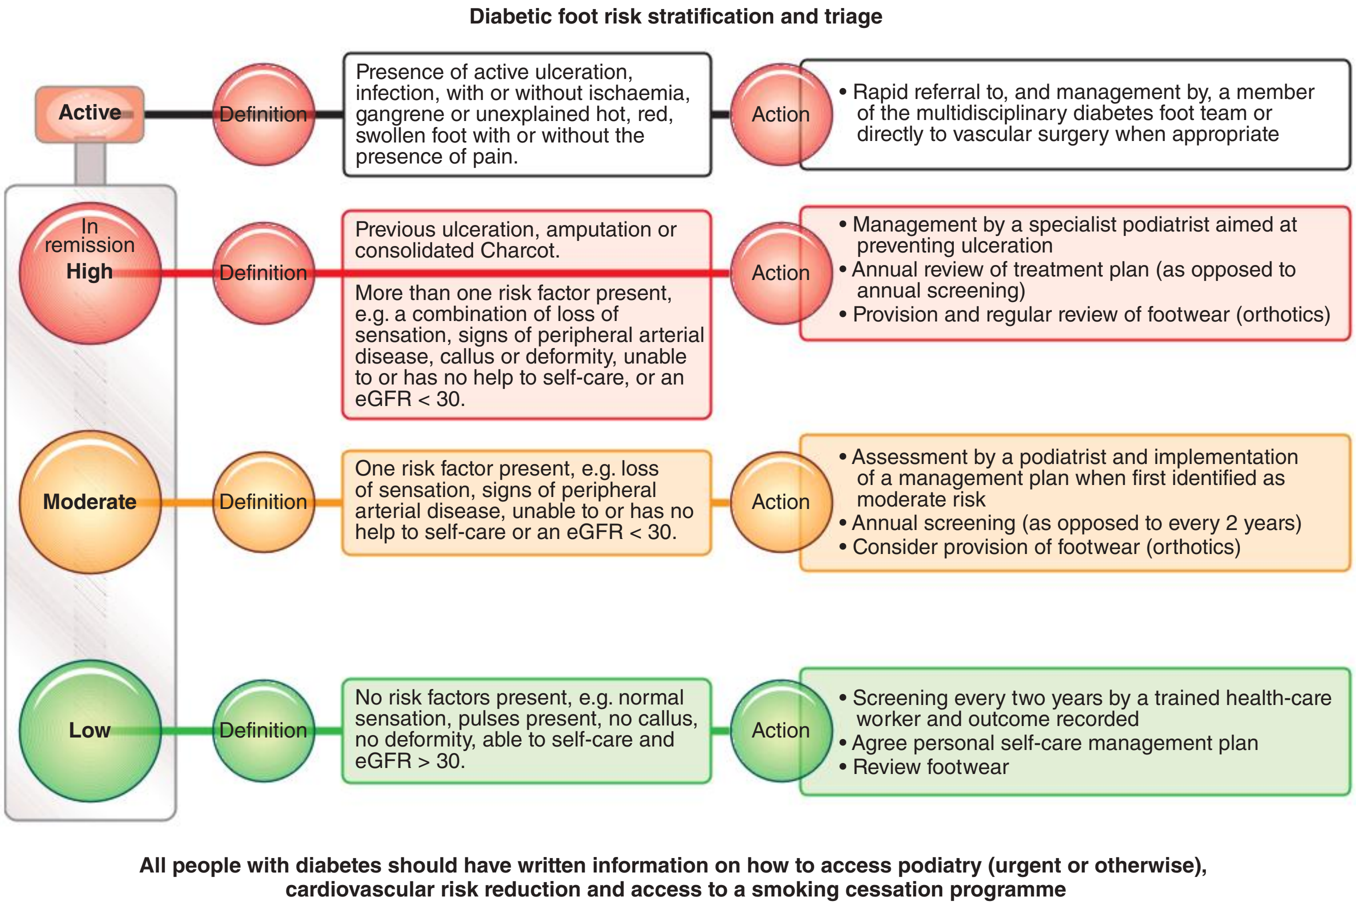
Foot ulceration

People with a foot ulcer require urgent assessment by a multidisciplinary foot team, involving a diabetes specialist, a podiatrist, a vascular surgeon and an orthotist.

Management involves:

- débridement of necrotic tissue
- antibiotic therapy (may be prolonged as infection can accelerate tissue necrosis and lead to gangrene)
- pressure relief (depending on site, severity and stage of healing): customised insoles, specialised orthotic footwear, total contact plaster cast, irremovable aircast boot.

Ulcers that do not heal promptly may progress to osteomyelitis (infection of the underlying bone). If an ulcer is neuroischaemic, a vascular assessment is often carried out by ultrasound or angiography, as revascularisation by angioplasty or surgery may be required to allow the ulcer to heal. In cases of severe secondary infection or gangrene, amputation of the affected toe or of the limb (below or above knee) may be required depending on the severity.



Diabetic foot risk stratification and triage

Active	Definition	Presence of active ulceration, infection, with or without ischaemia, gangrene or unexplained hot, red, swollen foot with or without the presence of pain.	Action	• Rapid referral to, and management by, a member of the multidisciplinary diabetes foot team or directly to vascular surgery when appropriate
In remission	Definition	Previous ulceration, amputation or consolidated Charcot.	Action	• Management by a specialist podiatrist aimed at preventing ulceration • Annual review of treatment plan (as opposed to annual screening) • Provision and regular review of footwear (orthotics)
High		More than one risk factor present, e.g. a combination of loss of sensation, signs of peripheral arterial disease, callus or deformity, unable to or has no help to self-care, or an eGFR < 30.		
Moderate	Definition	One risk factor present, e.g. loss of sensation, signs of peripheral arterial disease, unable to or has no help to self-care or an eGFR < 30.	Action	• Assessment by a podiatrist and implementation of a management plan when first identified as moderate risk • Annual screening (as opposed to every 2 years) • Consider provision of footwear (orthotics)
Low	Definition	No risk factors present, e.g. normal sensation, pulses present, no callus, no deformity, able to self-care and eGFR > 30.	Action	• Screening every two years by a trained health-care worker and outcome recorded • Agree personal self-care management plan • Review footwear

All people with diabetes should have written information on how to access podiatry (urgent or otherwise), cardiovascular risk reduction and access to a smoking cessation programme

Fig. 21.36 Risk assessment and management of foot problems in diabetes. *Reproduced with permission of the Scottish Diabetes Foot Action Group.*

21.33 Care of the feet in diabetes

Advice aimed at prevention of ulceration

Low risk (as per general population)
- Wash feet every day
- Cut or file toenails regularly
- Change socks or stockings every day
- Moisturise skin if dry
- Cover minor cuts with sterile dressings
- Treat fungal skin and nail infections promptly
- Do not burst blisters

Moderate and high risk
- Inspect feet every day
- Avoid walking barefoot
- Wear well-fitting shoes (e.g. trainers)
- Avoid over-the-counter corn/callus remedies
- Do not attempt corn removal
- Check footwear for foreign bodies
- Avoid high and low temperatures

Podiatry
- Access should be available appropriate to level of risk (see Fig. 21.36)
- Access to a multidisciplinary foot team, including a specialised podiatrist, should be available for urgent referrals and care of active foot ulcers

Orthotic footwear
- Specially manufactured and fitted orthotic footwear is required to prevent recurrence of ulceration and to protect the feet of patients with Charcot neuroarthropathy

Charcot neuroarthropathy

This is a rare but severe complication of neuropathy affecting the bones and joints of the foot characterised by early inflammation and then joint dislocation, subluxation and pathological fractures of the foot. It was originally described as a complication of neurosyphilis, but now that this is near eradicated it is almost exclusively seen in diabetes. The pathophysiological mechanisms remain poorly understood.

Charcot neuroarthropathy presents in a structurally abnormal foot with localised swelling, erythema and increased temperature (> 2°C compared with the contralateral foot). Early diagnosis can prevent progressive and debilitating deformity (see Fig. 21.35) and sepsis. The initial X-ray may show bony destruction but is often normal. As about 40% of patients with a Charcot joint also have a foot ulcer, it can be difficult to differentiate from osteomyelitis. Magnetic resonance imaging (MRI) of the foot is a sensitive diagnostic test. Management involves pressure relief and immobilisation (with a plaster cast or inflatable 'aircast' boot) and treating infection. This may take 3–6 months and sometimes longer.

Skin and rheumatological complications of diabetes

Glycation of collagen in skin, subcutaneous and periarticular tissues, perhaps supplemented by an effect of tissue ischaemia from microangiopathy, can cause thickening of the skin, leading to a painless limited mobility of the joints of the hands and feet (cheiroarthropathy or 'diabetic stiff hand syndrome') and a waxy, tight feel to the skin. In the most severe cases it can resemble scleroderma. The inability to extend to 180° the metacarpophalangeal or interphalangeal joints of at least one finger bilaterally can be demonstrated in the 'prayer sign' (p. 746). Adhesive capsulitis (e.g. causing frozen shoulder), Dupuytren contracture and trigger finger are all more common in people with diabetes.

Diabetic dermopathy manifests as rounded red papules in the pretibial area that become pigmented with time. It is commoner in men and is associated with other complications of diabetes (Fig. 21.37A).

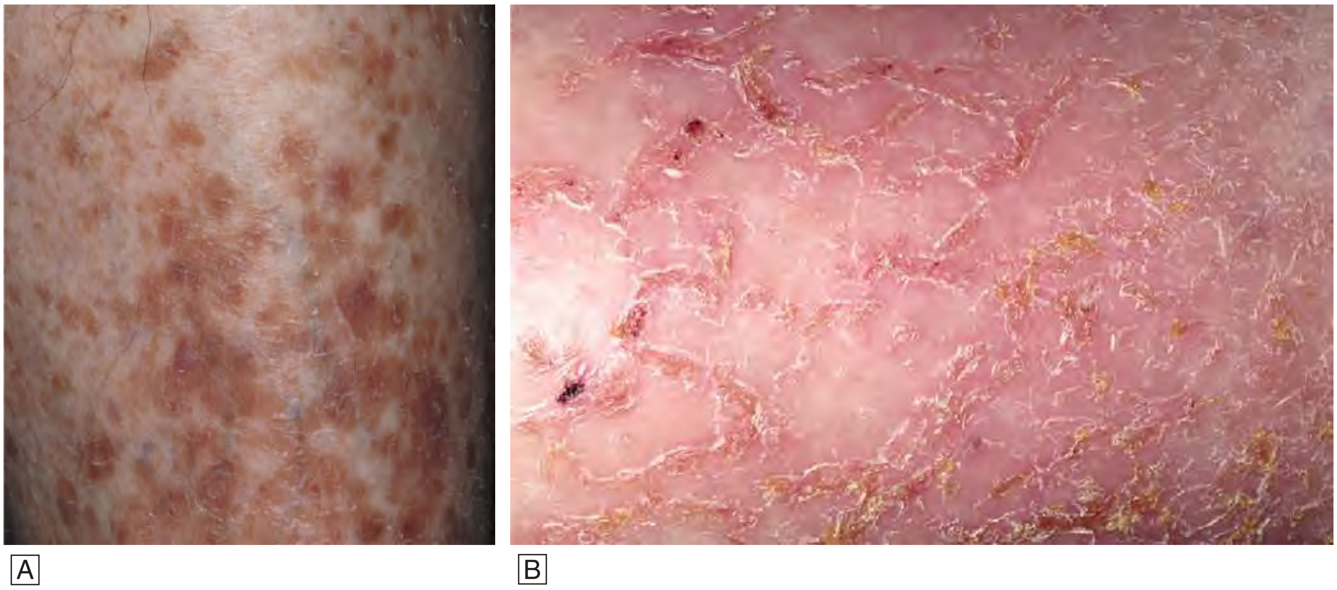


Fig. 21.37 Cutaneous manifestations of diabetes. A Diabetic dermopathy presents initially as small red papules, which resolve to the flattened hyperpigmented lesions shown here. B Xerosis results in drying and cracking of the skin. *(A) From James WD, Elston DM, Treat JR, Rosenbach M. Andrews' diseases of the skin. 14th ed. Elsevier; 2024. (B) From Williams PA. Basic geriatric nursing. 8th ed. Elsevier; 2023.*

Necrobiosis lipoidica is a rare granulomatous disorder that occurs predominantly in women with type 1 diabetes and is characterised by reddened plaques, with a yellowish central area that has atrophic skin and telangiectasia (see p. 746). Xerosis (or abnormal dryness of the skin) may be a cutaneous manifestation of autonomic neuropathy and can lead to cracks in the skin that act as a portal for infection (Fig. 21.37B).

Multiple Choice Questions

21.1. A 53-year-old woman with type 1 diabetes is currently an inpatient recovering from an elective hernia repair and is now eating and drinking and back on her usual subcutaneous insulin (NovoRapid 1 unit for 10 g CHO and Levemir 4 units am, 16 units pm). Morning insulin is due to be prescribed and the pre-breakfast meal capillary glucose is 2.9 mmol/L (3.5–5.5). This has been a consistent pattern. The patient is conscious, orientated and is able to swallow. What is it most appropriate to give the patient?

A. 100 mL IV 20% glucose
B. Give breakfast
C. 2 tubes of buccal Glucogel
D. 4–6 Glucotabs
E. 1 mg glucagon IM

Answer: D.

The patient has mild hypoglycaemia. The most appropriate treatment is 15–20 g of fast-acting CHO orally. Other examples are 5–7 Dextrosol tabs. It is important to treat hypoglycaemia first with fast-acting CHO and then repeat glucose in 15 minutes rather than just eating breakfast. If the next meal is not due, then advise 20 g of slower-acting CHO (1 slice of bread, 2 biscuits) to prevent recurrence of hypoglycaemia. If an insulin bolus is due, then it should be administered after correction of hypoglycaemia, in a dose appropriate for the CHO content of the meal, but it is important not to take further insulin for the CHO used to correct hypoglycaemia.

21.2. A 35-year-old man with diabetic ketoacidosis (DKA) has now stepped down to your ward from the medical high-dependency unit (HDU) on the DKA care pathway following admission early this morning. He normally takes NovoRapid (1 unit for 10 g) and had Lantus 20 units at bedtime last night. ECG is normal. On examination he is well and had lunch and is about to have his evening meal. Investigations:

HbA1c 134 mmol/mol (target 53 mmol/mol)
Sodium 138 mmol/L (137–144)
Potassium 4.8 mmol/L (3.5–4.9)
Urea 5.2 mmol/L (2.5–7.0)
Creatinine 64 μmol/L (60–110)
Glucose 8.4 mmol/L (3.5–5.5)
Bicarbonate 23 mmol/L (20–28)
Amylase 172 U/L (60–180)
C-reactive protein 5 mg/L (< 10)
Capillary ketones 0.3 mmol/L (< 0.6)

What is the most likely precipitant of his DKA episode?

A. Myocardial infarction
B. Issue with insulin administration
C. Acute pancreatitis
D. Sepsis
E. A carbohydrate counting error

Answer: B.

HbA1c is very elevated, suggesting patient has a chronic deficiency of insulin. One carbohydrate counting error should not result in DKA. There is no evidence of sepsis, myocardial infarction or acute pancreatitis and the patient has made a swift recovery. The patient should be referred to the diabetes team the following morning before discharge to check insulin administration (omissions, equipment, injection technique and sites), with further education required.

21.3. A 56-year-old woman with bowel carcinoma and type 2 diabetes (HbA1c is 90 mmol/mol) treated with Humalog Mix 25 twice daily (20 units am, 16 units pm) attends the surgical outpatient clinic. You are arranging for the patient to attend for urgent abdominal surgery. The patient is likely to miss more than one meal in theatre and post-operative recovery. What is the next management step?

A. Advise her to take 75% of the usual insulin on the morning
B. Admit the day before surgery for a variable rate insulin infusion
C. Advise her to take 50% of the usual dose of insulin on the morning
D. Advise her to take 25% of the usual dose of insulin on the morning
E. Withhold her morning insulin until after the procedure

Answer: B.

This is urgent major surgery in a patient with suboptimal control who will miss more than one meal. Admission pre-operatively for VRII is therefore required.

21.4. After surgery a 68-year-old man undergoing a colectomy is recovering post-operatively. He has a history of type 2 diabetes treated with Humalog Mix 25 twice daily (42 units am, 42 units pm). Subcutaneous insulin was commenced 15 minutes before a normal breakfast. The nurses ask you to review the glucose chart at lunchtime as the patient required treatment for a moderate hypoglycaemic episode at 11am:

	Before breakfast			Before dinner		
Date	Blood sugar	Insulin	Dose (Units)	Blood sugar	Insulin	Dose (Units)
1/4	8.9	Humalog	25			

What was the most likely cause of the hypoglycaemic episode?

A. Wrong insulin and wrong dose
B. Wrong dose of insulin
C. Wrong insulin
D. Wrong time of insulin
E. Wrong time of insulin and wrong dose

Answer: A.

Humalog Mix 25 (Lispro 25%, Lispro Protamine 75%): onset 10–20 minutes, duration 16–20 hours, peak 1–6.5 hours. Humalog (Lispro): onset 10–20 minutes, peak 1–3 hours, duration 2–4 hours. Humalog has been given instead of Humalog Mix 25. '25' refers to the proportion of short-acting insulin in the Humalog Mix 25 preparation; it has been wrongly prescribed as a dose of short-acting Humalog insulin. 'Insulin' should have been written as 'Humalog Mix 25', and 'Dose' should have been written as '42 units'. Blood glucose chart should have dose in units and not written 'as charted'. The ideal time to administer Humalog Mix 25 is 15 minutes before breakfast.

21.5. A 65-year-old man with type 1 diabetes is admitted and requires emergency surgery. You are asked to prescribe a variable rate insulin infusion. His insulin regimen is normally NovoMix 30 twice daily. He had breakfast 2 hours ago and his current capillary blood glucose is 10.5 mmol/L. Post-operative recovery is swift. What is the next management step?

A. Give usual subcutaneous (SC) insulin dose with lunch, stop intravenous insulin 30 minutes later

B. Give usual SC insulin dose with lunch and stop intravenous insulin immediately
C. Give usual SC insulin dose with evening meal, stop intravenous insulin 30 minutes later
D. Give usual SC insulin dose now and stop intravenous insulin immediately
E. Give usual SC insulin dose now and stop intravenous insulin 30 minutes later

Answer: E.

NovoMix 30: biphasic insulin aspart 30%/aspart protamine 70%; onset 10–20 minutes, duration up to 16–20 hours, peak action 2.4 hours. Patients can be converted back onto their usual subcutaneous insulin once eating normally and serum urea and electrolytes (U&Es) are at baseline and bicarbonate is normal (> 18 mmol/L). This should be done at the next convenient meal. This patient is on twice-daily mixed insulin and so this will be the patient's evening meal. Once the IV insulin is stopped, the patient will have no endogenous insulin (IV insulin half life = 2.5 mins) on board and so it should always be continued for 30 minutes after the subcutaneous insulin has been administered.

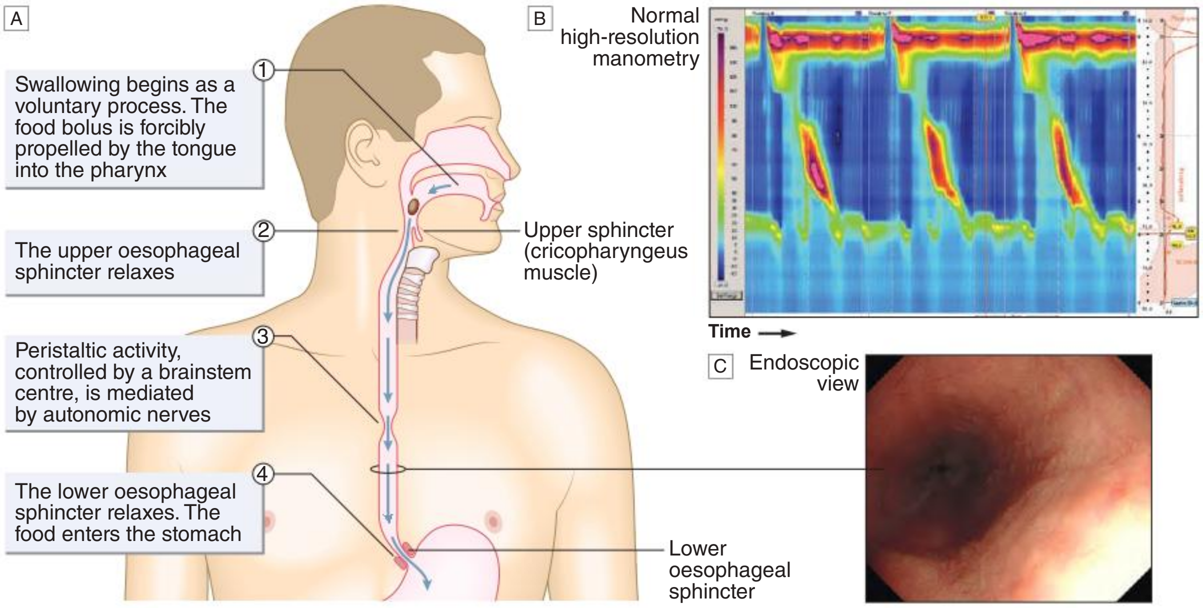
Diseases of the gastrointestinal tract are a major cause of morbidity and mortality. Around 10% of all consultations in primary care are for gastroenterological problems, split equally between the upper and lower gastrointestinal tract. Infective diarrhoea and malabsorption are responsible for much ill health and many deaths in low- and middle-income countries. The gastrointestinal tract is the most common site for cancer development. Colorectal cancer is the third most common cancer in men and second most common in women, with population-based screening programmes existing in many countries. Functional gastrointestinal disorders account for at least 40% of all referrals to gastroenterology services and consume considerable health-care resources. The inflammatory bowel diseases, Crohn disease and ulcerative colitis, together affect 1 in 250 people in the Western world, with substantial associated morbidity.

Functional anatomy and physiology

Oesophagus, stomach and duodenum

The oesophagus is a muscular tube that extends 25 cm from the cricoid cartilage to the cardiac orifice of the stomach, with the gastroesophageal junction being 40 cm from the incisors. The oesophagus has both an upper and a lower sphincter. A peristaltic swallowing wave propels the food bolus into the stomach (Fig. 22.1A). The swallowing wave can be detected by oesophageal manometry. This involves passing a tube into the oesophagus with pressure sensors at 1 cm intervals to record intra-oesophageal pressure during swallowing.

The stomach acts as a 'hopper', retaining and grinding food, and then actively propelling it into the duodenum (Fig. 22.2).



A
Swallowing begins as a voluntary process. The food bolus is forcibly propelled by the tongue into the pharynx
①
The upper oesophageal sphincter relaxes
②
Peristaltic activity, controlled by a brainstem centre, is mediated by autonomic nerves

Gastric secretion

Gastrin, histamine and acetylcholine are the key stimulants of acid secretion. Hydrogen ions are secreted from the apical membrane of gastric parietal cells into the lumen of the stomach by a hydrogen–potassium adenosine triphosphate ATPase ('proton pump'). In the lumen they combine with chloride ions extruded from parietal cells through chloride channels to form hydrochloric acid (Fig. 22.3). The hydrochloric acid sterilises the upper gastrointestinal tract and converts the zymogen pepsinogen, which is secreted by chief cells, to pepsin, which digests proteins to polypeptides. The glycoprotein intrinsic factor, secreted in parallel with acid, is necessary for vitamin B_{12} absorption in the terminal ileum. In addition, gastric acid facilitates absorption of iron and calcium within the duodenum in particular.

Gastrin, somatostatin and ghrelin

The hormone gastrin is produced by G cells mainly in the gastric antrum, with somatostatin being secreted from D cells throughout the gastrointestinal tract. Gastrin stimulates acid secretion and mucosal growth while somatostatin suppresses it. Ghrelin, secreted from P/D1 cells within oxyntic glands in the gastric fundus, stimulates acid secretion, as well as appetite and gastric emptying.

Protective factors

Bicarbonate ions, stimulated by prostaglandins, mucins and trefoil factor family (TFF) peptides, together protect the gastroduodenal mucosa from the ulcerative properties of acid and pepsin.

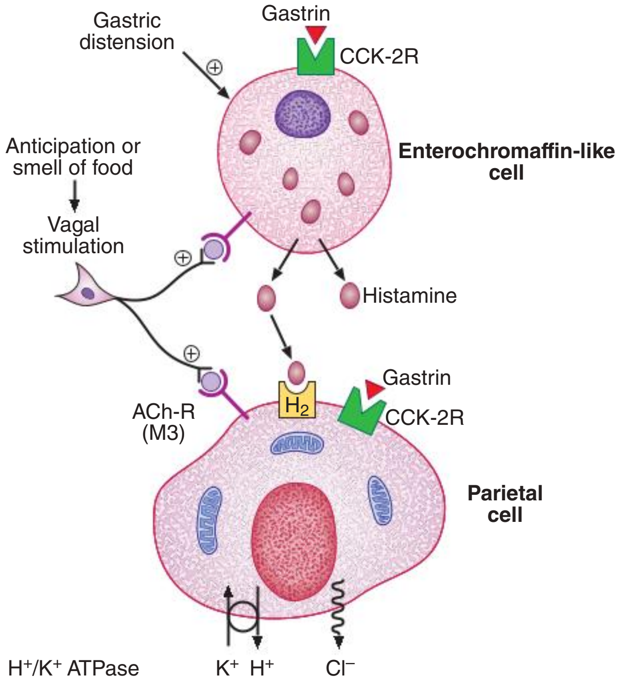

Fig. 22.3 Control of acid secretion. Gastrin released from antral G cells in response to food (protein) binds to cholecystokinin receptors (CCK-2R) on the surface of enterochromaffin-like (ECL) cells, which in turn release histamine. The histamine binds to H_2 receptors on parietal cells, and this leads to secretion of hydrogen ions in exchange for potassium ions at the apical membrane. Parietal cells also express CCK-2R and it is thought that activation of these receptors by gastrin is involved in regulating proliferation of parietal cells. Cholinergic (vagal) activity and gastric distension also stimulate acid secretion; somatostatin, vasoactive intestinal polypeptide (VIP) and gastric inhibitory polypeptide (GIP) may inhibit it. (ACh-R = acetylcholine receptor; ATPase = adenosine triphosphatase)

Small intestine

The jejunum begins at the ligament of Treitz, and the ileum ends at the ileocaecal valve (Fig. 22.4). During fasting, the migrating motor complex, a wave of peristaltic activity, passes down the small bowel every 1–2 hours. Entry of food into the gastrointestinal tract stimulates small bowel peristaltic activity. Functions of the small intestine are:

- digestion (mechanical, enzymatic and peristaltic)
- absorption – the products of digestion, water, electrolytes and vitamins
- protection against ingested toxins
- immune regulation.

Digestion and absorption

Fat

Dietary lipids comprise long-chain triglycerides, cholesterol esters and lecithin. Lipids are insoluble in water and undergo lipolysis and incorporation into mixed micelles before they can be absorbed into enterocytes

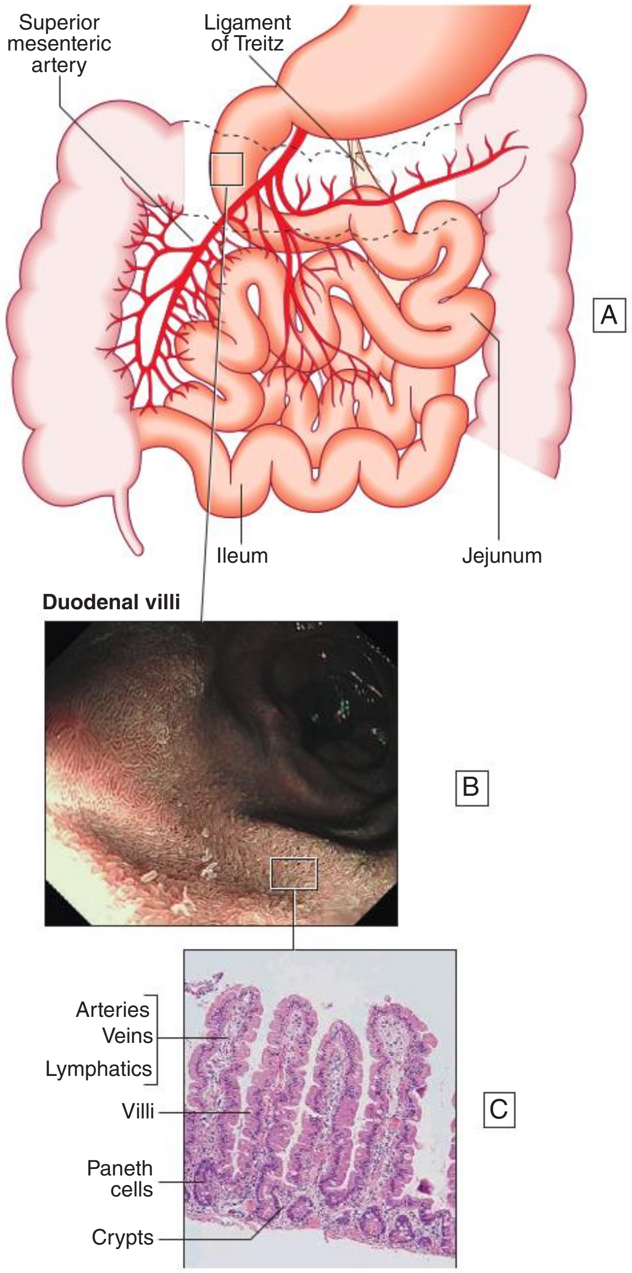

Fig. 22.4 Small intestine anatomy. A Anatomy. B Endosopic view. C Histology. Epithelial cells are formed in crypts and differentiate as they migrate to the tip of the villi to form enterocytes (absorptive cells) and goblet cells.

Fig. 22.5 Fat digestion. *Step 1: Luminal phase.* Fatty acids stimulate cholecystokinin (CCK) release from the duodenum and upper jejunum. The CCK stimulates release of amylase, lipase, colipase and proteases from the pancreas, causes gallbladder contraction and relaxes the sphincter of Oddi, allowing bile to flow into the intestine. *Step 2: Fat solubilisation.* Bile acids and salts combine with dietary fat to form mixed micelles, which also contain cholesterol and fat-soluble vitamins. *Step 3: Digestion.* Pancreatic lipase, in the presence of its co-factor, colipase, cleaves long-chain triglycerides, yielding fatty acids and monoglycerides. *Step 4: Absorption.* Mixed micelles diffuse to the brush border of the enterocytes. Within the brush border, long-chain fatty acids bind to proteins, which transport the fatty acids into the cell, whereas cholesterol, short-chain fatty acids, phospholipids and fat-soluble vitamins enter the cell directly. The bile salts remain in the small intestinal lumen and are actively transported from the terminal ileum into the portal circulation and returned to the liver (the enterohepatic circulation). *Step 5: Re-esterification.* Within the enterocyte, fatty acids are re-esterified to form triglycerides. Triglycerides combine with cholesterol ester, fat-soluble vitamins, phospholipids and apoproteins to form chylomicrons. *Step 6: Transport.* Chylomicrons leave the enterocytes by exocytosis, enter mesenteric lymphatics, pass into the thoracic duct and eventually reach the systemic circulation.

along with the fat-soluble vitamins A, D, E and K. The lipids are processed within enterocytes and pass via lymphatics into the systemic circulation. Fat absorption and digestion can be considered as a stepwise process, as outlined in Figure 22.5.

Carbohydrates

Starch is hydrolysed by salivary and pancreatic amylases to:

- α-limit dextrins containing 4–8 glucose molecules
- the disaccharide maltose
- the trisaccharide maltotriose.

Disaccharides are digested by enzymes fixed to the microvillous membrane to form the monosaccharides glucose, galactose and fructose. Glucose and galactose enter the cell by an energy-requiring process involving a carrier protein. Fructose is absorbed by facilitated diffusion through the GLUT5 transporter. and absorbed in the small intestine via SGLT1.

Protein

The steps involved in protein digestion are shown in Figure 22.6. Intragastric digestion by pepsin is quantitatively modest, but important, because the resulting polypeptides and amino acids stimulate cholecystokinin (CCK) release from the mucosa of the proximal jejunum, which in turn stimulates release of pancreatic proteases, including trypsinogen, chymotrypsinogen, pro-elastases and procarboxypeptidases, from the pancreas. On exposure to brush border enterokinase, inert trypsinogen is converted to the active proteolytic enzyme trypsin, which activates the other pancreatic pro-enzymes. Trypsin digests proteins to produce oligopeptides, peptides and amino acids. Oligopeptides are further hydrolysed by brush border enzymes to yield dipeptides, tripeptides and amino acids. These small peptides and the amino acids are actively transported into the enterocytes, where intracellular peptidases further digest peptides to amino acids. Amino acids are then actively transported across the basal cell membrane of the enterocyte into the portal circulation and the liver.

Water and electrolytes

Absorption and secretion of electrolytes and water occur throughout the intestine. Electrolytes and water are transported by two pathways:

- *the paracellular route*, in which passive flow through tight junctions between cells is a consequence of osmotic, electrical or hydrostatic gradients
- *the transcellular route* across apical and basolateral membranes by energy-requiring specific active transport carriers (pumps).

In healthy individuals, fluid balance is tightly controlled, such that only 100 mL of the 8 litres of fluid entering the gastrointestinal tract daily is excreted in stools (Fig. 22.7).

Vitamins and trace elements

Water-soluble vitamins are absorbed throughout the intestine. The absorption of folic acid, vitamin B_{12}, calcium and iron is described in Chapter 24.

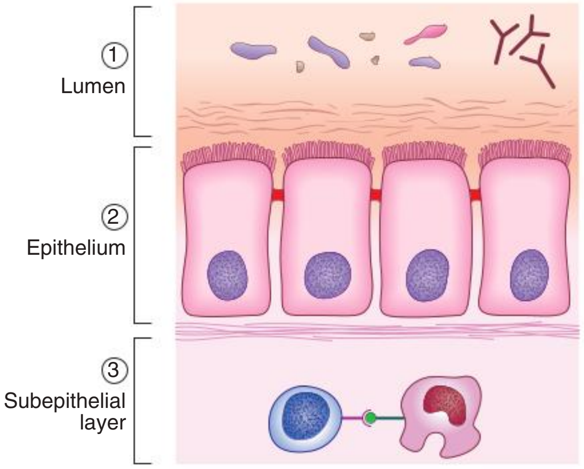
Protective function of the small intestine

Physical defence mechanisms

There are several levels of defence in the small bowel (Fig. 22.8). Firstly, the gut lumen contains host bacteria, mucins and secreted antibacterial products, including defensins and immunoglobulins that help combat pathogenic infections. Secondly, epithelial cells have relatively impermeable brush border membranes, and passage of substances between cells is prevented by both tight and adherens junctions. These cells can react to foreign peptides using pattern recognition receptors (PRRs). These include Toll receptors on the cell surfaces and NOD receptors, which are intracellular (see Ch. 4). Lastly, in the subepithelial layer, immune responses occur under control of the adaptive immune system in response to pathogenic substances.



① Lumen
② Epithelium
③ Subepithelial layer

Fig. 22.8 **Intestinal defence mechanisms.** *See text for details.*

Immunological defence mechanisms

Gastrointestinal mucosa-associated lymphoid tissue (MALT) constitutes 25% of the total lymphatic tissue of the body and is at the heart of adaptive immunity. Within Peyer patches, B lymphocytes differentiate to plasma cells following exposure to antigens and these migrate to mesenteric lymph nodes to enter the blood stream through the thoracic duct. The plasma cells return to the lamina propria of the gut through the circulation and release immunoglobulin A (IgA), which is transported into the lumen of the intestine. Intestinal T lymphocytes help localise plasma cells to the site of antigen exposure, as well as producing inflammatory mediators. Macrophages in the gut phagocytose foreign materials and secrete a range of cytokines, which mediate inflammation. Similarly, activation of mast-cell surface IgE receptors leads to degranulation and release of other molecules involved in inflammation. MAdCAM-1 is peptide expressed on endothelial cells of intestinal lymphoid tissue. It binds the $\alpha 4\beta 7$ integrin expressed on T lymphocytes and regulates migration of lymphocytes from the bloodstream to the lamina propria, helping to defend against pathogens. Increased expression of MAdCAM-1 can lead to chronic inflammation such as is seen in inflammatory bowel disease (IBD).

Pancreas

The exocrine pancreas is necessary for the digestion of fat, protein and carbohydrate. Pancreatic acinar cells secrete various pro-enzymes which are activated by trypsin (Box 22.1). Secretion of these enzymes is stimulated by various circulating gastrointestinal hormones, as illustrated in Figure 22.9. Bicarbonate-rich fluid is secreted from ductular cells to produce an optimum alkaline pH for enzyme activity. The endocrine pancreas is discussed in Chapters 20 and 21.

Colon

Anatomy of the colon is shown in Figure 22.10. The colon acts as a storage organ and has contractile activity. Two types of contraction occur. The first of these is segmentation (ring contraction), which leads to mixing but not propulsion; this promotes absorption of water and electrolytes. Propulsive (peristaltic contraction) waves occur several times a day and propel faeces to the rectum. All activity is stimulated after meals through the gastrocolic reflex in response to release of hormones such as 5-hydroxytryptamine (5-HT, serotonin), motilin and CCK.

i 22.1 Pancreatic enzymes

Enzyme	Substrate	Products
Amylase	Starch and glycogen	Limit dextrans Maltose Maltriose
Lipase **Colipase**	Triglycerides	Monoglycerides and free fatty acids
Proteolytic enzymes **Trypsinogen** **Chymotrypsinogen** **Pro-elastase** **Pro-carboxypeptidases**	Proteins and polypeptides	Short polypeptides

Faecal continence depends on maintenance of the anorectal angle and tonic contraction of the external anal sphincters. On defaecation, there is relaxation of the anorectal muscles, increased intra-abdominal pressure from the Valsalva manoeuvre and contraction of abdominal muscles, and relaxation of the anal sphincters.

Intestinal microbiota

The human microbiota comprises 10^{14} microbial residents in and on the human body, vastly outnumbering host cells. Indeed, the number of bacterial genes in the microbiota genome exceeds that of the host by 100-fold or more. This represents a vast ecosystem that is central to health and homeostasis and is disordered in disease. In terms of nomenclature, 'microbiota' refers to the microorganisms that live in a particular niche, while 'microbiome' refers to the collective genomes of these microbiota. Host genetic factors influence the microbiota, but many environmental factors also play a role, including diet, drugs, physical activity, smoking, stress and ageing. Generally, the adult intestinal microbiota is acquired by the age of 2 years. A dysbiosis or imbalance between the different components of the intestinal microbiota has been associated with diseases of the gastrointestinal tract, such as inflammatory bowel disease and colorectal cancer; liver disease, including hepatocellular carcinoma; and pathologies outside the gastrointestinal tract, such as diabetes, obesity, cardiovascular disorders, cerebrovascular disorders, asthma and psychiatric disorders, such as depression. Many challenges remain in understanding the intestinal microbiota and how it impacts on health and disease.

Control of gastrointestinal function

Secretion, absorption, motor activity, growth and differentiation of the gut are all modulated by a combination of neuronal and hormonal factors.

The nervous system and gastrointestinal function

The central nervous system (CNS), the autonomic system (ANS) and the enteric nervous system (ENS) interact to regulate gut function. The ANS comprises:

- *parasympathetic pathways* (vagal and sacral efferent), which are cholinergic, and increase smooth muscle tone and promote sphincter relaxation

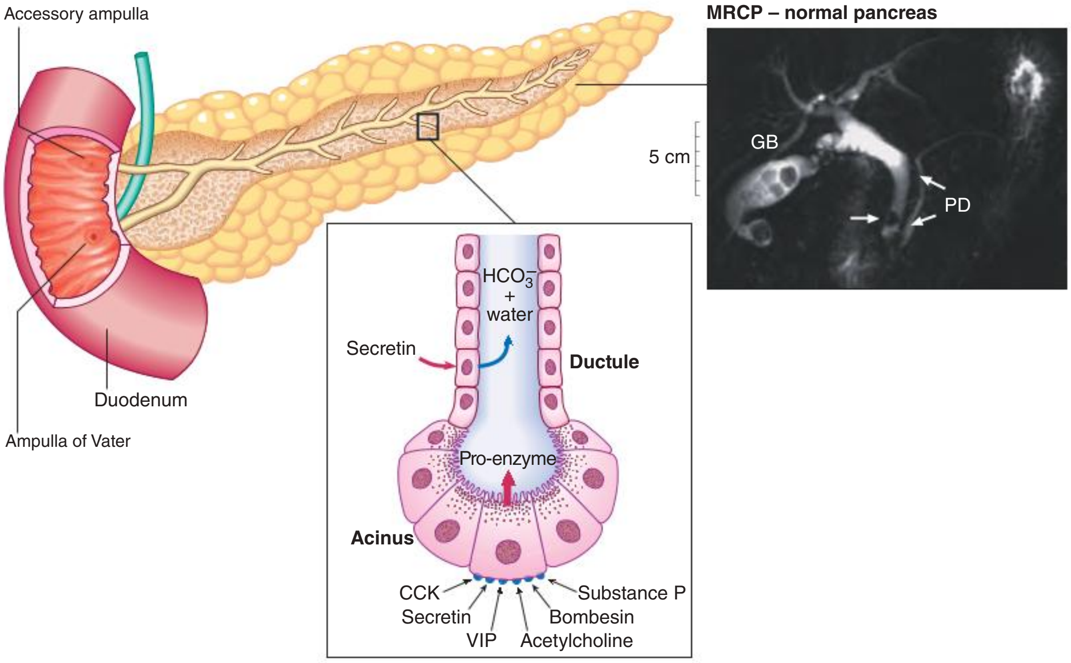


Fig. 22.9 Pancreatic structure and function. Ductular cells secrete alkaline fluid in response to secretin. Acinar cells secrete digestive enzymes from zymogen granules in response to a range of secretagogues. The photograph shows a normal pancreatic duct (PD) and side branches, as defined at magnetic resonance cholangiopancreatography (MRCP). Note the incidental calculi in the gallbladder (GB) and common bile duct (arrow). (CCK = cholecystokinin; VIP = vasoactive intestinal polypeptide)

- *sympathetic pathways* (thoracolumbar sympathetic chain ganglia, coeliac, superior mesenteric, inferior mesenteric ganglia), which release noradrenaline (norepinephrine), reduce smooth muscle tone and stimulate sphincter contraction.

The enteric nervous system

The enteric nervous system (ENS) is considered to be part of the ANS. It senses gut contents and conditions, regulates motility, fluid exchange, secretion, blood flow and other key gut functions. It comprises two major networks intrinsic to the gut wall. The myenteric (Auerbach) plexus in the smooth muscle layer regulates motor control, and the submucosal (Meissner) plexus exerts secretory control over the epithelium, entero-endocrine cells and submucosal vessels. Together, these plexuses form a two-layered neuronal mesh along the length of the gut. Although the ENS and ANS work together, the ENS can function autonomously using a variety of neurotransmitters, including acetylcholine, noradrenaline (norepinephrine), 5-HT, nitric oxide, substance P and calcitonin gene–related peptide (CGRP). There are local reflex loops within the ENS but also loops involving the coeliac and mesenteric ganglia and the paravertebral ganglia. The parasympathetic system generally stimulates motility and secretion, while the sympathetic system generally acts in an inhibitory manner.

Peristalsis

Peristalsis is a reflex triggered by gut wall distension, which consists of a wave of circular muscle contraction to propel contents from the oesophagus to the rectum. It can be influenced by innervation but functions independently. It results from a basic electrical rhythm originating from the interstitial cells of Cajal in the circular layer of intestinal smooth muscle. These are stellate cells of mesenchymal origin with smooth muscle features, which act as the ‘pacemaker’ of the gut.

Migrating motor complexes

Migrating motor complexes (MMCs) are waves of contraction spreading from the stomach to the ileum, occurring at a frequency of about 5 per minute every 90 minutes or so, between meals and during fasting. They may serve to sweep intestinal contents distally in preparation for the next meal and are inhibited by eating.

Gut hormones

The origin, action and control of the major gut hormones, peptides and non-peptide signalling transmitters are summarised in Box 22.2.

Investigation of gastrointestinal disease

A wide range of tests is available for the investigation of patients with gastrointestinal symptoms. These can be classified broadly into tests of structure, tests for infection and tests of function.

Imaging

Plain X-rays

Plain X-rays of the abdomen are useful in the diagnosis of intestinal obstruction or paralytic ileus, where dilated loops of bowel may be seen (Fig. 22.11A). In the erect position, fluid levels may also be observed. Chest X-ray (performed with the patient in erect position) is useful in the diagnosis of suspected perforation, as it shows subdiaphragmatic free air (Fig. 22.11B). Other abnormalities that can be observed on plain X-rays include calcified lymph nodes, gallstones and renal stones.

Contrast studies

X-rays with contrast medium are usually performed to assess not only anatomical abnormalities but also motility. Barium sulphate provides good mucosal coating and excellent opacification but can precipitate impaction proximal to an obstructive lesion. Water-soluble contrast is used to opacify bowel prior to abdominal computed tomography and in cases of suspected perforation. The double contrast technique improves mucosal visualisation by using gas to distend the barium-coated

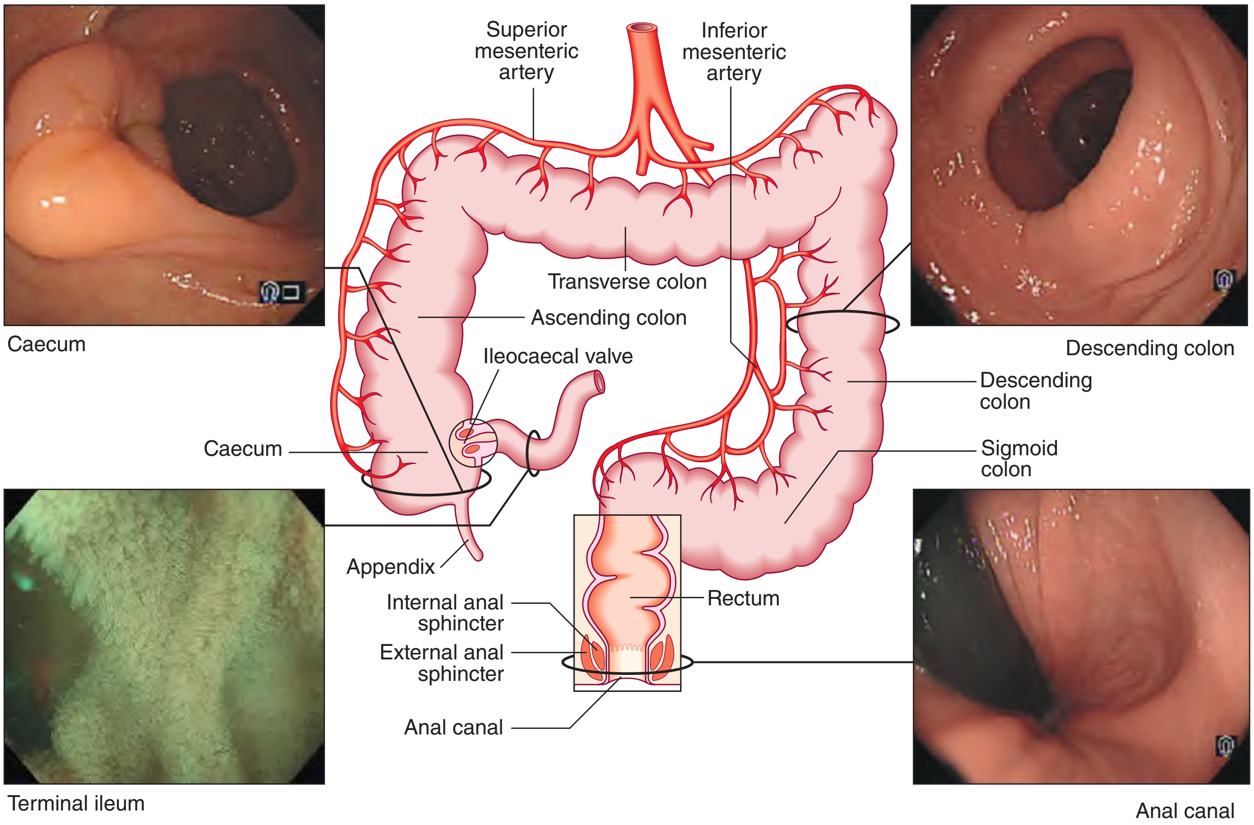

Fig. 22.10 The central panel shows the anatomy of the terminal ileum, normal colon rectum and anal canal. The peripheral panels show endocsopic views.

22.2 Gut hormones and peptides

Hormone	Origin	Stimulus	Action
Gastrin	Predominantly stomach (G cell)	Products of protein digestion Suppressed by acid and somatostatin	Stimulates gastric acid secretion Stimulates growth of gastrointestinal mucosa
Somatostatin	Throughout gastrointestinal tract (D cell)	Fat ingestion	Inhibits gastrin and insulin secretion Decreases acid secretion Decreases absorption Inhibits pancreatic secretion
Cholecystokinin (CCK)	Duodenum and jejunum (I cells); also ileal and colonic nerve endings	Products of protein digestion Fat and fatty acids Suppressed by trypsin	Stimulates pancreatic enzyme secretion Stimulates gallbladder contraction Relaxes sphincter of Oddi Modulates satiety Decreases gastric acid secretion Reduces gastric emptying Regulates pancreatic growth
Secretin	Duodenum and jejunum (S cells)	Duodenal acid Fatty acids	Stimulates pancreatic fluid and bicarbonate secretion Decreases acid secretion Reduces gastric emptying
Motilin	Duodenum, small intestine and colon (Mo cells)	Fasting Dietary fat	Regulates peristaltic activity, including migrating motor complexes (MMCs)
Gastric inhibitory polypeptide (GIP)	Duodenum (K cells) and jejunum	Glucose and fat	Stimulates insulin release Inhibits acid secretion Enhances satiety
Glucagon-like peptide-1 (GLP-1)	Ileum and colon (L cells)	Carbohydrates, protein and fat	Stimulates insulin release Inhibits acid secretion and gastric emptying Enhances satiety
Glucagon-like peptide-2 (GLP-2)	Ileum and colon (L cells)	Carbohydrates, protein and fat	Increase intestinal epithelial proliferation Inhibits gastric emptying Enhances satiety
Vasoactive intestinal peptide (VIP)	Nerve fibres throughout gastrointestinal tract	Unknown	Has vasodilator action Relaxes smooth muscle Stimulates water and electrolyte secretion
Ghrelin	Stomach	Fasting Inhibited by eating	Stimulates appetite, acid secretion and gastric emptying
Peptide YY	Ileum and colon	Feeding	Modulates satiety

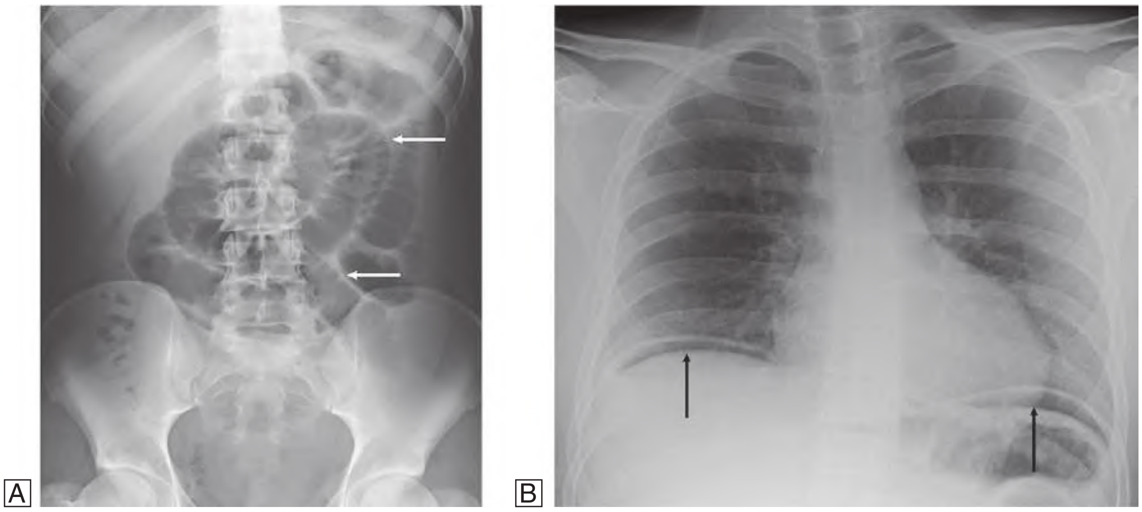

Fig. 22.11 **A** Abdominal X-ray showing dilatation of loops of small bowel (arrows), consistent with mechanical small bowel obstruction secondary to adhesions from previous surgery. **B** Chest X-ray showing free air under both hemidiaphragms (arrows), secondary to a perforated gastric ulcer.

intestinal surface. Contrast studies are useful for detecting filling defects, such as tumours, strictures, ulcers and motility disorders, but are inferior to endoscopic procedures and more sophisticated cross-sectional imaging techniques, such as computed tomography and magnetic resonance imaging. The major uses and limitations of various contrast studies are shown in Box 22.3 and Figure 22.12.

Ultrasound, computed tomography, magnetic resonance imaging and PET/CT

Ultrasound, computed tomography (CT) and magnetic resonance imaging (MRI) are key tests in the evaluation of intra-abdominal disease. They are non-invasive and offer detailed images of the abdominal contents; portable ultrasound devices are increasingly used at the bedside to provide rapid diagnostic information in patients with acute abdominal pain and to assist with investigations such as paracentesis. Fluorodeoxyglucose positron emission tomography (FDG PET) is used in the staging of malignancies and images may be fused with CT to enhance localisation. Their main applications are summarised in Box 22.4 and Figure 22.13.

22.3 Contrast radiology in the investigation of gastrointestinal disease

	Barium swallow/meal	Barium follow-through	Barium enema
Indications and major uses	Motility disorders (achalasia and gastroparesis)	Diarrhoea and abdominal pain of small bowel origin Possible obstruction by strictures Suspected malabsorption Assessment of Crohn disease	Altered bowel habit Evaluation of strictures or diverticular disease Megacolon
Limitations	Risk of aspiration Poor mucosal detail Low sensitivity for early cancer Inability to biopsy	Time-consuming nature Radiation exposure Relative insensitivity	Difficulty in frail or incontinent patients Sigmoidoscopy needed to see rectum Low sensitivity for lesions < 1 cm

Endoanal ultrasound and anorectal manometry

Endoanal ultrasound is primarily used in the evaluation of anal fistula and anal sphincter pathology, in individuals presenting with faecal incontinence. In conjunction with this, anorectal manometry is commonly performed to detect abnormalities of sphincter function and recto-anal coordination. Anorectal manometry is also commonly used to assess constipation, particularly when thought due to obstructive defaecation.

Endoscopy

Videoendoscopes provide high-definition imaging, and accessories can be passed down the endoscope to allow both diagnostic and therapeutic procedures, some of which are illustrated in Figure 22.14. Endoscopes with magnifying lenses allow almost microscopic detail to be observed, and imaging modalities, such as confocal endomicroscopy, autofluorescence and 'narrow-band imaging', are increasingly used to detect subtle abnormalities not visible by standard 'white light' endoscopy. The implications of endoscopic procedures in older people are shown in Box 22.5.

Upper gastrointestinal endoscopy

This is performed under light sedation, or using only local anaesthetic throat spray after the patient has fasted for at least 4 hours. With the patient in the left lateral position, the entire oesophagus (excluding pharynx), stomach and first two parts of duodenum can be seen. Indications, contraindications and complications are given in Box 22.6. While upper gastrointestinal endoscopy is mainly performed through the transoral route, transnasal endoscopy is also possible and has the advantage that patients can breathe normally, speak, and swallow freely during the procedure.

Fig. 22.12 Examples of contrast radiology. A Barium swallow showing a large pharyngeal pouch (P) with retained contrast creating an air–fluid level. B Barium follow-through. There are multiple diverticula (arrows) in this patient with jejunal diverticulosis. C Barium enema showing severe diverticular disease. There is tortuosity and narrowing of the sigmoid colon with multiple diverticula (arrows).

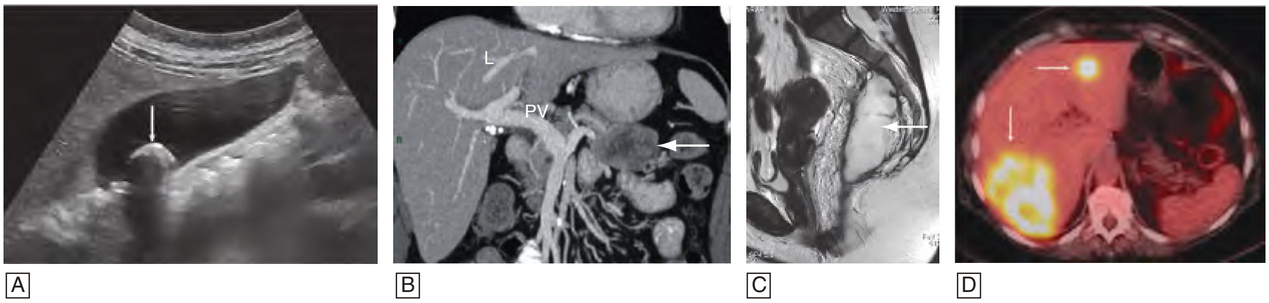

Fig. 22.13 Examples of ultrasound, CT, MRI, and PET/CT. A Ultrasound showing large gallstone (arrow) with acoustic shadowing. B Multidetector coronal CT showing large solid and cystic malignant tumour in the pancreatic tail (arrow). C Pelvic MRI showing large pelvic abscess (arrow) posterior to the rectum in a patient with Crohn disease. D Fused PET-CT image showing two liver metastases (arrows). (L = liver; PV = portal vein)

22.4 Imaging in gastroenterology

	Ultrasound	Computed tomography (CT)	Magnetic resonance imaging (MRI)	Positron emission tomography–CT (PET-CT)
Indications and major uses	Abdominal masses Organomegaly Ascites Biliary tract dilatation Gallstones Guided biopsy of lesions Small bowel imaging	Assessment of pancreatic disease Hepatic tumour deposits CT colonography ('virtual colonoscopy') Tumour staging Assessment of lesion vascularity Abscesses and collections	Hepatic tumour staging MRCP Pelvic/perianal disease Crohn fistulae Small bowel visualisation	Detection of metastases not seen on ultrasound or CT Images can be fused with CT to form composite image
Limitations	Low sensitivity for small lesions Little functional information Operator-dependent Gas and obesity may obscure view	Cost Radiation dose	Claustrophobic patients Contraindicated in presence of metallic prostheses, some cardiac pacemakers, cochlear implants	Signal detection depends on metabolic activity within tumour – not all are metabolically active

(MRCP = magnetic resonance cholangiopancreatography)

22.5 Endoscopy in old age

- **Tolerance**: endoscopic procedures are generally well tolerated, even in very old people.
- **Side-effects from sedation**: older people are more sensitive, and respiratory depression, hypotension and prolonged recovery times are more common.
- **Bowel preparation for colonoscopy**: can be difficult in frail, immobile people. Sodium phosphate–based preparations can cause dehydration or hypotension and should be avoided in those with underlying cardiac or renal failure. Minimal-preparation CT colonograms provide an excellent alternative in these individuals.
- **Antiperistaltic agents**: hyoscine should be avoided in those with glaucoma and can also cause tachyarrhythmias. Glucagon is preferred if an antiperistaltic agent is needed.

(CT = computed tomography)

22.6 Upper gastrointestinal endoscopy

Indications

- Dyspepsia in patients > 55 years of age or with alarm symptoms
- Atypical chest pain
- Dysphagia
- Vomiting
- Weight loss
- Acute or chronic gastrointestinal bleeding
- Screening for oesophageal varices in chronic liver disease
- Abnormal CT scan or barium meal
- Duodenal biopsies in the investigation of malabsorption and confirmation of a diagnosis of coeliac disease prior to commencement of gluten-free diet
- Therapy, including treatment of bleeding lesions, banding/injection of varices, dilatation of strictures, insertion of stents, placement of percutaneous gastrostomies, ablation of Barrett oesophagus and resection of high-grade dysplastic lesions and early neoplasia in the upper gastrointestinal tract

Contraindications

- Severe shock
- Recent myocardial infarction, unstable angina, cardiac arrhythmia
- Severe respiratory disease*
- Atlantoaxial subluxation*
- Possible visceral perforation

Complications

- Cardiorespiratory depression due to sedation
- Aspiration pneumonia
- Perforation

(CT = computed tomography)
*These are relative contraindications as in experienced hands, endoscopy can often be performed in such patients.

Endoscopic ultrasound

Endoscopic ultrasound (EUS) combines endoscopy with intraluminal ultrasonography using a high-frequency transducer to produce high-resolution ultrasound images. This allows visualisation through the wall of the gastrointestinal tract and into surrounding tissues, such as the pancreas or lymph nodes. It can therefore be used to perform fine needle aspiration or biopsy of mass lesions. EUS is helpful in the diagnosis of pancreatic tumours, chronic pancreatitis, pancreatic cysts, cholangiocarcinoma, common bile duct stones, ampullary lesions and submucosal tumours. It also plays an important role in the staging of cancers of oesophagus and pancreas. The role of EUS as a therapeutic modality has increased and can be used in the drainage of pancreatic fluid collections and coeliac plexus block for pain management. Possible complications of EUS include bleeding, infection, cardiopulmonary events and perforation.

Capsule endoscopy

Capsule endoscopy (Fig. 22.15) uses a capsule containing an imaging device, battery, transmitter and antenna; as it traverses the small intestine, it transmits images to a battery-powered recorder worn on a belt round the patient's waist. After approximately 8 hours, the capsule is excreted. Images from the capsule are analysed as a video sequence and it is usually possible to localise the segment of small bowel where lesions are seen. Abnormalities detected usually require enteroscopy for confirmation and therapy. Indications, contraindications and complications are listed in Box 22.7.

Push enteroscopy and double balloon enteroscopy

While upper gastrointestinal endoscopy can reach the proximal small intestine in most patients, enteroscopy is an endoscopic technique that allows more extensive evaluation of the small intestine, extending into the jejunum and/or ileum. Push enteroscopy uses a long endoscope to examine up to the proximal jejunum. Deeper evaluation of the small bowel can be assessed by using a technique called double balloon enteroscopy, which uses a long endoscope with a flexible overtube. Sequential and repeated inflation and deflation of balloons on the tip of the overtube and enteroscope allow the operator to push and pull along the entire length of the small intestine to the terminal ileum, to diagnose or treat small bowel lesions detected by capsule endoscopy or other imaging modalities. This technique can be performed via an antegrade approach (via the mouth) or retrograde approach (via the anus), dependent upon the site of the lesion. Indications, contraindications and complications are listed in Box 22.8.

Sigmoidoscopy and colonoscopy

Sigmoidoscopy can be carried out either in the outpatient clinic using a rigid plastic sigmoidoscope or in the endoscopy suite using a colonoscope following bowel preparation. When sigmoidoscopy is combined

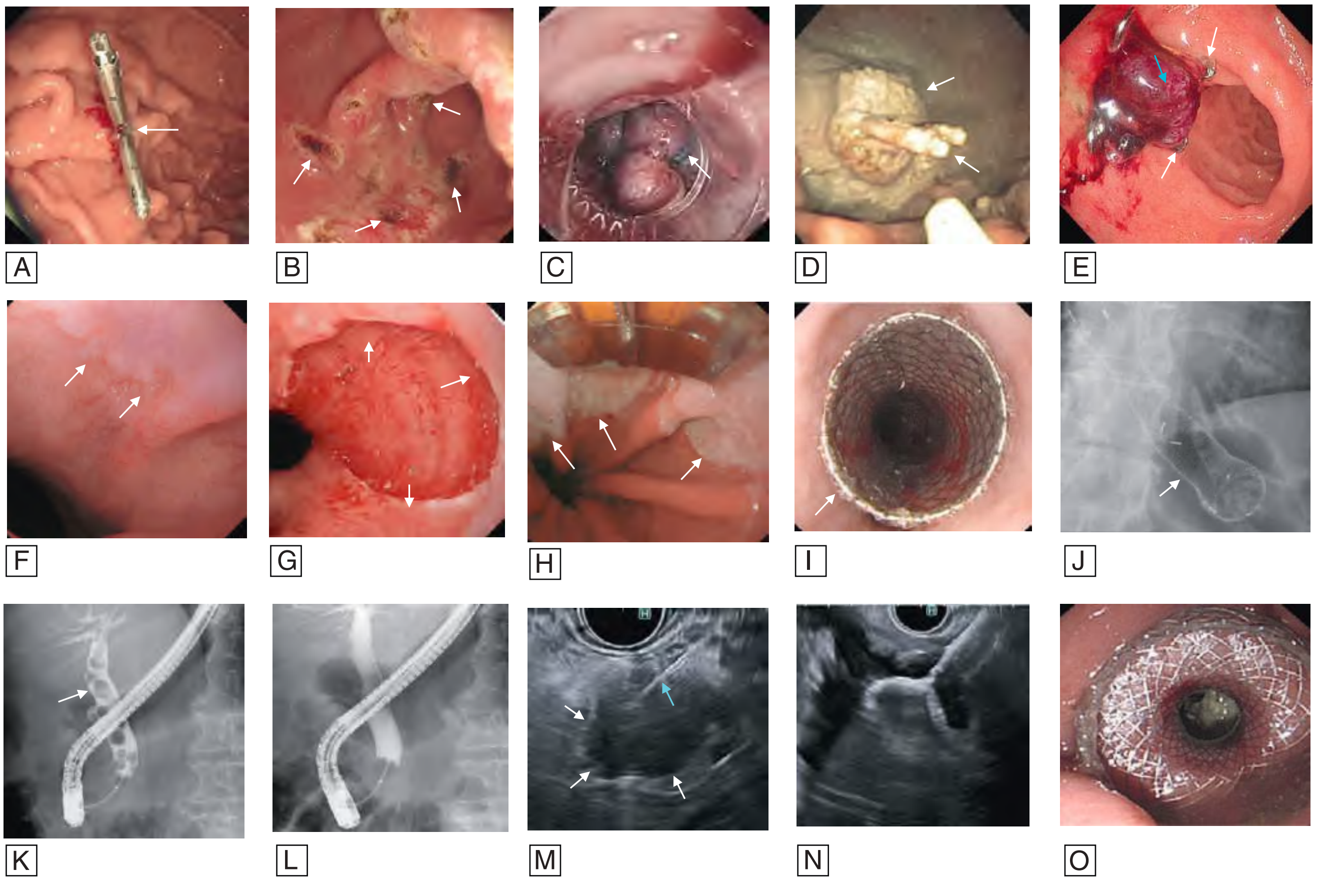

Fig. 22.14 Therapeutic techniques in endoscopy. Top row: Management of bleeding. Second row: The oesophagus. Bottom row: The pancreas and biliary tract. **A** Clipping of a bleeding vessel (white arrow). **B** Argon plasma coagulation. The treated areas are indicated by white arrows. **C** Ligation of oesophageal varices. The band is indicated by a white arrow. **D** Use of haemostatic spray on bleeding vessel. **E** Over-the-scope clip (OTSC) for large bleeding vessels. The jaws of the clip are indicated by white arrows and the blue arrow indicates clot overlying the vessel. **F** A small, intramucosal adenocarcinoma at the gastro-oesophageal junction (arrows). **G** The same area as in **F** following removal by endoscopic mucosal resection (EMR). **H** Treatment of flat dysplasia in Barrett oesophagus using radiofrequency ablation (RFA). Treated areas are indicated by white arrows. **I** Insertion of stent in oesophageal carcinoma (white arrow). **J** Confirmation of position of stent by X-ray (arrow). **K** Endoscopic retrograde cholangiopancreatography (ERCP) to perform sphincterotomy and extraction of common bile duct stones (filling defects, arrowed). **L** Cholangiogram to confirm successful duct clearance. **M** Endoscopic ultrasound (EUS) biopsy of pancreatic mass (white arrows). The biopsy needle is indicated by a blue arrow. **N** EUS cystogastrostomy drainage of pancreatic pseudocyst using a lumen-apposing metal stent (LAMS). **O** Endoscopic view following cystogastrostomy and stent placement (same case as **N**). *Courtesy of Dr Ian Penman.*

with proctoscopy, accurate detection of haemorrhoids, ulcerative colitis and distal colorectal neoplasia is possible. After full bowel cleansing, it is possible to examine the entire colon and the terminal ileum using a colonoscope. Indications, contraindications and complications of colonoscopy are listed in Box 22.9.

Magnetic resonance cholangiopancreatography

Magnetic resonance cholangiopancreatography (MRCP) has largely replaced endoscopic retrograde cholangiopancreatography (ERCP) in the evaluation of obstructive jaundice since it produces comparable images of the biliary tree and pancreas, providing information that complements that obtained from CT and EUS.

Endoscopic retrograde cholangiopancreatography

The technique of endoscopic retrograde cholangiopancreatography (ERCP) involves using a side-viewing duodenoscope, to cannulate the main pancreatic duct and common bile duct. ERCP is used mainly in the treatment of a range of biliary and pancreatic diseases that have been identified by other imaging techniques such as MRCP, EUS and CT. Indications for and risks of ERCP are listed in Box 22.10.

Histology

Biopsy material obtained endoscopically or percutaneously can provide useful diagnostic information (Box 22.11).

Tests of infection

Stool cultures

Stool cultures are essential in the investigation of diarrhoea, especially when it is acute or bloody, in order to identify pathogenic organisms (see Ch. 14). In many laboratories, molecular testing has replaced microscopy for parasitic conditions such as *Giardia lamblia*, *Entamoeba histolytica* and cryptosporidium, but microscopy is still widely used for detection of these pathogens in low- and middle-income countries.

Serology

Detection of antibodies plays a limited role in the diagnosis of gastrointestinal infection except that caused by organisms such as *Helicobacter pylori*, *Salmonella* species and *Entamoeba histolytica*.

Breath tests

Non-invasive breath tests for *H. pylori* infection are discussed on page 832 and breath tests for suspected small intestinal bacterial overgrowth on page 840.

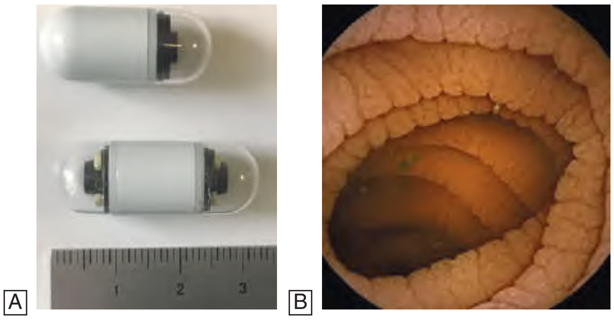

Fig. 22.15 **Wireless capsule endoscopy.** **A** Examples of capsules. **B** Capsule endoscopy image of scalloping of the small bowel suggestive of coeliac disease.

22.7 Wireless capsule endoscopy

Indications

- Obscure gastrointestinal bleeding
- Small bowel Crohn disease
- Assessment of coeliac disease and its complications
- Screening and surveillance in familial polyposis syndromes

Contraindications

- Known or suspected small bowel stricture (risk of capsule retention)
- Caution in people with pacemakers or implantable defibrillators

Complications

- Capsule retention ($<1\%$)

22.8 Double balloon enteroscopy

Indications

Diagnostic

- Obscure gastrointestinal bleeding
- Malabsorption or unexplained diarrhoea
- Suspicious radiological findings
- Suspected small bowel tumour
- Surveillance of polyposis syndromes

Therapeutic

- Coagulation/diathermy of bleeding lesions
- Jejunostomy placement

Contraindications

- As for upper gastrointestinal endoscopy

Complications

- As for upper gastrointestinal endoscopy
- Post-procedure abdominal pain ($\leq 20\%$)
- Pancreatitis (1%–3%)
- Perforation (especially after resection of large polyps)

Tests of function

A number of dynamic tests can be used to investigate aspects of gut function, including digestion, absorption, inflammation and epithelial permeability. Some of the more common ones are listed in Box 22.12. In the assessment of suspected malabsorption, blood tests (full blood count, erythrocyte sedimentation rate (ESR), and measurement of C-reactive protein (CRP), folate, vitamin B_{12}, iron status, albumin, calcium and phosphate) are essential, and endoscopy is undertaken to obtain mucosal biopsies. Faecal calprotectin is very sensitive at detecting mucosal inflammation.

Oesophageal motility

A barium swallow can give useful information about oesophageal motility. Videofluoroscopy, with joint assessment by a speech and language therapist and a radiologist, may be necessary in difficult cases to assess for oropharyngeal dysphagia. High-resolution oesophageal manometry (see Fig. 22.1) often in conjunction with 24-hour pH measurements, is of value in diagnosing cases of refractory gastro-oesophageal reflux, achalasia and non-cardiac chest pain. Oesophageal impedance testing is useful

22.9 Colonoscopy

Indications

- Suspected inflammatory bowel disease
- Chronic diarrhoea
- Altered bowel habit
- Rectal bleeding or iron deficiency anaemia
- Assessment of abnormal radiology
- Colorectal cancer screening
- Colorectal adenoma and carcinoma follow-up
- Therapeutic procedures, including endoscopic resection, dilatation of strictures, laser, stent insertion and argon plasma coagulation

Contraindications

- Acute severe ulcerative colitis (unprepared flexible sigmoidoscopy is preferred)
- As for upper gastrointestinal endoscopy

Complications

- Cardiorespiratory depression due to sedation
- Perforation
- Bleeding

22.10 Endoscopic retrograde cholangiopancreatography

Indications

Diagnostic

- Biliary or pancreatic disease where other imaging is equivocal or contraindicated
- Ampullary biopsy or biliary cytology

Therapeutic

- Biliary disease:
  Removal of common bile duct calculi*
  Palliation of malignant biliary obstruction
  Management of biliary leaks/damage complicating surgery
  Dilatation of benign strictures
  Primary sclerosing cholangitis
- Pancreatic disease:
  Drainage of pancreatic pseudocysts and fistulae
  Removal of pancreatic calculi (selected cases)

Contraindications

- Severe cardiopulmonary comorbidity
- Coagulopathy

Complications

- Occur in 5%–10% with a 30-day mortality of 0.5%–1%

General

- As for upper gastrointestinal endoscopy

Specific

- Biliary disease:
  Bleeding following sphincterotomy
  Cholangitis (if biliary obstruction is not relieved by ERCP)
  Gallstone impaction
- Pancreatic disease:
  Acute pancreatitis
  Infection of pseudocyst

*Laparoscopic surgery is preferred to ERCP in fit individuals who also require cholecystectomy.

22.11 Reasons for biopsy or cytological examination

- Suspected malignant lesions
- Assessment of mucosal abnormalities
- Diagnosis of infection (*Candida*, *Helicobacter pylori*, *Giardia lamblia*)
- Analysis of genetic mutations

i 22.12 Tests of gastrointestinal function

Process	Test	Principle	Comment
Absorption			
Lactose	Lactose H_2 breath test	Measurement of breath H_2 content after 50 g oral lactose. Undigested sugar is metabolised by colonic bacteria in hypolactasia and expired hydrogen is measured	Non-invasive and accurate. May provoke pain and diarrhoea in sufferers
Fructose	Fructose H_2 breath test	Measurement of breath H_2 content after 25–50 g oral fructose. Unabsorbed fructose is fermented by colonic bacteria with expired hydrogen measured	Results can be difficult to interpret as breath testing does not reflect fructose ingestion in everyday life
Bile acids	^{75}SeHCAT test	Isotopic quantification of 7-day whole-body retention of oral dose ^{75}Se-labelled homocholyltaurine ($>15\%$ = normal, 5%–15% borderline, $<5\%$ = abnormal)	Accurate and specific but requires two visits and involves radiation. Results can be equivocal
	Serum 7α-hydroxycholestenone	Intermediate metabolite of the bile acid synthetic pathway. Serum levels indicate activity of the pathway and are elevated in bile acid diarrhoea	Simple to perform and only marginally less sensitive and specific than ^{75}SeHCAT test
Pancreatic exocrine function	Faecal elastase	Immunoassay of pancreatic enzymes on stool sample	Simple, quick and avoids urine collection. Does not detect mild disease
Mucosal inflammation/ permeability	Faecal calprotectin or lactoferrin	Proteins secreted non-specifically by neutrophils into the colon in response to inflammation or neoplasia	Useful screening test for gastrointestinal inflammation and for monitoring patients with Crohn disease and ulcerative colitis. Poor sensitivity for cancer

(^{75}SeHCAT = ^{75}Se-homocholic acid taurine)

for detecting non-acid or gas reflux events, especially in patients with atypical symptoms or those who respond poorly to acid suppression.

Colonic and anorectal motility

A plain abdominal X-ray taken on day 5 after ingestion of different-shaped inert plastic pellets on days 1–3 gives an estimate of whole-gut transit time. The test is useful in the evaluation of chronic constipation, when the position of any retained pellets can be observed and helps to differentiate cases of slow transit from those due to dyssynergic defaecation. The mechanism of defaecation and anorectal function can be assessed by anorectal manometry, electrophysiological tests and defaecating proctography.

Radioisotope tests

Many different radioisotope tests are used (Boxes 22.12 and 22.13). In some, structural information is obtained, such as the localisation of a Meckel diverticulum. Others provide functional information, such as the rate of gastric emptying or ability to reabsorb bile acids. Others are tests of infection and rely on the presence of bacteria to hydrolyse a radio-labelled test substance followed by detection of the radioisotope in expired air, such as the urea breath test for *H. pylori*.

Gut hormone testing

Excess gut hormone secretion by some gastrointestinal and pancreatic neuroendocrine tumours can be assessed by measuring levels in blood. Commonly measured hormones include gastrin, somatostatin, vasoactive intestinal polypeptide (VIP) and pancreatic polypeptide.

Presenting problems in gastrointestinal disease

Dysphagia

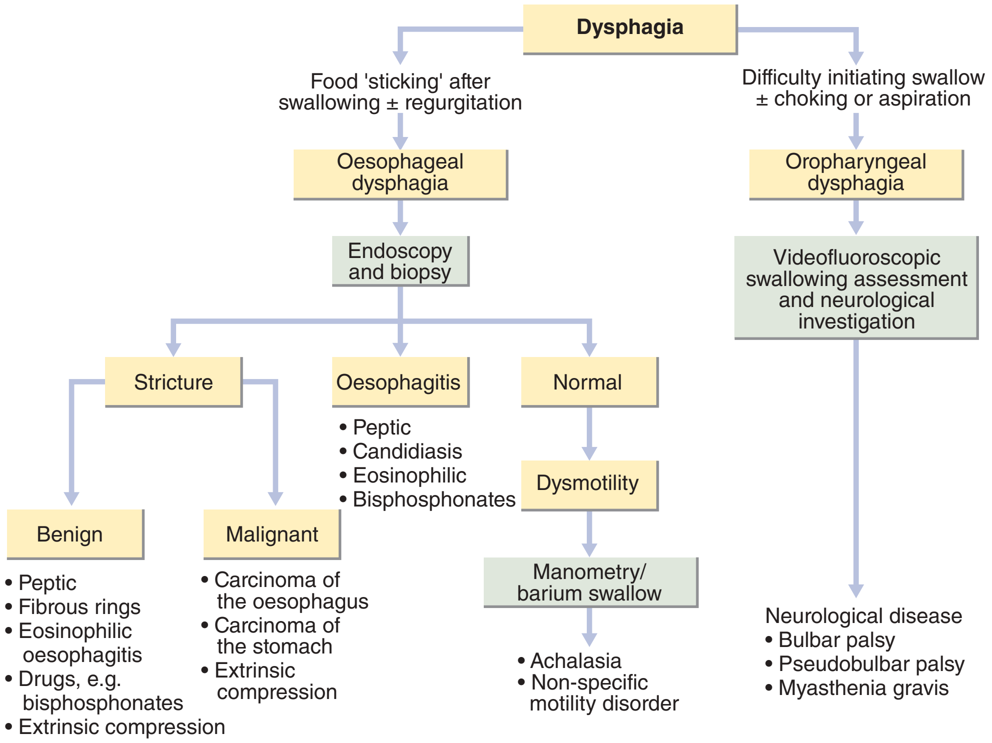
Dysphagia is defined as difficulty in swallowing. It may coexist with heartburn or vomiting but should be distinguished from both globus sensation (in which anxious people feel a lump in the throat without organic cause) and odynophagia (pain during swallowing, usually from gastro-oesophageal reflux or candidiasis).

i 22.13 Functional tests involving radioisotopes

Test	Isotope	Major uses and principle of test
Gastric emptying study	^{99m}Tc-sulphur ^{111}In-DTPA	Assessment of gastric emptying, particularly for possible gastroparesis
Urea breath test	^{13}C-urea	Non-invasive diagnosis of *Helicobacter pylori*. Bacterial urease enzyme splits urea to ammonia and CO_2, which is detected in expired air
Meckel scan	^{99m}Tc-pertechnetate	Diagnosis of Meckel diverticulum in cases of obscure gastrointestinal bleeding. Isotope is injected intravenously and localises in ectopic parietal mucosa within diverticulum
Somatostatin receptor scintigraphy (SRS)	^{111}In-DTPA-octreotide ^{99m}Tc-tektrotyd	Staging neuroendocrine tumours. Labelled somatostatin analogues bind to cell surface somatostatin receptors on neuroendocrine cancer cells
Positron emission tomography–CT (PET-CT)	^{18}F-FDG ^{68}Ga-labelled somatostatin analogue	Staging high-grade cancers More sensitive and specific than SRS for staging neuroendocrine tumours

(C = carbon; DTPA = diethylenetriaminepentaacetic acid; FDG = fluorodeoxyglucose; Ga = gallium; In = indium; Tc = technetium)

Dysphagia can occur due to problems in the oropharynx or oesophagus. Figure 22.16 summarises a diagnostic approach to dysphagia and lists the major causes. Oropharyngeal disorders affect the initiation of swallowing at the pharynx and upper oesophageal sphincter. The patient has difficulty initiating swallowing and complains of choking, nasal regurgitation or tracheal aspiration. Drooling, dysarthria, hoarseness and cranial nerve or other neurological signs may be present. Oesophageal disorders cause dysphagia by obstructing the lumen or by affecting motility. Patients with oesophageal disease complain of food 'sticking'



Dysphagia
Food 'sticking' after swallowing ± regurgitation
Difficulty initiating swallow ± choking or aspiration

• Non-specific motility disorder
Neurological disease
• Bulbar palsy
• Pseudobulbar palsy
• Myasthenia gravis

Fig. 22.16 Investigation of dysphagia.

after swallowing, although the level at which this is felt correlates poorly with the true site of obstruction. Swallowing of liquids is normal until strictures become extreme.

Investigations

Dysphagia should always be investigated urgently. Endoscopy is the investigation of choice because it allows biopsy and dilatation of strictures. Even if the appearances are normal, biopsies should be taken to look for eosinophilic oesophagitis. If no abnormality is found, then barium swallow with videofluoroscopic swallowing assessment can be used to detect major motility disorders. In some cases, high-resolution oesophageal manometry is required, allowing accurate classification of abnormalities.

Dyspepsia

Dyspepsia describes symptoms such as discomfort, bloating and nausea, which are thought to originate from the upper gastrointestinal tract. There are many causes (Box 22.14) including some arising outside the digestive system. Heartburn and other 'reflux' symptoms are separate entities and are considered elsewhere. Although symptoms often correlate poorly with the underlying diagnosis, a careful history is important to detect 'alarm' features requiring urgent investigation (Box 22.15) and to detect atypical symptoms that might be due to problems outside the gastrointestinal tract.

Dyspepsia affects up to 80% of the population at some time in life and most patients have no serious underlying disease. People who present with new dyspepsia at an age of more than 55 years and younger patients unresponsive to empirical treatment require investigation to exclude serious disease. An algorithm for the investigation of dyspepsia is outlined in Figure 22.17.

22.14 Causes of dyspepsia

Upper gastrointestinal disorders

- Peptic ulcer disease
- Acute gastritis
- Gallstones
- Oesophageal spasm
- Non-ulcer dyspepsia
- Irritable bowel syndrome

Other gastrointestinal disorders

- Pancreatic disease (cancer, chronic pancreatitis)
- Colonic carcinoma
- Hepatic disease (hepatitis, metastases)

Systemic disease

- Renal failure
- Hypercalcaemia

Drugs

- Non-steroidal anti-inflammatory drugs (NSAIDs)
- Glucocorticoids
- Iron and potassium supplements
- Digoxin

Others

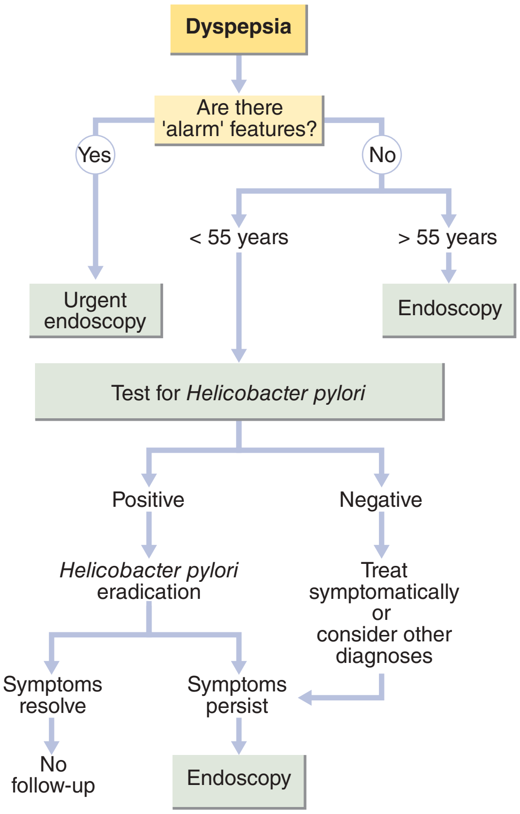
Psychological (anxiety, depression)
Alcohol

22.15 Alarm features in dyspepsia

- Unintentional weight loss
- Anaemia
- Persistent vomiting
- Haematemesis and/or melaena
- Dysphagia
- Palpable abdominal mass

Heartburn and regurgitation

Heartburn describes retrosternal, burning discomfort, often rising up into the chest and sometimes accompanied by regurgitation of acidic or bitter fluid into the throat. These symptoms often occur after meals, on lying down or with bending, straining or heavy lifting. They are classical symptoms of gastro-oesophageal reflux but up to 50% of patients present with other symptoms, such as chest pain, belching, halitosis, chronic cough or sore throats. In young patients with typical symptoms and a good response to dietary changes, antacids or acid suppression



Dyspepsia
Are there 'alarm' features?
Yes

Endoscopy

Fig. 22.17 **Investigation of dyspepsia.**

investigation is not required, but patients aged over 55 years and those with alarm symptoms or atypical features need urgent endoscopy.

Vomiting

Vomiting is a complex reflex involving both autonomic and somatic neural pathways. Synchronous contraction of the diaphragm, intercostal muscles and abdominal muscles raises intra-abdominal pressure and combined with relaxation of the lower oesophageal sphincter, results in forcible ejection of gastric contents. It is important to distinguish true vomiting from regurgitation and to elicit whether the vomiting is acute or chronic (recurrent), as the underlying causes may differ. The major causes are shown in Box 22.16.

22.16 Causes of vomiting

Drugs

- Alcohol excess
- NSAIDs
- Opiates
- Digoxin
- Antibiotics
- Cytotoxins

Infections

- Hepatitis
- Gastroenteritis
- Urinary tract infection

Metabolic

- Diabetic ketoacidosis
- Addison disease

Psychogenic

Central nervous system disorders

- Vestibular neuronitis
- Migraine
- Raised intracranial pressure
- Meningitis

Gastroduodenal

- Peptic ulcer disease
- Gastric cancer
- Gastroparesis

Uraemia

The acute abdomen

- Appendicitis
- Cholecystitis
- Pancreatitis
- Intestinal obstruction

Gastrointestinal bleeding

Acute upper gastrointestinal bleeding

This is the most common gastrointestinal emergency, with an estimated incidence of 134 per 100 000 of the population in the UK; the mortality of patients admitted to hospital is around 10%. Risk scoring systems such as the modified Blatchford Score have been developed to stratify the risk of needing endoscopic therapy or of having a poor outcome (Box 22.17). The advantage of the Blatchford score is that it may be used before endoscopy to predict the need for intervention to treat bleeding. Low scores (2 or less) are associated with a very low risk of adverse outcome. The common causes are shown in Figure 22.18.

Clinical assessment

Haematemesis is red with clots when bleeding is rapid and profuse, or black ('coffee grounds') when less severe. Syncope may occur and is caused by hypotension from intravascular volume depletion. Symptoms of anaemia suggest chronic bleeding. Melaena is the passage of black, tarry stools containing altered blood; it is usually caused by bleeding from the upper gastrointestinal tract, although haemorrhage from the right side of the colon is occasionally responsible. The characteristic colour and smell are the result of the action of digestive enzymes and of bacteria on haemoglobin. Severe acute upper gastrointestinal bleeding can sometimes cause maroon or bright red stool.

Management

The principles of emergency management of non-variceal bleeding are discussed in detail below. Management of variceal bleeding is discussed in Chapter 23.

Intravenous access

The first step is to gain intravenous access, ideally using two large-bore cannulae.

Initial clinical assessment

- *Define circulatory status*. Severe bleeding causes tachycardia, hypotension and oliguria. The patient is cold and sweating, and may be agitated.
- *Seek evidence of liver disease*. Jaundice, cutaneous stigmata, hepatosplenomegaly and ascites may be present in decompensated cirrhosis.
- *Identify comorbidity*. The presence of cardiorespiratory, cerebrovascular or renal disease is important, both because these may be worsened by acute bleeding and because they increase the hazards of endoscopy and surgical operations. These comorbidities are, therefore, a common cause of death following acute gastrointestinal haemorrhage, even after successful haemostasis.

22.17 Modified Blatchford score: risk stratification in acute upper gastrointestinal bleeding

Admission risk marker	Score component value
Blood urea

None of the above	0

Basic investigations

- *Full blood count*. Chronic or subacute bleeding leads to anaemia, but the haemoglobin concentration may be normal after sudden, major bleeding until haemodilution occurs. Thrombocytopenia may be a clue to the presence of hypersplenism in chronic liver disease.
- *Urea and electrolytes*. This test may show evidence of renal failure. The blood urea rises as the absorbed products of luminal blood are metabolised by the liver; an elevated blood urea with normal creatinine concentration implies severe bleeding.
- *Liver function tests*. These may show evidence of chronic liver disease.
- *Prothrombin time*. Check when there is a clinical suggestion of liver disease or patients are anticoagulated.
- *Cross-matching*. At least 2 units of blood should be cross-matched if a significant bleed is suspected.

Resuscitation

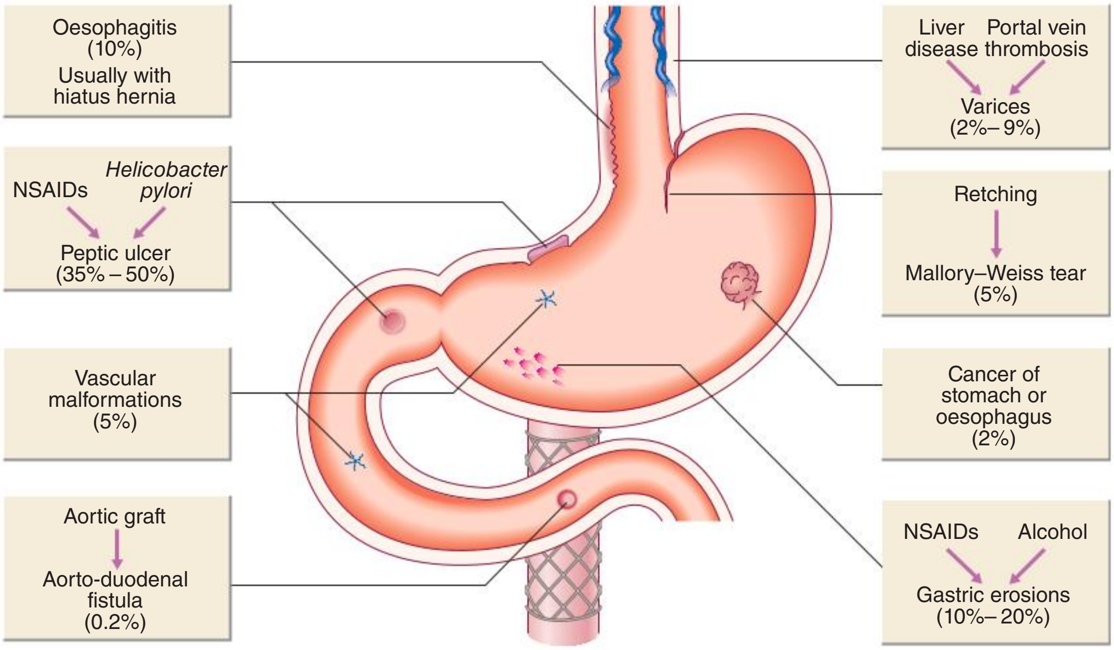
Intravenous crystalloid fluids should be given to raise the blood pressure, with a 500 mL bolus recommended over less than 15 minutes in haemodynamically unstable patients. In most patients, blood should be transfused when haemoglobin is less than 70 g/L, although transfusion should be considered at higher levels in those with haemodynamic instability or ischaemic heart disease.

Oxygen

Oxygen saturations should be monitored with pulse oximetry, with a target saturation of 94%–98% and oxygen prescribed as required.

Antithrombotic drugs

An increasing number of individuals present with an upper gastrointestinal bleed while using antithrombotic medication. Aspirin can be continued during an upper gastrointestinal bleed. P2Y12-receptor antagonists like clopidogrel should be temporarily stopped (unless prescribed following coronary artery stenting), as well as warfarin and directly acting oral anticoagulant drugs. However, early reintroduction of these medications should occur after haemostasis has been achieved to reduce thrombotic events and death.



Oesophagitis (10%)
Usually with hiatus hernia
NSAIDs
Helicobacter pylori
Peptic ulcer (35% – 50%)
Vascular malformations (5%)
Aortic graft
Aorto-duodenal fistula (0.2%)
Liver disease
Portal vein thrombosis
Varices (2%– 9%)
Retching
Mallory–Weiss tear (5%)
Cancer of stomach or oesophagus (2%)
NSAIDs
Alcohol
Gastric erosions (10%– 20%)

Fig. 22.18 Causes of acute upper gastrointestinal haemorrhage. Frequency is given in parentheses. (NSAIDs = non-steroidal anti-inflammatory drugs)

Proton pump inhibitor therapy

Intravenous proton pump inhibitor (PPI) infusion should be given in non-variceal bleeding, in individuals who have a high-risk ulcer post endoscopy (ulcers with a clot and/or those which require endoscopic haemostasis). PPIs work by reducing gastric acid secretion, neutralising intragastric pH, promoting clot stability by reducing pepsin-induced clot lysis and increasing platelet aggregation. While intravenous PPI infusion is most frequently used, intermittent intravenous PPI and oral high-dose PPI can be considered as alternatives. Box 22.18 summarises the dose regiments of the most common PPIs used.

Endoscopy

This should be carried out after adequate resuscitation, ideally within 24 hours; it yields a diagnosis in approximately 80% of cases. Patients with major endoscopic stigmata of recent haemorrhage (Fig. 22.19) can be treated endoscopically using a thermal or mechanical modality, such as a 'heater probe' or endoscopic clips, combined with injection of dilute adrenaline (epinephrine) into the bleeding point ('dual therapy'). A biologically inert haemostatic mineral powder (TC325, 'haemospray') can be used as rescue therapy when standard therapy fails. This may stop active bleeding and combined with PPI therapy may prevent rebleeding, thus avoiding the need for surgery. Newer techniques, such as 'over-the-scope clips', may also be used as a rescue therapy when standard therapy fails, treating large vessels or fibrotic lesions. Patients found to have bled from varices should be treated by band ligation (p. 902); balloon tamponade is another option if this fails, while arrangements are made for a transjugular intrahepatic portosystemic shunt (TIPSS). Balloon tamponade can be associated with serious complications, and newer techniques such as removable, self-expanding, covered metal oesophageal stents may be used as an alternative option.

i 22.18 Dosages of commonly used proton pump inhibitors for peptic ulcer disease

Oral administration		
	Standard dose	High dose
Lansoprazole	30 mg OD	30 mg BD
Omeprazole	20 mg OD	40 mg OD
Pantoprazole	40 mg OD	40 mg BD
Rabeprazole	20 mg OD	20 mg BD
Esomeprazole	20 mg OD	40 mg OD
Intravenous infusion		
	Dose	
Omeprazole Pantoprazole Esomeprazole	80 mg IV bolus, followed by 8 mg/hr for 72 hrs	

(BD = twice daily; IV = intravenous; OD = once daily)

Monitoring

Patients should be closely observed, with hourly measurements of pulse, blood pressure, oxygen saturations and urine output.

Radiology and surgery

Patients who have recurrent bleeding, where endoscopic attempts at haemostasis have failed, should be considered for radiological or surgical intervention. If available, angiographic control of bleeding is generally preferred to surgery in older, frail patients. If surgery is required, the choice of operation depends on the site and diagnosis of the bleeding lesion. Duodenal ulcers are treated by under-running, with or without pyloroplasty. Under-running for gastric ulcers can also be carried out (a biopsy must be taken to exclude carcinoma). Local excision may be performed, but when neither is possible, partial gastrectomy is required.

Eradication

Following treatment for ulcer bleeding, all patients should avoid non-steroidal anti-inflammatory drugs (NSAIDs) and those who test positive for *H. pylori* infection should receive eradication therapy (p. 832). Successful eradication should be confirmed by urea breath or faecal antigen testing.

Lower gastrointestinal bleeding

The incidence of lower gastrointestinal bleeding is around 30–90 per 100 000 of the population in the UK, with an in-hospital mortality of around 4%. This may be caused by haemorrhage from the colon, anal canal or small bowel. It is useful to distinguish those patients who present with profuse, acute bleeding from those who present with chronic or subacute bleeding of lesser severity (Box 22.19).

Severe acute lower gastrointestinal bleeding

This presents with profuse red or maroon diarrhoea and with hypovolaemic shock. If available, CT angiography should be performed initially to localise the site of blood loss. If the bleeding source is identified, then catheter angiography with embolisation should be performed. If no source of bleeding is found, then a colonoscopy should be performed.

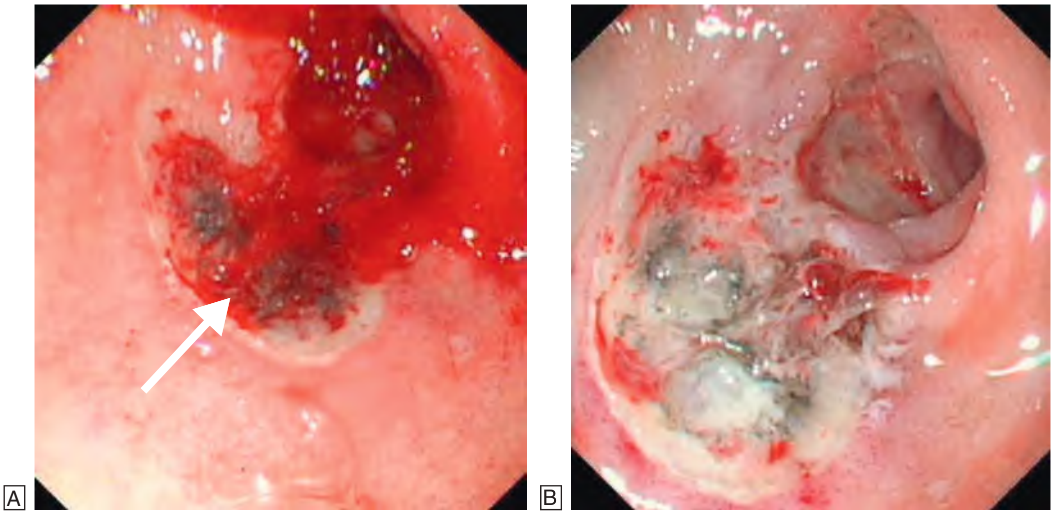


Fig. 22.19 Major stigmata of recent haemorrhage and endoscopic treatment. A Active bleeding from a duodenal ulcer (arrow). B Haemostasis is achieved after endoscopic injection of adrenaline (epinephrine) and application of a heater probe.

i 22.19 Causes of lower gastrointestinal bleeding

Severe acute

- Diverticular disease
- Angiodysplasia
- Ischaemia
- Meckel diverticulum
- Inflammatory bowel disease (rarely)

Moderate, subacute or chronic

- Fissure
- Haemorrhoids
- Inflammatory bowel disease
- Carcinoma
- Large polyps
- Angiodysplasia
- Radiation enteritis
- Solitary rectal ulcer

Some patients presenting with an apparent severe lower gastrointestinal bleed are ultimately found to have a significant upper gastrointestinal bleed and may require an upper gastrointestinal endoscopy.

The commonest cause of lower gastrointestinal bleeding is diverticular disease, with up to two-thirds of cases being classified as severe. Bleeding from diverticular disease is often due to erosion of an artery within the mouth of a diverticulum. Multiple endoscopic options are available, with endoscopic clipping either alone or after the injection of dilute adrenaline (epinephrine) considered as first-line treatment in the UK. Angiodysplasia is a disease of older adults, in which vascular malformations develop within the gastrointestinal tract, commonly in the caecum. Bleeding can be acute and profuse; it usually stops spontaneously but commonly recurs. Diagnosis is often difficult. Colonoscopy may reveal characteristic vascular spots, and in the acute phase, angiography can show bleeding into the intestinal lumen and an abnormal large, draining vein. The treatment of choice is endoscopic thermal ablation, but resection of the affected bowel may be required if bleeding continues. Bowel ischaemia due to occlusion of the inferior mesenteric artery can present with abdominal colic and rectal bleeding. It should be considered in patients (particularly older patients) who have evidence of generalised atherosclerosis. The diagnosis is made at colonoscopy. Resection is required only in the presence of peritonitis. Meckel diverticulum with ectopic gastric epithelium may ulcerate and erode into a major artery. The diagnosis should be considered in children or adolescents who present with profuse or recurrent lower gastrointestinal bleeding. A Meckel technetium-99m (^{99m}Tc)-pertechnetate scan is sometimes positive, but the diagnosis is commonly made only by laparotomy, at which time the diverticulum is excised.

Subacute or chronic lower gastrointestinal bleeding

This can occur at all ages and can be due to haemorrhoids or anal fissure. Haemorrhoidal bleeding is bright red and occurs during or after defaecation. Proctoscopy can be used to make the diagnosis, but individuals who have altered bowel habit and those who present over the age of 40 years should undergo colonoscopy to exclude coexisting colorectal cancer. Anal fissure should be suspected when fresh rectal bleeding and anal pain occur during defaecation.

Major gastrointestinal bleeding of unknown cause

In some patients who present with major gastrointestinal bleeding, upper endoscopy, colonoscopy and CT angiography may fail to reveal a diagnosis. Wireless capsule endoscopy is increasingly used in such patients. The diagnostic yield is highest when performed as close as possible to the bleeding episode, particularly within the first 48 hours of presenting with bleeding. Wireless capsule endoscopy is often used to define a source of bleeding prior to enteroscopy (Fig. 22.20) with push or double balloon enteroscopy being used to visualise the small intestine and treat the bleeding source. When all else fails, laparotomy with on-table endoscopy is indicated.

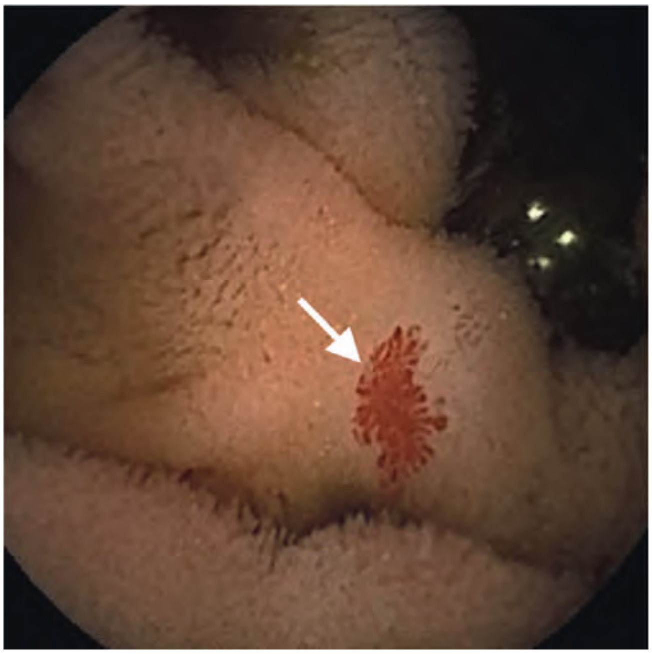

Fig. 22.20 Angiodysplastic lesion (arrow) noted on capsule endoscopy.

Chronic occult gastrointestinal bleeding

In this context, occult means that blood or its breakdown products are present in the stool but cannot be seen by the naked eye. Occult bleeding may reach 200 mL per day and cause iron deficiency anaemia. Any cause of gastrointestinal bleeding may be responsible, but the most important is colorectal cancer, particularly carcinoma of the caecum, which may produce no gastrointestinal symptoms. In clinical practice, investigation of the upper and lower gastrointestinal tract should be performed whenever a patient presents with unexplained iron deficiency anaemia.

Diarrhoea

Diarrhoea is defined as the passage of three or more loose or liquid stools per day. The most severe symptom in many patients is urgency of defaecation, while faecal incontinence can occur in acute and chronic diarrhoeal illnesses.

Acute diarrhoea

This is extremely common and is usually caused by faecal–oral transmission of bacteria or their toxins, viruses or parasites (see Ch. 14). Infective diarrhoea is usually short-lived and patients who present with a history of diarrhoea lasting more than 10 days rarely have an infective cause. A variety of drugs, including antibiotics, cytotoxic drugs, PPIs and NSAIDs, may be responsible.

Chronic or relapsing diarrhoea

Chronic diarrhoea can be categorised as being caused by disease of the colon or small bowel, or due to malabsorption (Box 22.20). Clinical presentation, examination of the stool, routine blood tests and imaging reveal a diagnosis in many cases. Young patients (< 40 years) with typical symptoms of a functional bowel disorder, with negative initial investigations, may have a diagnosis of irritable bowel syndrome (p. 865).

i 22.20 Causes of chronic or relapsing diarrhoea

	Colonic	Malabsorption	Small bowel
Clinical features	Blood and mucus in stool Cramping lower abdominal pain	Steatorrhoea Undigested food in the stool Weight loss and nutritional disturbances	Large-volume, watery stool Abdominal bloating Cramping mid-abdominal pain
Causes	Inflammatory bowel disease Microscopic colitis Neoplasia Ischaemia Irritable bowel syndrome	Pancreatic: Chronic pancreatitis Cancer of pancreas Cystic fibrosis Enteropathy: Coeliac disease Tropical sprue Lymphoma Lymphangiectasia	Crohn disease Neuroendocrine tumour Small bowel carcinoid VIPoma Drug-induced: NSAIDs Aminosalicylates SSRIs
Investigations	Faecal calprotectin Ileocolonoscopy with biopsies	Faecal elastase Ultrasound, CT and MRCP Small bowel biopsy Barium follow-through or small bowel MRI	Faecal calprotectin Stool volume Serum gut hormone profile and 24 hr urine 5HIAA Barium follow-through or small bowel MRI

(5HIAA = 5-hydroxyindoleacetic acid; CT = computed tomography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; NSAIDs = non-steroidal anti-inflammatory drugs; SSRIs = selective serotonin re-uptake inhibitors; VIP = vasoactive intestinal polypeptide)

Malabsorption

Diarrhoea and weight loss in patients with a normal diet are likely to be caused by malabsorption. The symptoms are diverse in nature and variable in severity. A few patients have apparently normal bowel habit, but diarrhoea usually occurs and may be watery and voluminous. Bulky, pale and offensive stools that float in the toilet (steatorrhoea) signify fat malabsorption. Abdominal distension, borborygmi, cramps, weight loss and undigested food in the stool may be present. Some patients complain only of malaise and lethargy. In others, symptoms related to deficiencies of specific vitamins, trace elements and minerals may occur (Fig. 22.21).

Pathophysiology

Malabsorption results from abnormalities of the three processes that are essential to normal digestion:

- *Intraluminal maldigestion* occurs when deficiency of bile or pancreatic enzymes results in inadequate solubilisation and hydrolysis of nutrients. Fat and protein malabsorption results. This may also occur with small bowel bacterial overgrowth.
- *Mucosal malabsorption* results from small bowel resection or conditions that damage the small intestinal epithelium, thereby diminishing the surface area for absorption and depleting brush border enzyme activity.
- *'Post-mucosal' lymphatic obstruction* prevents the uptake and transport of absorbed lipids into lymphatic vessels. Increased pressure in these vessels results in leakage into the intestinal lumen, leading to protein-losing enteropathy.

Investigations

Investigations should be performed both to confirm the presence of malabsorption and to determine the underlying cause. Routine blood tests may show one or more of the abnormalities listed in Box 22.21. Tests to confirm fat and protein malabsorption should be performed (see Box 22.12). An approach to the investigation of malabsorption is shown in Figure 22.22.

Weight loss

Weight loss may be physiological, due to dieting, exercise, starvation or the decreased nutritional intake that accompanies old age. Weight loss of more than 5% of usual body weight over 6–12 months is clinically important and can indicate the presence of an underlying disease. Hospital and general practice weight records may be valuable in confirming that weight loss has occurred, as may reweighing patients at intervals; sometimes weight is regained or stabilises in those with no obvious cause. Pathological weight loss can be due to psychiatric illness, systemic disease, gastrointestinal causes or advanced disease of many organ systems (Fig. 22.23).

Physiological causes

Weight loss can occur in the absence of serious disease in healthy individuals who have changes in physical activity or social circumstances. It may be difficult to be sure of this diagnosis in older patients, when the dietary history may be unreliable, and professional help from a dietitian may be required.

Psychiatric illness

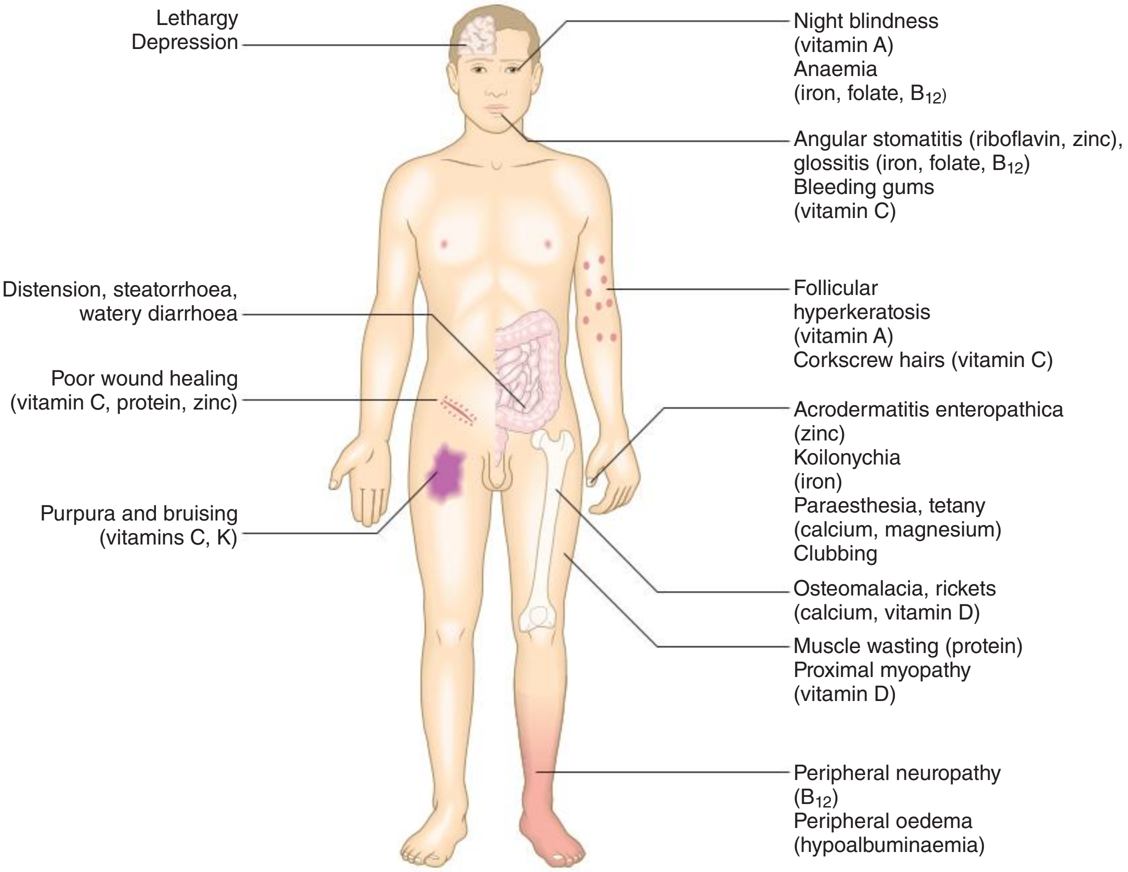
Features of anorexia nervosa, bulimia and affective disorders (see Ch. 29) may be apparent only after formal psychiatric input. Patients with alcohol dependence lose weight as a consequence of self-neglect and poor dietary intake. Depression as well as some psychiatric medications may cause weight loss.

Systemic disease

Chronic infections, including tuberculosis (Ch. 17), recurrent urine or chest infections, and a range of parasitic and protozoan infections (Ch. 14), should be considered. A history of foreign travel, high-risk activities and specific features, such as fever, night sweats, rigors, productive cough and dysuria, must be sought. High-risk sexual activity and recreational drug misuse may suggest human immunodeficiency virus (HIV)-related illness (Ch. 14). Weight loss is a late feature of disseminated malignancy, but by the time the patient presents, other features of cancer are often present. Chronic inflammatory diseases, such as rheumatoid arthritis and polymyalgia rheumatica (Ch. 25), are often associated with weight loss.

Gastrointestinal disease

Almost any disease of the gastrointestinal tract can cause weight loss. Dysphagia and gastric outflow obstruction (p. 834) cause weight loss by reducing food intake. Malignancy at any site may cause weight loss by mechanical obstruction, anorexia or cytokine-mediated systemic effects. Malabsorption from pancreatic diseases (p. 868) or small bowel causes



Lethargy
Depression
Night blindness
(vitamin A)
Anaemia
(iron, folate, B_{12})
Angular stomatitis (riboflavin, zinc),

i 22.21 Routine blood test abnormalities in malabsorption

Haematology

- Microcytic anaemia (iron deficiency)
- Macrocytic anaemia (folate or B_{12} deficiency)
- Increased prothrombin time (vitamin K deficiency)

Biochemistry

- Hypoalbuminaemia
- Hypocalcaemia
- Hypomagnesaemia
- Hypophosphataemia
- Low serum zinc

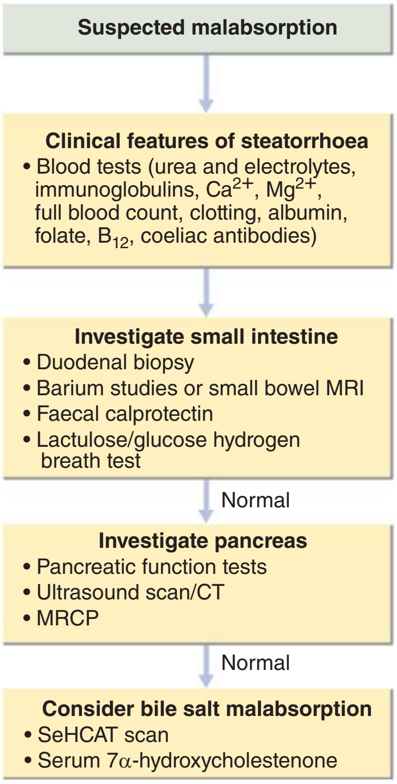
may lead to profound weight loss with specific nutritional deficiencies (p. 100). Inflammatory diseases, such as Crohn disease or ulcerative colitis (p. 853), cause anorexia, fear of eating and loss of protein, blood and nutrients from the gut.

Metabolic disorders and miscellaneous causes

Weight loss may occur in association with metabolic disorders, such as a new presentation of type 1 diabetes or thyrotoxicosis, as well as end-stage respiratory and cardiac disease.

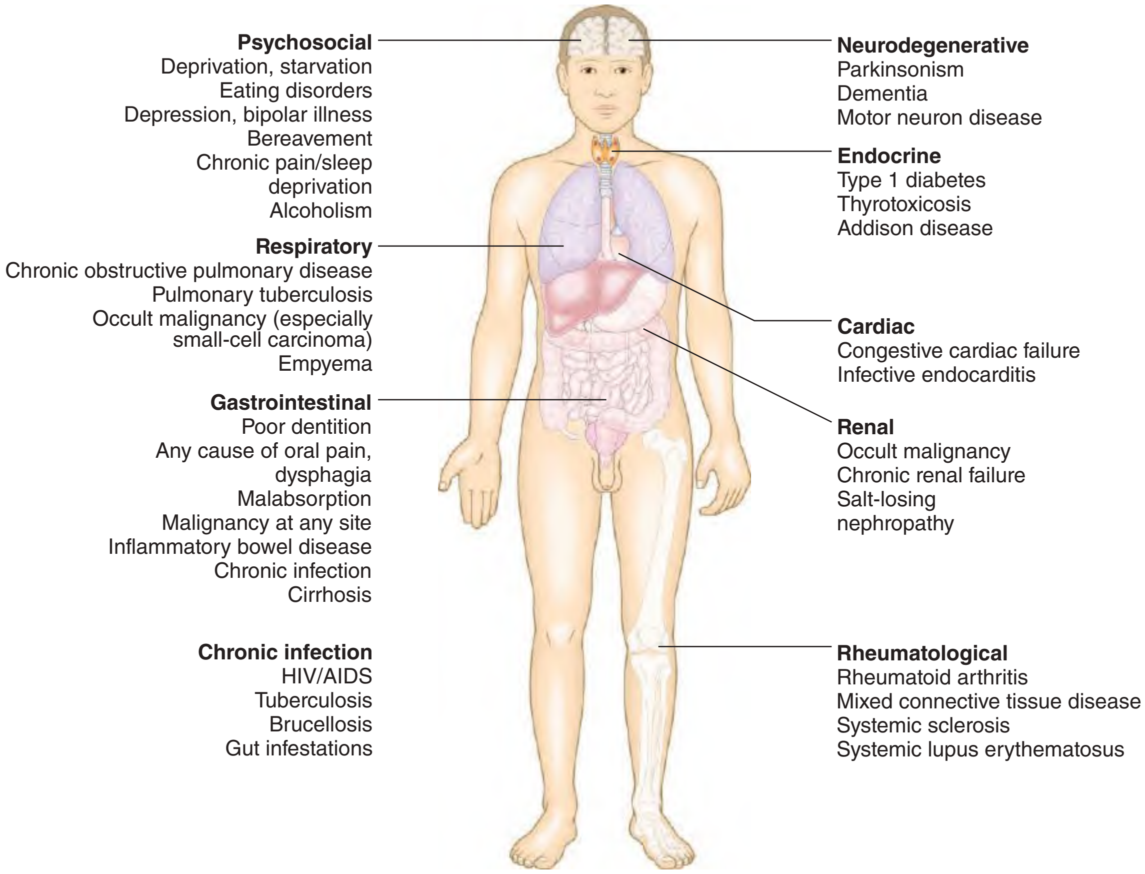
Investigations

In cases where the cause of weight loss is not obvious after thorough history-taking and physical examination, or where an existing condition is considered unlikely, the following investigations are indicated: urinalysis for glucose, protein and blood; blood tests, including liver



Suspected malabsorption
Clinical features of steatorrhoea
• Blood tests (urea and electrolytes, immunoglobulins, Ca^{2+}, Mg^{2+}, full blood count, clotting, albumin, folate, B_{12}, coeliac antibodies)
Investigate small intestine
• Duodenal biopsy
• Barium studies or small bowel MRI
• Faecal calprotectin
• Lactulose/glucose hydrogen breath test
Normal
Investigate pancreas
• Pancreatic function tests
• Ultrasound scan/CT
• MRCP
Normal
Consider bile salt malabsorption
• SeHCAT scan
• Serum 7α-hydroxycholestenone

Fig. 22.22 **Investigation for suspected malabsorption.** (CT = computed tomography; MRCP = magnetic resonance cholangiopancreatography; MRI = magnetic resonance imaging; ^{75}SeHCAT = ^{75}Se-homocholic acid taurine)



Psychosocial
Deprivation, starvation
Eating disorders
Depression, bipolar illness
Bereavement
Chronic pain/sleep deprivation
Alcoholism
Respiratory
Chronic obstructive pulmonary disease
Pulmonary tuberculosis
Occult malignancy (especially small-cell carcinoma)
Empyema
Gastrointestinal

Mixed connective tissue disease
Systemic sclerosis
Systemic lupus erythematosus

Fig. 22.23 Some important causes of weight loss.

function tests, random blood glucose and thyroid function tests; CRP and ESR (may be raised in unsuspected infections, such as tuberculosis, connective tissue disorders and malignancy); and faecal calprotectin. Where the cause of weight loss is still unclear, chest X-ray, whole-body CT imaging and/or endoscopic investigation may be required. Rarely, tests such as bone marrow aspiration or liver biopsy may be necessary to identify conditions like cryptic miliary tuberculosis (Ch. 17). Before embarking on invasive or costly investigations, it is always worth revisiting the patient's history and reweighing at intervals.

Constipation

Constipation is defined as infrequent passage of hard stools. Patients may also complain of straining, a sensation of incomplete evacuation and either perianal or abdominal discomfort. Constipation can be acute, typically lasting less than 1 week, or chronic, lasting greater than 4 weeks. Chronic constipation is normally due to a diet with insufficient fibre, a sedentary lifestyle or disorders of rectal evacuation.

Secondary causes of chronic constipation are numerous, including drugs such as opiates. The causes of constipation are summarised in Box 22.22.

Clinical assessment and management

The onset, duration and characteristics are important; for example, a neonatal onset suggests Hirschsprung disease, while a recent change in bowel activity in middle age should raise the suspicion of an organic disorder, such as colonic carcinoma. The presence of rectal bleeding, pain and weight loss is important, as are excessive straining, symptoms suggestive of irritable bowel syndrome, a history of childhood constipation and emotional distress.

Careful examination contributes more to the diagnosis than extensive investigation. A search should be made for general medical disorders, as well as signs of intestinal obstruction. Neurological disorders, especially spinal cord lesions, should be sought. Perineal inspection and rectal examination are essential and may reveal abnormalities of the pelvic floor (abnormal descent, impaired sensation), anal canal or rectum (masses, faecal impaction, prolapse).

It is neither possible nor appropriate to investigate every person with constipation. For those with chronic constipation, investigation will usually proceed along the lines described below.

Initial investigations

A thorough history and physical examination should be performed. Careful digital rectal examination and inspection of the perineum is essential, and useful in the assessment of pelvic floor abnormalities. A full blood count, routine biochemistry, including serum calcium and thyroid function tests, should be carried out. If these are normal, then dietary and lifestyle modifications should be advised, such as increased fluid intake, dietary fibre supplementation and exercise. Laxatives should be commenced if individuals fail to respond. Organic causes should be explored using colonoscopy in individuals with concerning symptoms such as rectal bleeding, pain or weight loss.

Further investigations

If no cause is found and disabling symptoms are present, then specialist referral for investigation of possible dysmotility may be necessary. The problem may be due to delayed transit of stool in the colon (slow transit constipation) or from functional abnormalities in the pelvic floor and anal sphincter muscles (dyssynergic defaecation). Intestinal marker studies, anorectal manometry, electrophysiological studies and magnetic resonance proctography can all be used to define the problem.

22.22 Causes of constipation

Gastrointestinal causes

Dietary

- Lack of fibre and/or fluid intake

Motility

- Slow-transit constipation
- Irritable bowel syndrome
- Drugs (see below)
- Chronic intestinal pseudo-obstruction

Structural

- Colonic carcinoma
- Diverticular disease
- Hirschsprung disease

Defaecation

- Anorectal disease (Crohn disease, fissures, haemorrhoids)
- Dyssynergic defaecation

Non-gastrointestinal causes

Drugs

- Opiates
- Anticholinergics
- Calcium antagonists
- Iron supplements
- Aluminium-containing antacids

Neurological

- Multiple sclerosis
- Spinal cord lesions
- Cerebrovascular accidents
- Parkinsonism

Metabolic/endocrine

- Diabetes mellitus
- Hypercalcaemia
- Hypothyroidism
- Pregnancy

Others

- Any serious illness with immobility, especially in old age
- Depression

Abdominal pain

There are four types of abdominal pain:

- *Visceral*. Gut organs are insensitive to stimuli such as burning and cutting but are sensitive to distension, contraction, twisting and stretching. Pain from unpaired structures is usually, but not always, felt in the midline.
- *Parietal*. The parietal peritoneum is innervated by somatic nerves and its involvement by inflammation, infection or neoplasia causes sharp, well-localised and lateralised pain.
- *Referred pain*. Gallbladder pain, for example, may be referred to the back or shoulder tip.
- *Psychogenic*. Cultural, emotional and psychosocial factors influence everyone's experience of pain. In some patients, no organic cause can be found despite investigation, and psychogenic causes (depression or somatisation disorder) may be responsible (see Ch. 29).

The causes, assessment and management of acute abdominal pain are discussed in Chapter 10.

Chronic or recurrent abdominal pain

It is essential to take a detailed history, paying particular attention to features of the pain and any associated symptoms (Boxes 22.23 and 22.24).

Note should be made of the patient's general demeanour, mood and emotional state, signs of weight loss, fever, jaundice or anaemia. If a thorough abdominal and rectal examination is normal, a careful search should be made for evidence of disease affecting other structures, particularly the vertebral column, spinal cord, lungs and cardiovascular system.

22.23 Extra-intestinal causes of chronic or recurrent abdominal pain

Retroperitoneal

- Aortic aneurysm
- Malignancy
- Lymphadenopathy
- Abscess

Psychogenic

- Depression
- Anxiety
- Hypochondriasis
- Somatisation

Locomotor

- Vertebral compression/fracture
- Abdominal muscle strain

Metabolic/endocrine

- Diabetes mellitus
- Acute intermittent porphyria
- Hypercalcaemia

Drugs/toxins

- Glucocorticoids
- Azathioprine
- Lead
- Alcohol

Haematological

- Sickle-cell disorder
- Haemolytic disorders

Neurological

- Spinal cord lesions
- Tabes dorsalis
- Radiculopathy

22.24 Features to consider when assessing patients with abdominal pain

- Duration
- Site and radiation
- Severity
- Precipitating and relieving factors (food, drugs, alcohol, posture, movement, defaecation)
- Nature (colicky, constant, sharp or dull, wakes patient at night)
- Pattern (intermittent or continuous)
- Associated features (vomiting, dyspepsia, altered bowel habit)

Investigations will depend on the clinical features elicited during the history and examination:

- Endoscopy and ultrasound are indicated for epigastric pain, and for dyspepsia and symptoms suggestive of gallbladder disease.
- Colonoscopy is indicated for patients with altered bowel habit, rectal bleeding or features of obstruction suggesting colonic disease.
- CT or MR angiography should be considered when pain is provoked by food in a patient with widespread atherosclerosis, as this may indicate mesenteric ischaemia.
- Persistent symptoms require exclusion of colonic or small bowel disease. However, young patients with pain related to defaecation, bloating and alternating bowel habit are more likely to have irritable bowel syndrome (p. 865). Simple investigations (blood tests, faecal calprotectin and sigmoidoscopy) are sufficient in the absence of rectal bleeding, weight loss and abnormal physical findings.
- Ultrasound, CT and faecal elastase are required for patients with upper abdominal pain radiating to the back. A history of alcohol misuse, weight loss and diarrhoea suggests chronic pancreatitis or pancreatic cancer.
- Recurrent attacks of pain in the loins radiating to the flanks with urinary symptoms should prompt investigation for renal or ureteric stones by abdominal X-ray, ultrasound and computed tomography of the kidneys, ureters and bladder (CT KUB).
- Chronic abdominal wall pain (CAWP) should be considered when pain is clearly related to movement. It is frequently overlooked and

patients may be misdiagnosed as having a functional disorder. The commonest cause is anterior cutaneous nerve entrapment syndrome. Worsening of the pain when abdominal muscles are tensed by asking the patient to lift their head and shoulders from the examination couch (Carnett sign) may help confirm the diagnosis.

- A past history of psychiatric disturbance, repeated negative investigations or vague symptoms that do not fit any disease or organ pattern suggest a psychological origin for the pain. Careful review of case notes and previous investigations, along with open and honest discussion with the patient, reduces the need for further cycles of unnecessary and invasive tests. Care must always be taken, however, not to miss rare pathology, such as acute intermittent porphyria (p. 687) or atypical presentations of common diseases.

Constant abdominal pain

Patients with chronic pain that is constant or nearly always present usually have features to suggest the underlying diagnosis. No cause will be found in a minority, despite thorough investigation, leading to consideration of functional causes of abdominal pain. Centrally mediated abdominal pain syndrome is characterised by severe constant or frequent abdominal pain that is rarely related to gut function, thought to result from abnormal CNS processing of normal visceral afferent sensory input and psychosocial factors are often operative (see Ch. 29). The management is reliant on establishing an effective patient–physician relationship, psychological support and the appropriate use of drugs such as tricyclic antidepressants to minimise the effects of the pain on social, personal and occupational life. Narcotic bowel syndrome may also present with constant abdominal pain and is associated with increased or continuous use of opioids, with opioid-induced hyperalgesia thought to be the cause for symptoms. Patients tend to have an improvement in pain on withdrawal of opiates.

Disorders of the mouth and salivary glands

Aphthous ulceration

Aphthous ulcers are superficial and painful; they occur in any part of the mouth. Recurrent ulcers occur in around 20% of the population and are particularly common in women prior to menstruation. The cause is unknown, but in severe cases other causes of oral ulceration must be considered Box 22.25. Biopsy is occasionally necessary for diagnosis.

Treatment is generally not required. Acute episodes may be treated with topical glucocorticoids (such as 0.1% triamcinolone in Orabase) or choline salicylate (8.7%) gel. Symptomatic relief is achieved using local anaesthetic mouthwashes. Rarely, patients with very severe, recurrent aphthous ulcers may need oral glucocorticoids.

Oral cancer

Squamous carcinoma of the oral cavity is common worldwide and is more common in males. Five-year survival is around 50%, largely as a result of late diagnosis. Poor diet, alcohol excess and smoking or tobacco chewing are the traditional risk factors, but high-risk, oncogenic strains of human papillomavirus (HPV-16 and HPV-18) have been identified as being responsible for much of the recent increase in incidence, especially in cases affecting the base of tongue, soft palate and tonsils. In parts of Asia, the disease is common among people who chew areca nuts wrapped in leaves of the betel plant ('betel nuts').

Oral cancer may present in many ways (Box 22.26) and a high index of suspicion is required. All possible sources of local trauma or infection should be treated in patients with suspicious lesions, and they should be reviewed after 2 weeks, with biopsy if the lesion persists. Small cancers can be resected but extensive surgery, with neck dissection to remove involved lymph nodes, may be necessary. Some patients can be treated with radical radiotherapy alone, and sometimes chemoradiotherapy is also given after surgery to treat microscopic residual disease. Some tumours may be amenable to photodynamic therapy (PDT), avoiding the need for surgery. Recurrent or metastatic disease may require treatment with the monoclonal antibody cetuximab (an epidermal growth factor receptor inhibitor), in combination with chemotherapy.

22.25 Causes of oral ulceration

Aphthous	
• Idiopathic	• Premenstrual
Infection	
• Fungal (candidiasis) • Viral (herpes simplex, HIV)	• Bacterial, including syphilis, tuberculosis
Gastrointestinal diseases	
• Crohn disease	• Coeliac disease
Dermatological conditions

22.26 Symptoms and signs of oral cancer

- Solitary ulcer without a precipitant
- Solitary white patch ('leucoplakia') that fails to wipe off
- Solitary red patch
- Fixed lump
- Lip numbness in absence of trauma or infection
- Trismus (pain/difficulty in opening the mouth)
- Cervical lymphadenopathy

Candidiasis

The yeast *Candida albicans* is a normal mouth commensal, but it may proliferate to cause thrush. This occurs in babies, debilitated patients, people receiving glucocorticoid or antibiotic therapy, individuals with diabetes and immunosuppressed patients, especially those receiving cytotoxic therapy and those with HIV infection. White patches are seen on the tongue and buccal mucosa. Odynophagia or dysphagia suggests pharyngeal and oesophageal candidiasis. A clinical diagnosis is sufficient to instigate therapy, although brushings or biopsies can be obtained for mycological examination. Oral thrush can be treated using topical treatments such as miconazole or nystatin. Resistant cases or immunosuppressed patients may require oral fluconazole.

Parotitis

Parotitis is caused by viral or bacterial infection. Mumps causes a self-limiting acute parotitis (p. 339). Bacterial parotitis usually occurs as a complication of major surgery. It is a consequence of dehydration and poor oral hygiene and can be avoided by good post-operative care. Patients present with painful parotid swelling, and this can be complicated by abscess formation. Broad-spectrum antibiotics are required, while surgical drainage is necessary for abscesses. Other causes of salivary gland enlargement are listed in Box 22.27 and considerations for oral health in older people are discussed in Box 22.28.

22.27 Causes of salivary gland swelling

- Infection:
  Mumps
  Bacterial (post-operative)
- Calculi
- Sjögren syndrome (Ch. 25)
- Sarcoidosis
- Tumours:
  Benign: pleomorphic adenoma (95% of cases)
  Intermediate: mucoepidermoid tumour
  Malignant: carcinoma

22.28 Oral health in old age

- **Dry mouth**: affects around 40% of healthy older people.
- **Gustatory and olfactory sensation**: declines and chewing power is diminished.
- **Salivation**: baseline salivary flow falls, but stimulated salivation is unchanged.
- **Root caries and periodontal disease**: common partly because oral hygiene deteriorates with increasing frailty.
- **Bacteraemia and sepsis**: may complicate gram-negative anaerobic infection in the periodontal pockets of the very frail.

Disorders of the oesophagus

Gastro-oesophageal reflux disease

Gastro-oesophageal reflux resulting in heartburn affects approximately 15% of the general population.

Pathophysiology

Occasional episodes of gastro-oesophageal reflux are common in healthy individuals. Reflux is normally followed by oesophageal peristaltic waves that efficiently clear the gullet, alkaline saliva neutralises residual acid and symptoms do not occur. Gastro-oesophageal reflux disease develops when the oesophageal mucosa is exposed to gastroduodenal contents for prolonged periods of time, resulting in symptoms and, in a proportion of cases, oesophagitis. Several factors are known to be involved in the development of gastro-oesophageal reflux disease, and these are shown in Figure 22.24.

Abnormalities of the lower oesophageal sphincter

The lower oesophageal sphincter is tonically contracted under normal circumstances, relaxing only during swallowing (see Fig. 22.1).

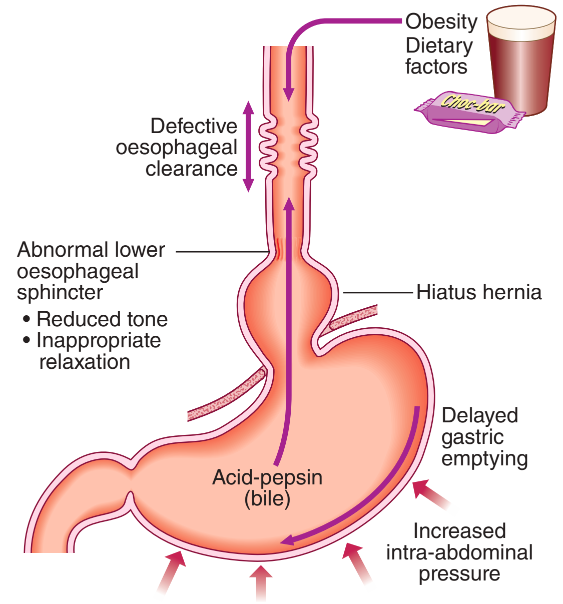
Some patients with gastro-oesophageal reflux disease have reduced lower oesophageal sphincter tone, permitting reflux when intra-abdominal pressure rises. In others, basal sphincter tone is normal, but reflux occurs in response to frequent episodes of inappropriate sphincter relaxation.

Hiatus hernia

Hiatus hernia (Box 22.29 and Fig. 22.25) causes reflux because the pressure gradient is lost between the abdominal and thoracic cavities, which normally pinches the hiatus. In addition, the oblique angle between the cardia and oesophagus disappears. Many patients who have large hiatus hernias develop reflux symptoms, but the relationship between the presence of a hernia and symptoms is poor. Nevertheless, almost all patients who develop oesophagitis, Barrett oesophagus or peptic strictures have a hiatus hernia.

Delayed oesophageal clearance

Defective oesophageal peristaltic activity is commonly found in patients who have oesophagitis. It is a primary abnormality, since it persists after oesophagitis has been healed by acid-suppressing drug therapy. Poor oesophageal clearance increases exposure to gastric acid through acid reflux.



Obesity
Dietary factors
Choc-bar
Defective oesophageal clearance
Abnormal lower oesophageal sphincter
• Reduced tone
• Inappropriate relaxation
Hiatus hernia
Delayed gastric emptying
Acid-pepsin (bile)
Increased intra-abdominal pressure

Fig. 22.24 Factors associated with the development of gastro-oesophageal reflux disease.

22.29 Important features of hiatus hernia

- Herniation of the stomach through the diaphragm into the chest
- Occurs in 30% of the population over the age of 50 years
- Often asymptomatic
- Heartburn and regurgitation can occur
- Gastric volvulus may complicate large hernias

Gastric contents

Gastric acid is the most important oesophageal irritant and there is a close relationship between acid exposure time and symptoms. Pepsin and bile also contribute to mucosal injury.

Defective gastric emptying

Gastric emptying is delayed in patients with gastro-oesophageal reflux disease. The reason is unknown.

Increased intra-abdominal pressure

Pregnancy and obesity are established predisposing causes. Weight loss may improve symptoms.

Dietary and environmental factors

Dietary fat, chocolate, alcohol, tea and coffee relax the lower oesophageal sphincter and may provoke symptoms. The foods that trigger symptoms vary widely between affected individuals.

Patient factors

Visceral sensitivity and patient vigilance play a role in determining symptom severity and consulting behaviour in individual patients.

Clinical features

The major symptoms are heartburn and regurgitation, often provoked by bending, straining or lying down. ‘Waterbrash’, which is salivation due to reflex salivary gland stimulation as acid enters the gullet, is often present. Gastro-oesophageal reflux is commoner in older people (Box 22.30) and in those who are overweight. Some patients are woken at night by

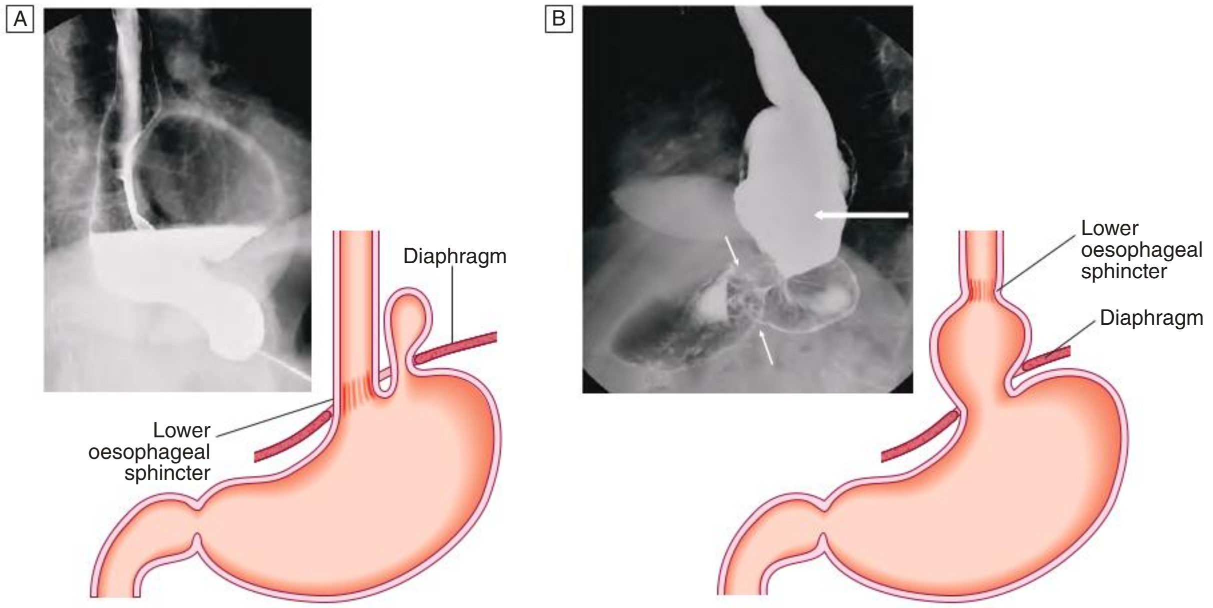


Fig. 22.25 Types of hiatus hernia. A Rolling or para-oesophageal. *Inset:* Barium meal showing a large para-oesophageal hernia with intrathoracic stomach. B Sliding. *Inset:* Barium meal showing a gastric volvulus (small arrows) complicating a sliding hiatus hernia (large arrow).

22.30 Gastro-oesophageal reflux disease in old age

- **Prevalence**: higher than in younger people.
- **Severity of symptoms**: does not correlate with the degree of mucosal inflammation.
- **Complications**: late complications, such as peptic strictures or bleeding from oesophagitis, are more common.
- **Recurrent pneumonia**: consider aspiration from occult gastro-oesophageal reflux disease.

choking as refluxed fluid irritates the larynx. Others develop odynophagia or dysphagia. A variety of other features have been described, such as atypical chest pain that may be severe and can mimic angina; it may be due to reflux-induced oesophageal spasm. Others include hoarseness ('acid laryngitis'), recurrent chest infections, chronic cough and asthma. The true relationship of these features to gastro-oesophageal reflux disease remains unclear.

Complications

Oesophagitis

A range of endoscopic findings may occur. In some patients the appearances may be normal whereas others may show evidence of extensive inflammation accompanied by superficial ulceration (Fig. 22.26). Others present with stricture formation. There is a poor correlation between symptoms and histological and endoscopic findings.

Barrett oesophagus

Barrett oesophagus is a pre-malignant condition, in which the normal squamous lining of the lower oesophagus is replaced by columnar mucosa (columnar-lined oesophagus; CLO) that may contain areas of intestinal metaplasia (Fig. 22.27). Barrett oesophagus is an adaptive response to chronic gastro-oesophageal reflux and is found in up to 8.3% of patients undergoing gastroscopy for reflux symptoms and about 1% of individuals older than 50 years. The relative risk of oesophageal cancer is increased 40- to 120-fold, but the absolute risk is low (0.1%–0.5% per year). Epidemiological studies have shown that the prevalence of Barrett oesophagus is increasing for reasons that are unclear. It is more common in men (especially of European ancestry), the obese (central obesity in particular), those over 50 years of age and smokers. The molecular events underlying progression of Barrett oesophagus to dysplasia and cancer are incompletely understood, but inactivation of the tumour suppression protein p16 by loss of heterozygosity or promoter hypermethylation is a key event, followed by somatic inactivation of *TP53*, which promotes aneuploidy and tumour progression.

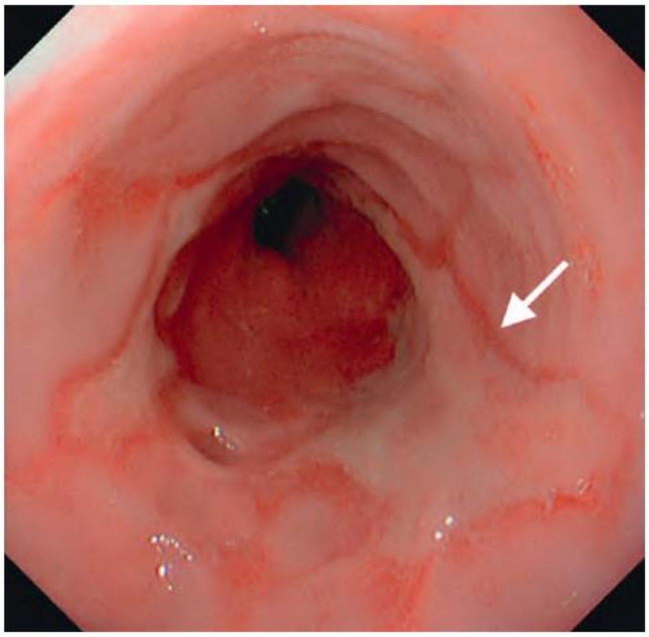

Fig. 22.26 Severe reflux oesophagitis. There is near-circumferential superficial ulceration (arrow) and inflammation extending up the gullet.

Diagnosis

Endoscopy is the gold standard for diagnosis. Multiple biopsies should be taken from normal-looking mucosa, in addition to sampling any visible lesions, to maximise the chance of detecting intestinal metaplasia and/or dysplasia.

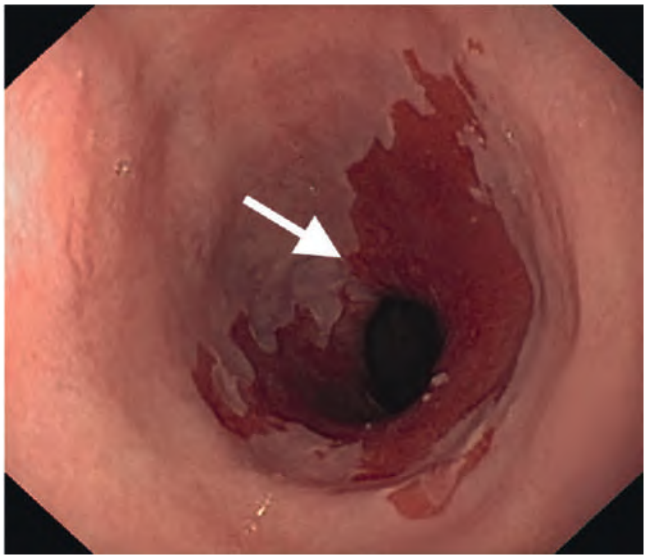

Fig. 22.27 **Barrett oesophagus.** Tongues of abnormal pink columnar mucosa (arrow) are seen extending upwards above the oesophago-gastric junction.

Management

Acid suppression with PPI or anti-reflux surgery are indicated for control of reflux symptoms but neither induces regression of Barrett oesophagus or progression to oesophageal carcinoma. Surveillance endoscopy is recommended at intervals of 3–5 years for non-dysplastic Barrett oesophagus, but in the presence of low-grade dysplasia, the screening interval should be shortened to 6 months. For those with high-grade dysplasia or intramucosal carcinoma, endoscopic resection followed by radiofrequency ablation (RFA) to eradicate areas of metaplasia is the preferred treatment option as it is successful in between 80% to 90% of patients. Oesophagectomy may be considered as an alternative where endoscopic resection is not available.

Anaemia

Iron deficiency anaemia can occur as a consequence of occult blood loss from long-standing oesophagitis. Most patients have a large hiatus hernia and bleeding can stem from subtle erosions in the neck of the sac (Cameron lesions). Nevertheless, hiatus hernia is very common and other causes of blood loss, particularly colorectal cancer, must be considered in anaemic patients, even when endoscopy reveals oesophagitis.

Benign oesophageal stricture

Fibrous strictures can develop as a consequence of long-standing oesophagitis, especially in older people and those with poor oesophageal peristaltic activity. The typical presentation is with dysphagia that is worse for solids than for liquids. Bolus obstruction following ingestion of meat causes absolute dysphagia. A history of heartburn is common but not invariable; many patients presenting in old age with strictures have no preceding heartburn.

Diagnosis is by endoscopy, when biopsies of the stricture can be taken to exclude malignancy. Endoscopic balloon dilatation or bougienage is helpful. Subsequently, long-term therapy with a PPI at full dose should be started to reduce the risk of recurrent oesophagitis and stricture formation. The patient should be advised to chew food thoroughly and it is important to ensure that dental health is optimised so that this can be achieved.

Gastric volvulus

Occasionally, a massive intrathoracic hiatus hernia may twist on itself, leading to a gastric volvulus. This gives rise to complete oesophageal or gastric obstruction and the patient presents with severe chest pain, vomiting and dysphagia. The diagnosis is made by chest X-ray (air bubble in the chest) and barium swallow (see Fig. 22.25 B). A nasogastric tube is normally inserted in the acute phase to facilitate decompression, with surgery usually advised after the acute episode. Endoscopic decompression may be an alternative option in selected patients in old age.

Investigations

Young patients who present with typical symptoms of gastro-oesophageal reflux, without worrying features such as dysphagia, weight loss or anaemia, can be treated empirically without investigation. Investigation is advisable if patients present over the age of 50–55 years, if symptoms are atypical or if a complication is suspected. Endoscopy is the investigation of choice. This is performed to exclude other upper gastrointestinal diseases that can mimic gastro-oesophageal reflux and to identify complications. A normal endoscopy in a patient with compatible symptoms should not preclude treatment for gastro-oesophageal reflux disease.

Oesophageal pH monitoring is indicated if the diagnosis is unclear or surgical intervention is under consideration. This involves tethering a slim catheter with a terminal radiotelemetry pH-sensitive probe above the gastro-oesophageal junction; wireless oesophageal pH monitoring is available in some centres for those intolerant of catheter-based monitoring. Intraluminal pH is recorded while the patient undergoes normal activities, and episodes of symptoms are noted and related to pH. An oesophageal pH of less than 4 for more than 6% of the study time is considered diagnostic for reflux disease. In patients with difficult reflux, impedance testing can detect weakly acidic or alkaline reflux that is not revealed by standard pH testing.

Management

A treatment algorithm for gastro-oesophageal reflux is outlined in Figure 22.28. Lifestyle advice should be given, including weight loss, avoidance of dietary items that worsen symptoms, elevation of the bed head in those who experience nocturnal symptoms, avoidance of late meals and cessation of smoking. Patients who fail to respond to these measures should be offered PPIs, which are usually effective in resolving symptoms and healing oesophagitis. Recurrence of symptoms is common when therapy is stopped, and some patients require life-long treatment at the lowest acceptable dose. When dysmotility features are prominent, prokinetics such as domperidone (not available in the United States) or metoclopramide can be helpful. There is no evidence that *H. pylori* eradication has any therapeutic value. Proprietary antacids and alginates can also provide symptomatic benefit. H_2-receptor antagonist drugs relieve symptoms without healing oesophagitis.

Long-term PPI therapy can lead to the development of parietal cell hyperplasia and hypertrophy, leading to acid rebound on withdrawal of PPIs after long-term usage. PPI therapy is also associated with reduced absorption of iron, vitamin B_{12} and magnesium. Treatment with PPI may also predispose to enteric infections with *Salmonella*, *Campylobacter* and possibly *Clostridioides difficile*. They may have an undesirable impact on the composition of the gut microbiota, although the clinical importance of this is unclear. An association between microscopic colitis and PPIs has also been suggested, as well as with acute interstitial nephritis. Long-term therapy increases the risk of *Helicobacter*-associated progression of gastric mucosal atrophy (see below) and *H. pylori* eradication is advised in patients requiring PPIs for more than 1 year. The risks described with PPIs are relatively modest, but patients should receive the lowest dose of PPIs to manage their symptoms.

Patients who fail to respond to medical therapy, those who are unwilling to take long-term PPIs and those whose major symptom is severe regurgitation should be considered for laparoscopic fundoplication (see this book's companion text, *Principles and Practice of Surgery*); endoscopic anti-reflux procedures are currently in development.

Other causes of oesophagitis

Infection

Oesophageal candidiasis occurs in debilitated patients and those taking broad-spectrum antibiotics or cytotoxic drugs. It is a particular problem in patients with HIV/AIDS, who are also susceptible to a spectrum of other oesophageal infections (p. 327).

Corrosives

Suicide attempt by ingestion of hydrochloric or sulphuric acid, sodium hydroxide or sodium hypochlorite (bleach) is followed by painful burns of the mouth and pharynx and by extensive erosive oesophagitis (p. 272). Late complications include oesophageal strictures, which may require endoscopic dilatation or stent insertion, or surgery in severe cases.

Drugs

Potassium supplements and NSAIDs may cause oesophageal ulcers when the tablets are trapped above an oesophageal stricture. Liquid preparations of these drugs should be used in such patients. Bisphosphonates can cause oesophageal ulceration and should be used with caution in patients with known oesophageal disorders. Tetracyclines, such as doxycycline, can also cause oesophagitis.

Eosinophilic oesophagitis

This is an increasingly recognised condition with an increasing prevalence, that affects both children and adults, with incidence peaking in early adulthood. It is more common in males and in White people. It occurs more often in atopic individuals and is characterised by eosinophilic infiltration of the oesophageal mucosa and appears to have seasonal variation, associated with higher pollen counts. Children commonly present with vomiting, difficulty feeding or failure to thrive. In contrast, adults present with dysphagia or food bolus obstruction more often than heartburn, while other symptoms, such as chest pain may be present. Endoscopy is usually normal, but mucosal rings, longitudinal furrows, exudates, oedema, strictures or a narrow-calibre oesophagus can occur (Fig. 22.29). To obtain a diagnosis, multiple biopsies (at least 6) should be taken from different levels of the oesophagus. One of the features noted on histology is an increase in eosinophil density (≥ 15 eosinophils per high-powered field (HPF)).

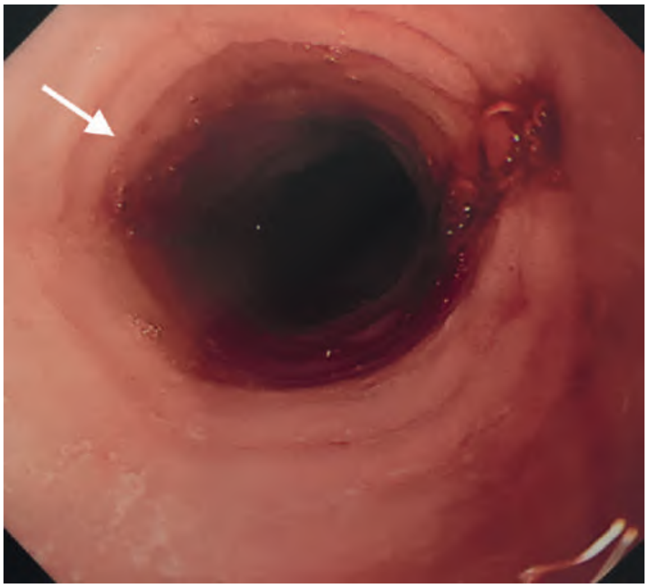

Fig. 22.29 **Endoscopic features suggestive of eosinophilic oesophagitis.** The arrow shows a mucosal ring typical of this disorder.

Dietary modifications are an effective first-line treatment and involve elimination of six common allergens (milk, egg, wheat, soy, fish and nuts), with reintroduction of components of the diet every 2–4 weeks to identify the causal allergen. When dietary therapy is ineffective or adherence is poor, high-dose PPI can be used in the first instance for up to 8 weeks. Around one-third of patients will respond to this, known as PPI-responsive oesophageal eosinophilia. In patients who do not respond, 8–12 weeks of therapy with topical glucocorticoids can be used, such as fluticasone and budesonide. Fluticasone is delivered by spraying into the mouth via a metered dose inhaler and swallowed rather than inhaled. Budesonide is administered as an oral viscous solution. The IL-4/IL-13 inhibitor dupilumab 300 mg monthly by subcutaneous injection is an effective treatment for patients who have failed to respond to the above measures. Endoscopic oesophageal dilatation may be considered in individuals with strictures or mucosal rings that have failed to respond to medical therapy.

Benign oesophageal stricture

Benign oesophageal stricture is usually a consequence of gastro-oesophageal reflux disease (Box 22.31) and occurs most often in older adults who have poor oesophageal clearance. Rings, caused by submucosal fibrosis, are found at the oesophago-gastric junction ('Schatzki ring') and cause intermittent dysphagia, often starting in middle age. A post-cricoid web is a rare complication of iron deficiency anaemia (Paterson–Kelly or Plummer–Vinson syndrome) and may be complicated by the development of squamous carcinoma. Benign strictures can be treated by endoscopic dilatation, in which wire-guided bougies or balloons are used to disrupt the fibrous tissue of the stricture.

Tumours of the oesophagus

Benign tumours

The most common is a leiomyoma. This is usually asymptomatic but may cause bleeding or dysphagia.

Carcinoma of the oesophagus

Squamous oesophageal cancer (Box 22.32) accounts for 90% of oesophageal cancers globally, being more common in Iran, areas of Africa and China. Squamous cancer can occur in any part of the oesophagus, although almost all tumours in the upper oesophagus are

22.31 Causes of oesophageal stricture

- Gastro-oesophageal reflux disease
- Webs and rings
- Carcinoma of the oesophagus or cardia
- Eosinophilic oesophagitis
- Extrinsic compression from bronchial carcinoma
- Corrosive ingestion
- Post-operative scarring following oesophageal resection
- Following radiotherapy
- Following long-term nasogastric intubation
- Bisphosphonates

22.32 Risk factors for squamous carcinoma of the oesophagus

- Smoking
- Alcohol excess
- Chewing betel nuts or tobacco
- Achalasia of the oesophagus
- Plummer–Vinson syndrome
- Post-caustic stricture
- Tylosis (familial hyperkeratosis of palms and soles)

squamous cancers. Adenocarcinomas typically arise in the lower third of the oesophagus from Barrett oesophagus or from the cardia of the stomach, and are more common in America, Australia and Europe. The incidence is increasing possibly as a result of the high prevalence of gastro-oesophageal reflux and Barrett oesophagus in Western populations. Despite modern treatment, the overall 5-year survival of patients presenting with oesophageal cancer is less than 20%.

Clinical features

Most patients have a history of progressive, painless dysphagia for solid foods. Others present acutely because of food bolus obstruction. In the late stages, weight loss is often extreme; chest pain or hoarseness suggests mediastinal invasion. Fistulation between the oesophagus and the trachea or bronchial tree leads to coughing after swallowing, pneumonia and pleural effusion. Physical signs may be absent but, even at initial presentation, cachexia, cervical lymphadenopathy or other evidence of metastatic spread is common.

Investigations

The investigation of choice is upper gastrointestinal endoscopy since this allows the tumour to be identified and biopsies taken (Fig. 22.30). Once a diagnosis has been made, investigations should be performed to stage the tumour and define operability. Thoracic and abdominal CT, often combined with positron emission tomography (PET-CT), should be carried out to identify metastatic spread and local invasion (Fig. 22.31). Invasion of the aorta, major airways or coeliac axis usually precludes surgery, but patients with resectable disease on imaging should undergo EUS to determine the depth of penetration of the tumour into the oesophageal wall and to detect locoregional lymph node involvement (Fig. 22.32). These investigations will define the TNM (tumour, node, metastases) stage of the disease (see Box 8.3).

Curative management

Endoscopic mucosal resection or endoscopic submucosal dissection, with or without radiofrequency ablation, have become established for Barrett oesophagus complicated by adenocarcinoma and in those with very early superficial tumours. For localised cancers (stage T1–3 N0–2 M0), oesophagectomy is the mainstay of curative treatment and is offered to patients who are medically fit for resection. Surgery should be carried out by experienced upper gastrointestinal surgical teams following appropriate multidisciplinary assessment. For individuals with ≥T2 and/or ≥N1 cancers, perioperative chemotherapy (5-fluorouracil, leucovorin, oxaliplatin and docetaxel) or pre-operative chemoradiotherapy improve survival compared to surgery alone and should be considered for those fit enough to undergo it. Definitive chemoradiotherapy can be considered for patients with squamous oesophageal cancers, T4 M0 cancers or for those who are unfit for surgery.

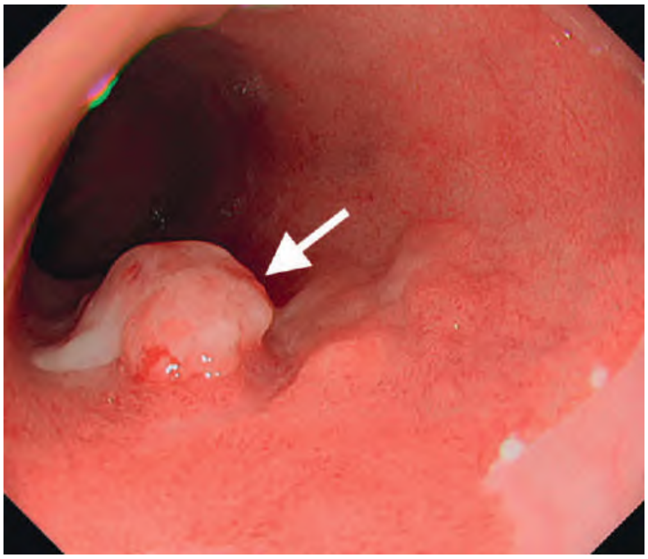

Fig. 22.30 Adenocarcinoma of the lower oesophagus. A polypoidal adenocarcinoma is shown (arrow) in association with Barrett oesophagus.

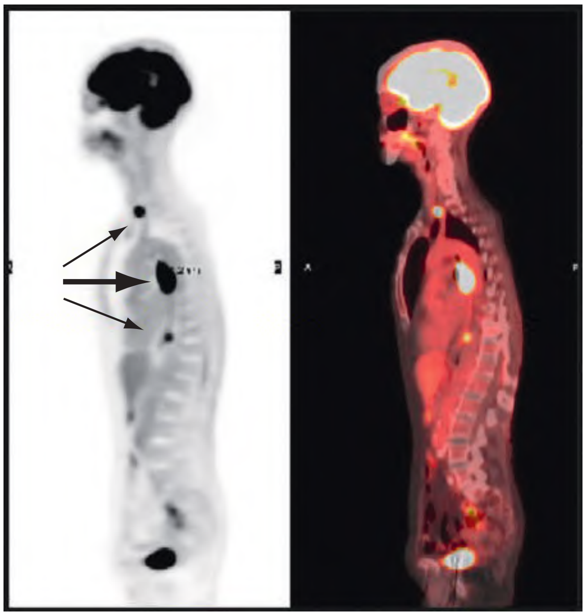

Fig. 22.31 Positron emission tomography–computed tomography (PET-CT) staging of oesophageal carcinoma. Whole-body PET scan showing avid uptake in the primary tumour (thick arrow) but also in distant paratracheal (upper thin arrow) and gastro-oesophageal (lower thin arrow) lymph nodes. Note normal uptake in brain and bladder.

Palliative management

Approximately 70% of patients have extensive disease at presentation, and in those individuals, good symptom management is essential. Palliative treatments such as laser therapy, argon plasma coagulation, radiotherapy, stent or chemotherapy can improve dysphagia, pain, bleeding, nutrition and quality of life in selected patients. Palliative

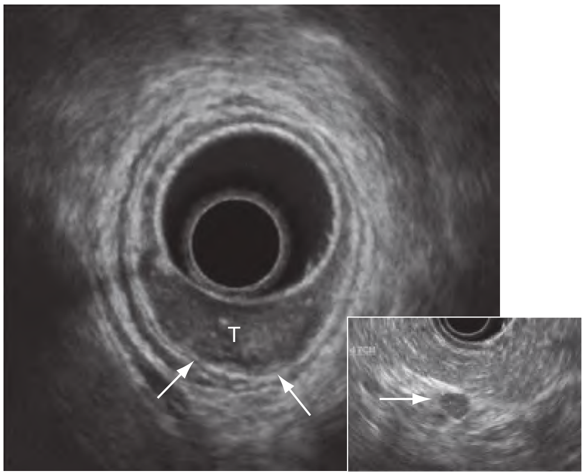

Fig. 22.32 Endoscopic ultrasound staging of oesophageal carcinoma. There is a superficial adenocarcinoma of the oesophagus (T). The submucosa (white band, white arrows) is not involved but there is a small involved local lymph node (white arrow, inset). The tumour is therefore staged T1a, N1.

5-fluorouracil and platinum-based chemotherapy can be used to improve symptoms and prolong life by some months in patients fit enough to benefit. Increasingly, molecular stratification is used to select those suitable for targeted therapy in addition to standard chemotherapy regimens. This would comprise trastuzumab for HER2-positive and nivolumab for HER2-negative, PD-L1-positive adenocarcinomas. Quality of life can also be improved by nutritional support and appropriate analgesia.

Perforation of the oesophagus

Oesophageal perforation is a rare but potentially life-threatening clinical condition. The most common cause is iatrogenic endoscopic perforation complicating dilatation or intubation. Malignant, corrosive or post-radiotherapy strictures are more likely to be perforated than peptic strictures.

Spontaneous oesophageal perforation (Boerhaave syndrome) results from forceful vomiting and retching, accounting for around 15% of cases. Severe chest pain and shock occur as oesophago-gastric contents enter the mediastinum and thoracic cavity. Subcutaneous emphysema, pleural effusions and pneumothorax develop. The diagnosis can be made using a water-soluble contrast swallow but, in difficult cases, both CT and careful endoscopy (usually in an intubated patient) may be required. Delay in diagnosis is a key factor in the high mortality associated with this condition.

Surgery remains the mainstay of treatment for oesophageal perforation. However, an increasing subgroup of patients are being managed via non-operative measures, such as individuals with small well-defined tears. Non-operative options include conservative management involving broad-spectrum antibiotics and parenteral nutrition, and endoscopic management such as clip placement.

Oesophageal motility disorders

Pharyngeal pouch

This occurs because of incoordination of swallowing within the pharynx, which leads to herniation through the cricopharyngeus muscle and formation of a pouch. It is rare, affecting 1 in 100 000 people; it occurs predominantly in men, and is most common in the seventh and eighth decades of life. Many patients have no symptoms, but regurgitation, halitosis and dysphagia can be present. Some notice gurgling in the throat after swallowing. The investigation of choice is a barium swallow (see Fig. 22.12 A), which demonstrates the pouch and reveals incoordination of swallowing, often with pulmonary aspiration. Treatment is indicated in symptomatic patients, and can be via a surgical approach, such as cricopharyngeus myotomy (diverticulotomy), with or without resection of the pouch. Recently, there has been the development of minimally invasive endoscopic approaches, such as endoscopic diverticulectomy.

Achalasia of the oesophagus

Pathophysiology

Achalasia is characterised by:

- a hypertonic lower oesophageal sphincter, which fails to relax in response to the swallowing wave
- failure of propagated oesophageal contraction, leading to progressive dilatation of the gullet.

The cause is unknown. It is associated with autoimmune diseases, such as type 1 diabetes mellitus, systemic lupus erythematosus, rheumatoid arthritis and Sjögren syndrome. Defective release of nitric oxide by inhibitory neurons in the lower oesophageal sphincter has been reported, and there is degeneration of ganglion cells within the sphincter and the body of the oesophagus. Loss of the dorsal vagal nuclei within the brainstem can be demonstrated in later stages. Infection with *Trypanosoma cruzi* in Chagas disease (Ch. 14) causes a syndrome that is clinically indistinguishable from achalasia.

Clinical features

The presentation is with dysphagia, typically to solids and liquids. Regurgitation to saliva and food can also occur, as well as some patients experiencing episodes of chest pain due to oesophageal spasm. Around one-third of patients can experience weight loss. As the disease progresses, dysphagia worsens, the oesophagus empties poorly and nocturnal pulmonary aspiration develops. Achalasia predisposes to squamous carcinoma of the oesophagus.

Investigations

Endoscopy should always be carried out because carcinoma of the cardia can mimic the presentation and radiological and manometric features of achalasia ('pseudo-achalasia'). A barium swallow shows tapered narrowing of the lower oesophagus, and, in late disease, the oesophageal body is dilated, aperistaltic and food-filled (Fig. 22.33A). Manometry confirms the presence of a high-pressure, non-relaxing lower oesophageal sphincter with poor contractility of the oesophageal body (Fig. 22.33B).

Management

Endoscopic

Forceful pneumatic dilatation using a 30–35 mm-diameter, fluoroscopically positioned balloon disrupts the oesophageal sphincter and improves symptoms in 80% of patients. Some patients require more than one dilatation, but those needing frequent dilatation are best treated surgically. Endoscopically directed injection of botulinum toxin into the lower oesophageal sphincter induces clinical remission, but relapse is common, with worsening response on repeated treatments. It tends to be reserved for frail individuals in old age where other treatments are too risky. Per-oral endoscopic myotomy (POEM) is a newer advanced endoscopic technique for the management of achalasia but is currently only performed in specialist centres (Fig. 22.34).

Surgical

Surgical myotomy (Heller operation), commonly performed laparoscopically or as an open operation, is effective but is more invasive than endoscopic dilatation. Both pneumatic dilatation and myotomy may be complicated by gastro-oesophageal reflux, and this can lead to severe oesophagitis because oesophageal clearance is so poor. For this reason, Heller myotomy is accompanied by a partial fundoplication anti-reflux procedure. PPI therapy is often necessary after surgery.

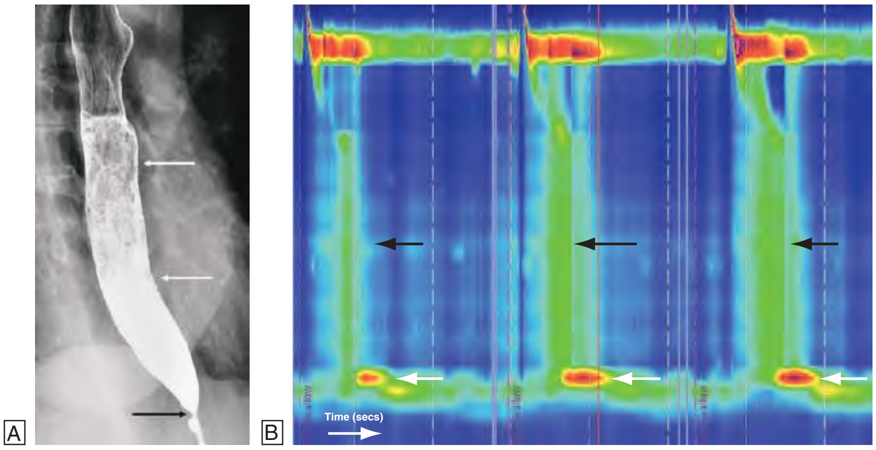

Fig. 22.33 Achalasia. A X-ray showing a dilated, barium-filled oesophagus (white arrows) and a closed lower oesophageal sphincter (black arrow). B High-resolution manometry in achalasia showing absence of peristaltic swallowing wave in oesophageal body (black arrows) and raised lower oesophageal pressure with failure of relaxation on swallowing (red, highlighted by white arrows). Compare with normal appearances in Figure 22.1.

Other oesophageal motility disorders

Distal oesophageal spasm presents in late middle age with episodic chest pain that may mimic angina but is sometimes accompanied by transient dysphagia. Some cases occur in response to gastro-oesophageal reflux. Treatment is based on the use of PPIs when gastro-oesophageal reflux is present. Oral or sublingual nitrates or nifedipine may relieve attacks of pain. The results of drug therapy are often disappointing, as are the alternatives such as pneumatic dilatation and surgical myotomy. ‘Nutcracker’ oesophagus is a condition in which extremely forceful peristaltic activity leads to episodic chest pain and dysphagia. Treatment is with nitrates or nifedipine. Some patients present with oesophageal motility disorders that do not fit into a specific disease entity. The patients usually present in old age and with dysphagia and chest pain. Manometric abnormalities occur, ranging from poor peristalsis to spasm. Treatment is with dilatation and/or vasodilators for chest pain.

Secondary causes of oesophageal dysmotility

In systemic sclerosis and some other connective tissue diseases (Ch. 25), the muscle of the oesophagus is replaced by fibrous tissue, which causes failure of peristalsis leading to heartburn and dysphagia. Oesophagitis is often severe and benign fibrous strictures occur. These patients require long-term therapy with PPIs. If patients remain symptomatic, endoscopic dilatation may be considered. Dermatomyositis, rheumatoid arthritis and myasthenia gravis may also cause dysphagia.

Disorders of the stomach and duodenum

Gastritis

Gastritis is a histological diagnosis, although it can also be recognised at endoscopy.

Acute gastritis

Acute gastritis is often erosive and haemorrhagic. Neutrophils are the predominant inflammatory cell in the superficial epithelium. Many cases result from alcohol, aspirin or NSAID ingestion (Box 22.33). Acute gastritis often produces no symptoms, but may cause dyspepsia, anorexia, nausea or vomiting, and haematemesis or melaena. Many cases resolve quickly and do not merit investigation; in others, endoscopy and biopsy may be necessary to exclude peptic ulcer or cancer. Treatment should be directed at the underlying cause. Short-term symptomatic therapy with antacids, and acid suppression using PPIs, prokinetics or antiemetics (domperidone, metoclopramide) may be necessary.

Chronic gastritis due to *Helicobacter pylori* infection

This is the most common cause of chronic gastritis. The predominant inflammatory cells are lymphocytes and plasma cells. Correlation between symptoms and endoscopic or pathological findings is poor. Most patients are asymptomatic and do not require treatment, but patients with dyspepsia may benefit from *H. pylori* eradication.

Autoimmune chronic gastritis

This involves the body of the stomach but spares the antrum; it results from autoimmune damage to parietal cells. The histological features are diffuse chronic inflammation, atrophy and loss of fundic glands, intestinal metaplasia and sometimes hyperplasia of enterochromaffin-like (ECL) cells. Circulating antibodies to parietal cell and intrinsic factor may be present. In some patients, the degree of gastric atrophy is severe and loss of intrinsic factor secretion leads to pernicious anaemia (p. 975). The gastritis itself is usually asymptomatic. Some patients have evidence of other organ-specific autoimmunity, particularly thyroid disease. In the long-term, there is a two- to threefold increase in the risk of gastric cancer (see below).

Ménétrier disease

In this rare condition, the gastric pits are elongated and tortuous, with replacement of the parietal and chief cells by mucus-secreting cells. The cause is unknown, but there is excessive production of transforming growth factor alpha (TGF-α). As a result, the mucosal folds of the body and fundus are greatly enlarged. Most patients are hypochlorhydric. While some patients have upper gastrointestinal symptoms, the majority present in middle or old age with protein-losing enteropathy (p. 842) due to exudation from the gastric mucosa. Endoscopy shows enlarged, nodular and coarse folds, although biopsies may not be deep enough to show all the histological features. Treatment with antisecretory drugs, such as PPIs with or without octreotide, may reduce protein loss and *H. pylori* eradication may be effective, but unresponsive patients require partial gastrectomy.

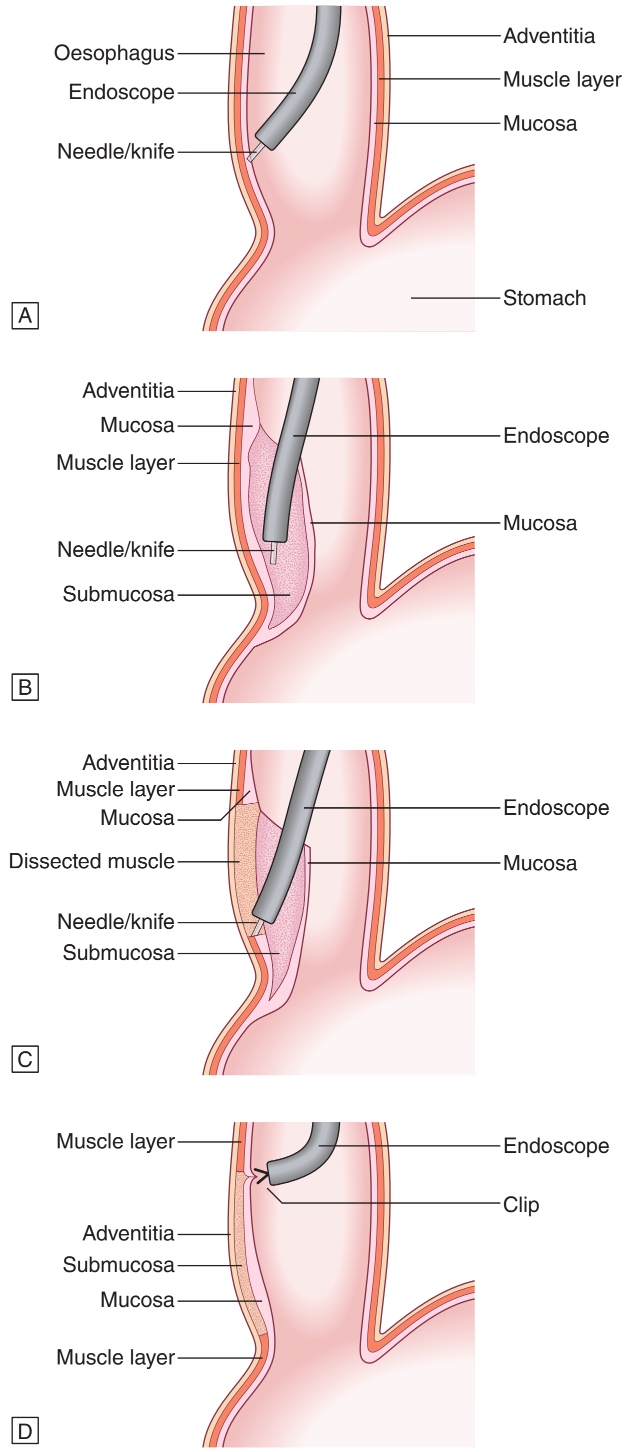

Fig. 22.34 **Per-oral endoscopic myotomy.** **A** Mucosal surface opened to access submucosal space. **B** A submucosal tunnel is created. **C** Circular muscle is dissected – endoscopic myotomy. **D** The entry site is closed with clips.

Peptic ulcer disease

Peptic ulcers are most commonly located in the stomach or duodenum, but can also occur in the lower oesophagus, in the jejunum after surgical anastomosis to the stomach or, rarely, in the ileum adjacent to a Meckel diverticulum. Ulcers in the stomach or duodenum may be acute or chronic; both penetrate the muscularis mucosae, but the acute ulcer shows no evidence of fibrosis. Erosions do not penetrate the muscularis mucosae.

i **22.33 Causes of gastritis**

Acute gastritis (often erosive and haemorrhagic)

- Aspirin, NSAIDs, iron supplements
- *H. pylori* (initial infection)
- Alcohol
- Severe physiological stress (burns, multi-organ failure, central nervous system trauma)
- Bile reflux, following gastric surgery
- Viral infections (CMV, herpes simplex virus)

Chronic non-specific gastritis

- *H. pylori* (chronic infection)
- Autoimmune (pernicious anaemia)
- Post-gastrectomy

Chronic specific forms (rare)

- Graft-versus-host disease
- Granulomatous gastritis (sarcoidosis, tuberculosis, Crohn disease)
- Ménétrier disease

(CMV = cytomegalovirus; HIV/AIDS = human immunodeficiency virus/acquired immunodeficiency syndrome; NSAIDs = non-steroidal anti-inflammatory drugs)

Gastric and duodenal ulcer

The lifetime prevalence of peptic ulcer is around 5%–10%. The incidence is decreasing in many high-income societies as a result of widespread use of *Helicobacter pylori* eradication therapy. The male-to-female ratio for duodenal ulcer varies from 5:1 to 2:1, while that for gastric ulcer is 2:1 or less. Chronic gastric ulcer is usually single; 90% are situated on the lesser curve within the antrum or at the junction between body and antral mucosa. Chronic duodenal ulcer usually occurs in the first part of the duodenum and 50% are on the anterior wall. Gastric and duodenal ulcers coexist in 10% of patients and more than one peptic ulcer is found in 10%–15% of patients.

Pathophysiology

Helicobacter pylori

Peptic ulceration is strongly associated with *H. pylori* infection. The prevalence of the infection in high-income societies rises with age, and in the UK approximately 50% of people over the age of 50 years are infected. In low- and middle-income countries, infection is more common, affecting up to 90% of adults. These infections are probably acquired in childhood by person-to-person contact. The vast majority of colonised people remain healthy and asymptomatic, and only a minority develop clinical disease. Around 90% of duodenal ulcer patients and 70% of gastric ulcer patients are infected with *H. pylori*.

H. pylori is gram-negative and spiral, and has multiple flagella at one end, which make it motile, allowing it to burrow and live beneath the mucous layer adherent to the epithelial surface. It uses an adhesin molecule (BabA) to bind to the Lewis b antigen on epithelial cells. Here the surface pH is close to neutral and any acidity is buffered by the organism's production of the enzyme urease. This produces ammonia from urea and raises the pH around the bacterium and between its two cell membrane layers. *H. pylori* exclusively colonises gastric-type epithelium and is found in the duodenum only in association with patches of gastric metaplasia. It causes chronic gastritis by provoking a local inflammatory response in the underlying epithelium (Fig. 22.35). This depends on numerous factors, notably expression of bacterial *CagA* and *VacA* genes. The CagA gene product is injected into epithelial cells using what is referred to as the type IV secretion system. The CagA protein interacts with numerous cell-signalling pathways involved in cell replication and apoptosis. *H. pylori* strains expressing CagA (CagA$^+$) are more often associated with disease than CagA$^-$ strains. Most strains also secrete a large pore-forming protein called VacA, which causes increased cell permeability, efflux of micronutrients from the epithelium, induction of

apoptosis and suppression of local immune cell activity. Several forms of VacA exist and pathology is most strongly associated with the s1/m1 form of the toxin.

The distribution and severity of *H. pylori*-induced gastritis determine the clinical outcome. In most people, *H. pylori* infection causes a mild pangastritis with little effect on acid secretion and no significant clinical consequences. In about 10% of people in Western societies, the infection causes an antral-predominant pattern of gastritis characterised by hypergastrinaemia and a greatly exaggerated acid production by parietal cells, which can lead to duodenal ulceration (Fig. 22.36). In a much smaller number of infected people, *H. pylori* causes a corpus-predominant pattern of gastritis leading to gastric atrophy and hypochlorhydria. This phenotype is much more common in Asian countries, particularly Japan, China and Korea. The hypochlorhydria allows other bacteria to proliferate within the stomach; these other bacteria continue to drive the chronic inflammation and produce mutagenic nitrites from dietary nitrates, predisposing to the development of gastric cancer. The effects of *H. pylori* are more complex in gastric ulcer patients compared to those with duodenal ulcers. The ulcer probably arises because of impaired mucosal defence resulting from a combination of *H. pylori* infection, NSAIDs and smoking, rather than excess acid.

22.34 Peptic ulcer disease in old age

- **Gastroduodenal ulcers**: have a greater incidence, admission rate and mortality.
- **Causes**: high prevalence of *Helicobacter pylori*, use of non-steroidal anti-inflammatory drugs and impaired defence mechanisms.
- **Atypical presentations**: pain and dyspepsia are frequently absent or atypical. Older people often develop complications, such as bleeding or perforation, without a dyspeptic history.
- **Bleeding**: older patients require more intensive management because they have more limited reserve to withstand hypovolaemia.

NSAIDs

There has been an increase in the use of NSAIDs and aspirin; these drugs account for 10% of peptic ulcers. NSAIDs increase the risk of complication of peptic ulcer disease fourfold, due to impairment of mucosal defences, as discussed on page 1035.

Smoking

Smoking confers an increased risk of gastric ulcer and, to a lesser extent, duodenal ulcer. Once the ulcer has formed, it is more likely to cause complications and less likely to heal if the patient continues to smoke.

Clinical features

Peptic ulcer disease is a chronic condition with spontaneous relapses and remissions lasting for decades, if not for life. The most common presentation is with recurrent abdominal pain that has three notable characteristics: localisation to the epigastrium, relationship to food and episodic occurrence. Occasional vomiting occurs in about 40% of ulcer subjects; persistent daily vomiting suggests gastric outlet obstruction. In one-third, the history is less characteristic, especially in older people or those taking NSAIDs (Box 22.34). In this situation, pain may be absent or so slight that it is experienced only as a vague sense of epigastric unease. Occasionally, the only symptoms are anorexia and nausea, or early satiety after meals. In some patients, the ulcer is completely asymptomatic presenting for the first time with anaemia from chronic undetected blood loss, as abrupt haematemesis or as acute perforation; in others, there is recurrent acute bleeding without ulcer pain. The diagnostic value of individual symptoms for peptic ulcer disease is poor; the history is therefore a poor predictor of the presence of an ulcer.

Investigations

Endoscopy is the preferred investigation (Fig. 22.37). Gastric ulcers may occasionally be malignant and therefore must always be biopsied and followed up to ensure healing. All patients should be tested for *H. pylori* infection. The current options available are listed in Box 22.35. Some are invasive and require endoscopy; others are non-invasive. They vary in sensitivity and specificity. Breath tests or faecal antigen tests are best because of accuracy, simplicity and non-invasiveness.

Management

The aims of management are to relieve symptoms, induce healing and prevent recurrence. *H. pylori* eradication is the cornerstone of therapy for peptic ulcers, as this will successfully prevent relapse and eliminate the need for long-term therapy in the majority of patients.

H. pylori eradication

All patients with proven ulcers who are *H. pylori*-positive should be offered eradication as primary therapy. Treatment is based on a PPI taken simultaneously with two antibiotics (from amoxicillin, clarithromycin and metronidazole) for at least 7 days. High-dose, twice-daily PPI therapy increases efficacy of treatment, as does extending treatment to 10–14 days. Success used to be achieved in greater than 90% of patients, but this has now fallen to below 70% in many countries as a result of antibiotic resistance. In addition, adherence and side-effects (Box 22.36) may influence success of eradication.

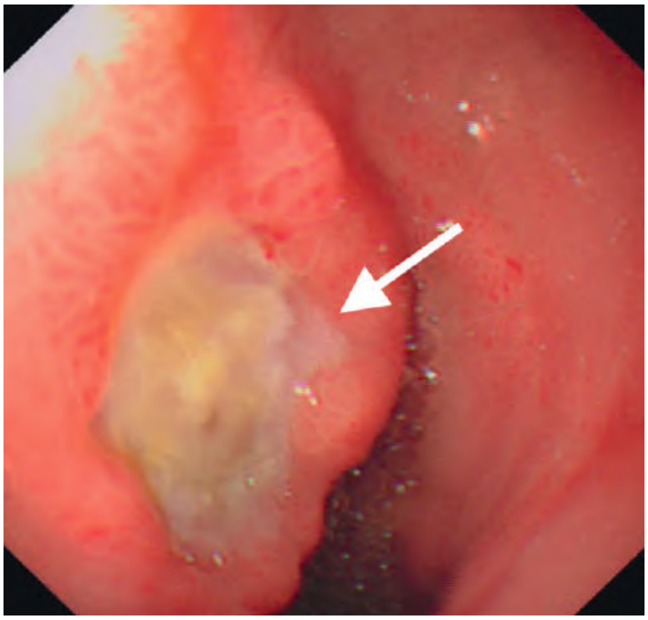

Fig. 22.37 Endoscopic identification of a duodenal ulcer. The ulcer (arrow) has a clean base and there are no stigmata of recent haemorrhage.

22.35 Methods for the diagnosis of *Helicobacter pylori* infection

Test	Advantages	Disadvantages
Non-invasive		
Serology	Rapid office kits available Good for population studies	Lacks specificity Cannot differentiate current from past infection
^{13}C-urea breath test	High sensitivity and specificity	Requires mass spectrometer
Faecal antigen test	Cheap, specific (> 95%)	Acceptability
Invasive (antral biopsy)		
Histology	Specificity	False negatives Takes several days to process
Rapid urease test	Cheap, quick, specific (> 95%)	Sensitivity 85%
Microbiological culture	'Gold standard' Defines antibiotic sensitivity	Slow and laborious Lacks sensitivity

22.36 Common side-effects of *Helicobacter pylori* eradication therapy

- Diarrhoea: 30%–50% of patients; usually mild, but *Clostridioides difficile*-associated diarrhoea can occur
- Flushing and vomiting when taken with alcohol (metronidazole)
- Nausea, vomiting
- Abdominal cramps
- Headache
- Rash

H. pylori and NSAIDs are independent risk factors for ulcer disease and patients requiring long-term NSAID therapy should first undergo eradication therapy to reduce ulcer risk. Subsequent co-prescription of a PPI along with the NSAID is advised but is not always necessary for patients being given low-dose aspirin, in whom the risk of ulcer complications is lower.

22.37 Indications for *Helicobacter pylori* testing

- Active or past history of peptic ulcer disease
- Extranodal marginal-zone lymphomas of MALT type
- Previous endoscopic resection for early gastric cancer
- Chronic dyspepsia
- Long-term NSAID or low-dose aspirin users
- Extra gastric disorders:
  Idiopathic thrombocytopenic purpura
  Unexplained iron deficiency anaemia
  Unexplained Vitamin B_{12} deficiency

(MALT = mucosa-associated lymphoid tissue; NSAID = non-steroidal anti-inflammatory drug)

22.38 Indications for surgery in peptic ulcer disease

Emergency

- Perforation
- Haemorrhage

Elective

- Gastric outflow obstruction
- Persistent ulceration despite adequate medical therapy
- Recurrent ulcer following gastric surgery

Indications for *H. pylori* testing are shown in Box 22.37. If positive, eradication therapy should be offered as described above. This may be of benefit in unexplained B_{12} deficiency and iron deficiency anaemia, once sources of gastrointestinal bleeding have been looked for and excluded. Platelet counts improve or even normalise after eradication therapy in patients with idiopathic thrombocytopenic purpura (p. 1006), but the mechanism for this is unclear.

General measures

Cigarette smoking, aspirin and NSAIDs should be avoided. Alcohol in moderation is not harmful, and no special dietary advice is required.

Maintenance treatment

Continuous maintenance treatment should not be necessary after successful *H. pylori* eradication. For the minority who do require it, the lowest effective dose of PPI should be used.

Surgical treatment

Surgery is now rarely required for peptic ulcer disease, but it is needed in some cases (Box 22.38).

Complications of gastric resection or vagotomy

Up to 50% of patients who undergo gastric surgery for peptic ulcer experience long-term adverse effects. In most cases these are minor, but in 10% they significantly impair quality of life.

Dumping Symptoms of dumping syndrome can be either early or late. Early dumping is more common and occurs within 30 minutes following a meal. Rapid gastric emptying leads to distension of the proximal small intestine as the hypertonic contents draw fluid into the lumen. This leads to abdominal discomfort and diarrhoea after eating. Autonomic reflexes release a range of gastrointestinal hormones that provoke vasomotor features, such as flushing, palpitations, sweating, tachycardia and hypotension. Patients should therefore avoid large meals with high carbohydrate content. Late dumping occurs 1–3 hours following a meal, with symptoms related to reactive hypoglycaemia, such as nausea, tremor and sweating, which are relieved by eating more food.

Chemical (bile reflux) gastropathy Duodenogastric bile reflux leads to chronic gastropathy. Treatment with ursodeoxycholic acid and sucralfate may be effective. A few patients require revisional surgery with creation of a Roux-en-Y loop to prevent bile reflux.

Diarrhoea and malabsorption Diarrhoea may develop after any peptic ulcer operation and usually occurs 1–2 hours after eating. Poor mixing of food in the stomach, with rapid emptying, inadequate mixing with pancreaticobiliary secretions, rapid transit and bacterial overgrowth, may lead to malabsorption. Diarrhoea often responds to small, dry meals with a reduced intake of refined carbohydrates. Antidiarrhoeal drugs, such as codeine phosphate (15–30 mg 4–6 times daily) or loperamide (2 mg after each loose stool), can also help.

Weight loss Most patients lose weight shortly after surgery and 30%–40% are unable to regain all the weight that is lost. The usual cause is reduced intake because of a small gastric remnant, but diarrhoea and mild steatorrhoea also contribute.

Anaemia Anaemia is common many years after subtotal gastrectomy. Iron deficiency is the most common cause; folic acid and B_{12} deficiency are much less frequent. Inadequate dietary intake of iron and folate, lack of acid and intrinsic factor secretion, mild chronic low-grade blood loss from the gastric remnant and recurrent ulceration are responsible.

Metabolic bone disease Both osteoporosis and osteomalacia can occur as a consequence of calcium and vitamin D malabsorption.

Gastric cancer An increased risk of gastric cancer has been reported from several epidemiological studies. Surgery itself is an independent risk factor for late development of malignancy in the gastric remnant, but the risk is higher in those with hypochlorhydria, duodenogastric reflux of bile, smoking and *H. pylori* infection. Although the relative risk is increased, the absolute risk of cancer remains low and endoscopic surveillance is not indicated following gastric surgery.

Complications of peptic ulcer disease

Perforation

When perforation occurs, the contents of the stomach escape into the peritoneal cavity, leading to peritonitis. This is more common in duodenal than in gastric ulcers and is usually found with ulcers on the anterior wall. About one-quarter of all perforations occur in acute ulcers and NSAIDs are often incriminated. Perforation can be the first sign of ulcer and a history of recurrent epigastric pain is uncommon. The most striking symptom is sudden, severe pain; its distribution follows the spread of the gastric contents over the peritoneum. The pain initially develops in the upper abdomen and rapidly becomes generalised; shoulder tip pain is caused by irritation of the diaphragm. The pain is accompanied by shallow respiration, due to limitation of diaphragmatic movements, and by shock. The abdomen is held immobile and there is generalised ‘board-like’ rigidity. Bowel sounds are absent and liver dullness to percussion decreases due to the presence of gas under the diaphragm. After some hours, symptoms may improve, although abdominal rigidity remains. Later, the patient’s condition deteriorates as general peritonitis develops. In at least 50% of cases, an erect chest X-ray shows free air beneath the diaphragm (see Fig. 22.11 B). If a plain X-ray is negative, a water-soluble contrast swallow will confirm leakage of gastroduodenal contents. After resuscitation, the acute perforation should be treated surgically, either by simple closure or by conversion of the perforation into a pyloroplasty if it is large. On rare occasions, a ‘Polya’ partial gastrectomy is required. Following surgery, *H. pylori* should be treated (if present) and NSAIDs avoided. Perforation carries a mortality of around 25%, reflecting the advanced age and significant comorbidity of the population that are affected.

22.39 Causes and management of gastric outlet obstruction

Cause	Management
Fibrotic stricture from duodenal ulcer (pyloric stenosis)	Balloon dilatation or surgery
Oedema from pyloric channel or duodenal ulcer	Proton pump inhibitor therapy
Carcinoma of antrum	Surgery
Adult hypertrophic pyloric stenosis	Surgery

Gastric outlet obstruction

The causes and management options for gastric outlet obstruction are shown in Box 22.39. The most common is an ulcer in the region of the pylorus. The presentation is with nausea, vomiting and abdominal distension. Large quantities of gastric content are often vomited and food eaten 24 hours or more previously may be recognised. Physical examination may show evidence of wasting and dehydration. A succussion splash may be elicited 4 hours or more after the last meal or drink. Visible gastric peristalsis is diagnostic of gastric outlet obstruction. Endoscopy should be performed after the stomach has been emptied using a wide-bore nasogastric tube. Intravenous correction of dehydration is undertaken and, in severe cases, at least 4 L of isotonic saline and 80 mmol of potassium may be necessary during the first 24 hours. In some patients, prescription of PPIs may heal ulcers, relieve pyloric oedema and overcome the need for surgery. Endoscopic balloon dilatation of benign stenoses may be possible in some patients, but in others partial gastrectomy is necessary; this is best done after a 7-day period of nasogastric aspiration, which enables the stomach to return to normal size. A gastroenterostomy is an alternative operation but, unless this is accompanied by vagotomy, patients will require long-term PPI therapy to prevent stomal ulceration.

Bleeding

See page 815.

Zollinger–Ellison syndrome

This is a rare disorder characterised by gastric acid hypersecretion and severe peptic ulceration, caused by a gastrin-secreting neuroendocrine tumour (‘gastrinoma’) (Ch. 20). It probably accounts for about 0.1% of all cases of duodenal ulceration. The syndrome can occur in either sex and at any age, although it is most common between 30 and 50 years of age.

Pathophysiology

Elevated gastrin stimulates acid secretion to its maximal capacity and increases the parietal cell mass three- to sixfold. The acid output may be so great that it reaches the upper small intestine, reducing the luminal pH to 2 or less. Pancreatic lipase is inactivated, and bile acids are precipitated. Diarrhoea and steatorrhoea result. Around 90% of tumours occur in the pancreatic head or proximal duodenal wall. Between 20% and 60% of patients have multiple endocrine neoplasia (MEN) type 1 (p. 742). In sporadic disease, the tumours are usually unifocal, but in MEN 1 there are invariably multifocal tumours. Individual tumour size can vary from 1 mm to 20 cm; approximately one-half to two-thirds are malignant, but like many neuroendocrine tumours they are often slow-growing.

Clinical features

The presentation is with severe and often multiple peptic ulcers in unusual sites, such as the post-bulbar duodenum, jejunum or oesophagus. There is a poor response to standard ulcer therapy. The history is usually short, and bleeding and perforations are common. Diarrhoea is seen in one-third or more of patients and can be the presenting feature.

Investigations

Serum gastrin levels are normally grossly elevated (10- to 1000-fold). Injection of the hormone secretin normally causes no change or a slight decrease in circulating gastrin concentrations, but in Zollinger–Ellison syndrome it produces a paradoxical and dramatic increase in gastrin. Tumour localisation (and staging) is best achieved by a combination of CT and EUS; radio-labelled somatostatin receptor scintigraphy and gallium-68 (^{68}Ga) DOTATATE PET scanning may also be used for tumour detection and staging.

Management

Unifocal tumours may be resected, but surgery may not be appropriate when there are multifocal tumours or if there is metastatic disease. In this situation, continuous therapy with a PPI in high dose can be successful in healing ulcers and alleviating diarrhoea. Somatostatin analogue therapy may reduce gastrin secretion and have an anti-tumour effect; other treatment options for pancreatic neuroendocrine tumours are discussed on page 742). Overall 5-year survival is 60%–75% and all patients should undergo genetic screening for MEN 1.

Tumours of the stomach

Gastric carcinoma

Around 90% of gastric cancers are adenocarcinomas. Gastric cancer is the fifth most common cancer, with marked geographical variation in incidence. It is most common in China, Japan, South Korea, Eastern Europe and parts of South America. In most countries the incidence is 50% lower in women. In both sexes it rises sharply after 50 years of age. Studies of Japanese migrants to the United States have revealed a much lower incidence in the second generation, confirming the importance of environmental factors. The overall prognosis is poor, with less than 30% surviving 5 years, except in Japan where there are much higher survival rates. The best hope for improved survival lies in more efficient detection of tumours at an earlier stage, and this has been achieved by the introduction of screening programmes for early gastric cancer in Japan and South Korea.

Pathophysiology

Infection with *H. pylori* plays a key pathogenic role and the infection has been classified by the International Agency for Research on Cancer (IARC) as a definite human carcinogen. It is associated with chronic atrophic gastritis, gastric mucosal atrophy and gastric cancer (Fig. 22.38). It has been estimated that *H. pylori* infection may contribute to the occurrence of gastric cancer in 70% of cases. Although the majority of *H. pylori*-infected individuals have normal or increased acid secretion, a few become hypo- or achlorhydric and these people are thought to be at greatest risk. *H. pylori*-induced chronic inflammation with generation of reactive oxygen species and depletion of the normally abundant antioxidant ascorbic acid are also important in pathogenesis. There is strong evidence that *H. pylori* eradication, especially if achieved before irreversible pre-neoplastic changes (atrophy and intestinal metaplasia) have developed, reduces the risk of cancer development in high-risk populations and is cost-effective.

Diets rich in salted, smoked or pickled foods and the consumption of nitrites and nitrates may increase cancer risk. Carcinogenic *N*-nitroso-compounds are formed from nitrates by the action of nitrite-reducing bacteria that colonise the achlorhydric stomach. Diets lacking in fresh fruit and vegetables, as well as vitamins C and A, may also contribute. Other risk factors are listed in Box 22.40. Genetic risk factors also play a role, such that 10%–20% of patients with gastric cancer have a family history of the disease. Rarely, gastric cancer may be inherited in an autosomal dominant manner in association with pathogenic variants of the *E-cadherin* (*CDH1*) gene. Several additional genomic regions have been identified that are associated with an increased risk of gastric cancer by genome-wide association studies and transcriptome-wide association studies, but the effect size of these loci is small.

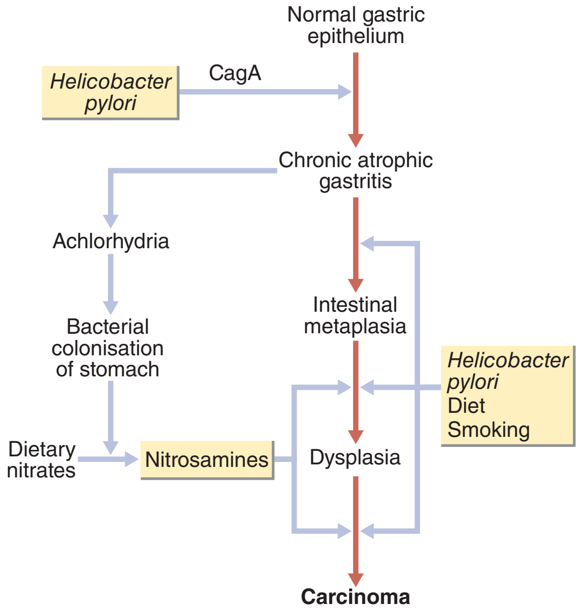

Fig. 22.38 Gastric carcinogenesis: a possible mechanism. (CagA = cytotoxin-associated gene)

22.40 Risk factors for gastric cancer

- *Helicobacter pylori*
- Smoking
- Alcohol
- Dietary associations (see text)
- Autoimmune gastritis (pernicious anaemia)
- Adenomatous gastric polyps
- Previous partial gastrectomy (> 20 years)
- Ménétrier disease
- Hereditary diffuse gastric cancer families (*CDH1* mutations)
- Lynch syndrome (p. 848)
- Familial adenomatous polyposis (p. 849)

Virtually all tumours are adenocarcinomas arising from mucus-secreting cells in the base of the gastric crypts. Most develop on a background of chronic atrophic gastritis with intestinal metaplasia and dysplasia. Cancers are either ‘intestinal’, arising from areas of intestinal metaplasia with histological features reminiscent of intestinal epithelium, or ‘diffuse’, arising from normal gastric mucosa. Intestinal-type carcinomas are more common and arise against a background of chronic mucosal injury. Diffuse cancers tend to be poorly differentiated and occur in younger patients. In low- and middle-income countries, 50% of gastric cancers develop in the antrum; 20%–30% occur in the gastric body, often on the greater curve; and 20% are found in the cardia. In Western populations, however, proximal gastric tumours are more common than those arising in the body and distal stomach. This change in disease pattern may reflect changes in lifestyle or the decreasing prevalence of *H. pylori* in high-income countries. Diffuse submucosal infiltration by a scirrhous cancer (linitis plastica) is uncommon. Early gastric cancer is defined as cancer confined to the mucosa or submucosa. It is more often recognised in Japan, where widespread screening for gastric cancer is carried out. Some cases can be cured by endoscopic mucosal or submucosal resection. The majority of patients (> 80%) in the West, however, present with advanced gastric cancer.

Clinical features

Early gastric cancer is usually asymptomatic but may be discovered during endoscopy for investigation of dyspepsia. Two-thirds of patients

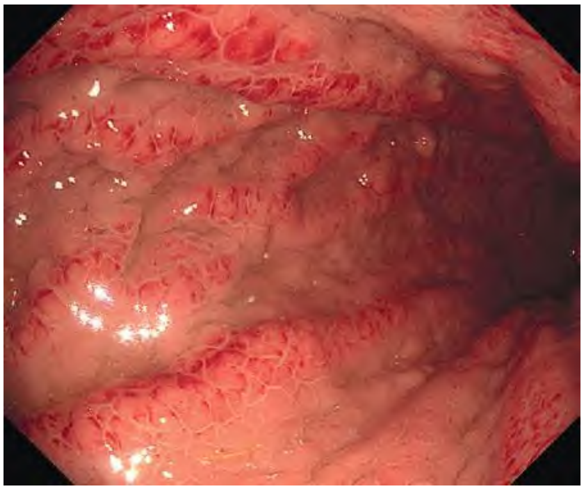

Fig. 22.39 **Gastric carcinoma.** Endoscopic finding of an early gastric cancer. The changes are subtle with widespread inflammation and diffuse mucosal irregularity.

with advanced cancers have weight loss and 50% have ulcer-like pain. Anorexia and nausea occur in one-third, while early satiety, haematemesis, melaena and dyspepsia alone are less common. Dysphagia occurs in tumours of the gastric cardia that obstruct the gastro-oesophageal junction. Anaemia from occult bleeding is also common. Examination may reveal no abnormalities, but signs of weight loss, anaemia and a palpable epigastric mass may be present. Jaundice or ascites signifies metastatic spread. Occasionally, tumour spread occurs to the supraclavicular lymph nodes (Virchow node), umbilicus (Sister Joseph nodule) or ovaries (Krukenberg tumour). Paraneoplastic phenomena, such as acanthosis nigricans, thrombophlebitis (Trousseau sign) and dermatomyositis may rarely occur. Metastases arise most commonly in the liver, lungs, peritoneum and bone marrow.

Investigations

Upper gastrointestinal endoscopy is the investigation of choice (Fig. 22.39) and should be performed promptly in any dyspeptic patient with ‘alarm features’ (see Box 22.15). Multiple biopsies from the edge and base of a gastric ulcer are required. Once the diagnosis is made, further imaging is necessary for staging and assessment of resectability. EUS and CT can be used to stage locally advanced gastric cancer; laparoscopy may be required to assess for peritoneal metastatic disease if resection is being contemplated.

Management

Curative management

Resection offers the only hope of cure, and this can be achieved in about 90% of patients with early gastric cancer. For the majority of patients, total gastrectomy with lymphadenectomy is the operation of choice, preserving the spleen if possible. Endoscopic mucosal resection or endoscopic submucosal dissection can also be considered for very early tumours. Perioperative chemotherapy (5-fluorouracil, leucovorin, oxaliplatin and docetaxel) is recommended for patients with ≥T2 or node positive disease, to improve survival. For individuals with stage II–III gastric cancer who did not receive pre-operative chemotherapy, post-operative adjuvant chemotherapy (5-fluorouracil, leucovorin and oxaliplatin) is recommended. Individuals with proximal tumours involving the oesophago-gastric junction also require a distal oesophagectomy. Small tumours sited distally can be managed by a partial gastrectomy with lymphadenectomy and either a Billroth I or a Roux-en-Y reconstruction. Even for those who cannot be cured, palliative resection may be necessary when patients present with bleeding or gastric outflow obstruction.

Palliative treatment

Metastatic gastric cancer has a poor outlook, with survival around 4 months with best supportive care. Patients with inoperable locally advanced disease, or metastatic disease should be considered for palliative chemotherapy depending upon fitness, which may extend survival to 12 months. Increasingly molecular stratification helps guide optimal treatment, with targeted treatments increasing median survival by some additional months. The biologic agent trastuzumab is recommended in conjunction with chemotherapy for patients whose tumours overexpress *HER2* (p. 179). The immune checkpoint inhibitor nivolumab is recommended in combination with chemotherapy for HER2 negative adenocarcinomas whose tumours express PD-L1 with a combined positive score of ≥5. Endoscopic laser ablation can help control dysphagia or bleeding for some patients and palliative radiotherapy can also help with problematic bleeding. Carcinomas at the cardia or pylorus may require endoscopic dilatation or insertion of expandable metallic stents for relief of dysphagia or vomiting. Insertion of a nasogastric tube (Box 22.41) may offer temporary relief of vomiting due to gastric outlet obstruction.

22.41 How to insert a nasogastric tube

Equipment

- 8–9 F ‘fine-bore’ tube for feeding or 16–18 F ‘wide-bore’ tube for drainage
- Lubricant jelly
- Cup of water and straw for sipping
- Adhesive tape
- pH (not litmus) paper
- Sickness bowl and tissues
- Catheter drainage bag and clamp (for drainage)

Technique

- A clear explanation and a calm patient are essential
- Establish a ‘stop signal’ for the patient to use, if needed
- Ask the patient to sit semi-upright
- Examine the nose for deformity or blockage to determine which side to use
- Measure the distance from ear to xiphoid process via the nose and mark the position on the tube
- Advance the lubricated tube tip slowly along the floor of the nasal passage to the oropharynx
- Ask the patient to sip water and advance the tube 2–3 cm with each swallow
- Stop, withdraw and retry if the patient is distressed or coughing, as the tube may have entered the larynx
- Advance until the mark on the tube reaches the tip of the nose and secure with tape
- Aspirate the contents and check pH (gastric acid confirmed if $\text{pH} < 5$). If in doubt, perform a chest X-ray to confirm tube position (usually necessary with feeding tubes)
- Attach the catheter drainage bag, if necessary, and clamp

Aftercare

- Flush the tube daily after feeding or drug dosing
- Check position regularly and look for signs of displacement
- Check with the pharmacist what drugs, if any, can be safely given via the tube

Gastric lymphoma

This is a rare tumour, accounting for less than 5% of all gastric malignancies. The stomach is, however, the most common site for extranodal non-Hodgkin lymphoma and 60% of all primary gastrointestinal lymphomas occur at this site. Gastric lymphoma is 2 to 3 times more common in males than females. Lymphoid tissue is not found in the normal stomach, but lymphoid aggregates develop in the presence of *H. pylori* infection. Indeed, *H. pylori* infection is closely associated with the development of a low-grade lymphoma (classified as extranodal marginal-zone lymphomas of MALT type). EUS plays an important role in staging these lesions by accurately defining the depth of invasion into the gastric wall. The clinical presentation is similar to that of gastric cancer and endoscopically the tumour appears as a polypoid or ulcerating mass. While initial treatment of low-grade lesions confined to the superficial layers of the gastric wall consists of *H. pylori* eradication and close observation, 25% contain t(11:18) chromosomal translocations. In these cases, additional radiotherapy or chemotherapy is usually necessary. High-grade B-cell lymphomas should be treated by a combination of rituximab, chemotherapy, surgery and radiotherapy. The choice depends on the site and extent of tumour, the presence of comorbid illnesses, and other factors, such as symptoms of bleeding and gastric outflow obstruction. The prognosis depends on the stage at diagnosis. Features predicting a favourable prognosis are stage I or II disease, small resectable tumours, tumours with low-grade histology and age below 60 years.

Other tumours of the stomach

Gastrointestinal stromal cell tumours (GISTs), arising from the interstitial cells of Cajal, are occasionally found incidentally at endoscopy and account for 1%–2% of gastrointestinal neoplasms. They are differentiated from other mesenchymal tumours by expression of the *c-kit* proto-oncogene, which encodes a tyrosine kinase receptor. These tumours, particularly the smaller lesions of less than 2 cm, are usually benign and asymptomatic, but larger ones may have malignant potential and may occasionally be responsible for dyspepsia, ulceration and gastrointestinal bleeding. Small lesions (<2 cm) can usually be removed by endoscopy, while larger ones require surgical resection. Very large lesions should be treated pre-operatively with imatinib (a tyrosine kinase inhibitor) to reduce their size and make surgery easier. Imatinib can also provide prolonged control of metastatic GISTs. Sunitinib and regorafenib are used as second-line agents.

A variety of different types of gastric polyps occur. Fundic gland polyps are common and usually not associated with an increased risk of malignancy, other than in the context of familial adenomatous polyposis (FAP) (see p. 852). Hyperplastic polyps are also common, with regression generally occurring after *H. pylori* eradication. Adenomatous polyps are rare but have malignant potential and should be removed endoscopically with subsequent surveillance by periodic endoscopy.

Occasionally, gastric neuroendocrine (carcinoid) tumours are seen in the fundus and body in patients with long-standing pernicious anaemia. These benign tumours arise from ECL or other endocrine cells and are often multiple but rarely invasive. Unlike carcinoid tumours arising elsewhere in the gastrointestinal tract, they usually run a benign and favourable course. Large (>2 cm) carcinoids may metastasise and should be removed. Rarely, small nodules of ectopic pancreatic exocrine tissue are found. These 'pancreatic rests' may be mistaken for gastric neoplasms and usually cause no symptoms. EUS is the most useful investigation.

Gastric motility disorders

Gastroparesis

Defective gastric emptying without mechanical obstruction of the stomach or duodenum can occur as a primary event, due to inherited or acquired disorders of the gastric pacemaker or can be secondary to disorders of autonomic nerves (particularly diabetic neuropathy) or the gastroduodenal musculature (systemic sclerosis, myotonic dystrophies and amyloidosis). Surgical procedures can also lead to gastroparesis by damaging the vagus nerve. Drugs such as opiates, calcium channel antagonists and those with anticholinergic activity (tricyclics, phenothiazines) can also cause gastroparesis. Early satiety and recurrent vomiting are the major symptoms; abdominal fullness and a succussion splash may be present on examination. Symptoms may overlap with functional dyspepsia (post-prandial distress syndrome). Treatment is based on small, frequent, low-fat meals and the use of prokinetics such as metoclopramide and domperidone. In severe cases, nutritional failure can occur and long-term jejunostomy feeding or rarely total parenteral nutrition is required. Surgical interventions may be considered in refractory cases such as laparoscopic pyloroplasty, although they may be associated with significant morbidity.

Disorders of the small intestine

Disorders causing malabsorption

Coeliac disease

Coeliac disease is an inflammatory disorder of the small bowel occurring in genetically susceptible individuals, which results from intolerance to wheat gluten and similar proteins found in rye, barley and, to a lesser extent, oats. It can result in malabsorption and responds to a gluten-free diet. The condition occurs worldwide but is more common in northern Europe. The prevalence in the UK is approximately 1%, although 50% of these people are asymptomatic. These include both undiagnosed patients with the disease and those with latent coeliac disease, which refers to the situation where genetically susceptible people do not have the disease, but later may develop it.

Pathophysiology

The precise mechanism of mucosal damage is unclear, but immunological responses to gluten play a key role (Fig. 22.40). There is a strong genetic component, with around 8% of first-degree relatives of an index case affected, and there is high (approximately 80%) concordance in monozygotic twins. There is a strong association with human leucocyte antigen (HLA)-DQ2/DQ8. Dysbiosis of the intestinal microbiota has been identified, but it is unclear if this is pathological or a response to the underlying mucosal changes.

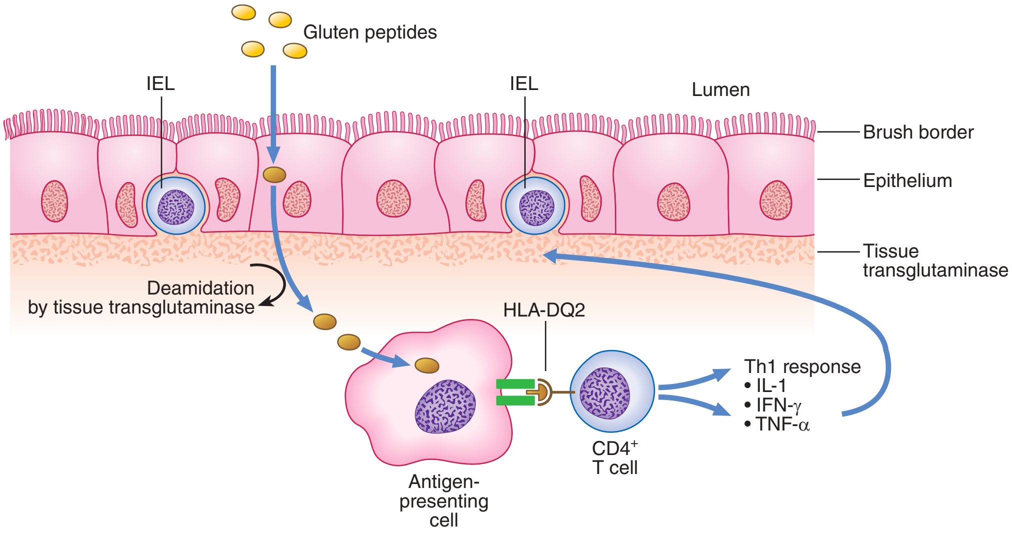

Fig. 22.40 Pathophysiology of coeliac disease. After being taken up by epithelial cells, gluten peptides are deamidated by the enzyme tissue transglutaminase in the subepithelial layer. They are then able to fit the antigen-binding motif on human leucocyte antigen (HLA)-DQ2-positive antigen-presenting cells. Recognition by CD4+ T cells triggers a Th1 immune response with generation of pro-inflammatory cytokines: interleukin-1 (IL-1), interferon gamma (IFN-γ) and tumour necrosis factor alpha (TNF-α). Lymphocytes infiltrate the lamina propria and an increase in intra-epithelial lymphocytes (IELs), crypt hyperplasia and villous atrophy ensue.

22.42 Malabsorption in old age

- **Coeliac disease**: symptoms such as dyspepsia tend to be vague; only 25% present classically with diarrhoea and weight loss. Metabolic bone disease, folate or iron deficiency, coagulopathy and small bowel lymphoma are more common.
- **Small bowel bacterial overgrowth**: more common due to atrophic gastritis, resulting in hypo- or achlorhydria, increased prevalence of jejunal diverticulosis and long-term adverse effects of gastric surgery for ulcer disease.

22.43 Disease associations of coeliac disease

- Type 1 diabetes mellitus (2%–8%)
- Thyroid disease (5%)
- Primary biliary cholangitis (3%)
- Sjögren syndrome (3%)
- Immunoglobulin A deficiency (2%)
- Pernicious anaemia
- Sarcoidosis
- Neurological complications:
    - Encephalopathy
    - Cerebellar atrophy
    - Peripheral neuropathy
    - Epilepsy
- Myasthenia gravis
- Dermatitis herpetiformis
- Down syndrome
- Enteropathy-associated T-cell lymphoma
- Small bowel carcinoma
- Squamous carcinoma of oesophagus
- Ulcerative jejunitis
- Pancreatic insufficiency
- Microscopic colitis
- Splenic atrophy

22.44 Important causes of subtotal villous atrophy

- Coeliac disease
- Tropical sprue
- Lymphoma
- HIV-related enteropathy
- Giardiasis
- Hypogammaglobulinaemia
- Radiation
- Whipple disease
- Zollinger–Ellison syndrome

(HIV = human immunodeficiency virus)

Clinical features

Coeliac disease can present at any age. In infancy, it occurs after weaning on to cereals and typically presents with diarrhoea, malabsorption and failure to thrive. In older children, it may present with non-specific features, such as delayed growth. Features of malnutrition are found on examination and mild abdominal distension may be present. Affected children have growth and pubertal delay, leading to short stature in adulthood.

In adults, the disease usually presents during the third or fourth decade and females are affected twice as often as males. The presentation is highly variable, depending on the severity and extent of small bowel involvement. Some have florid malabsorption, while others develop non-specific symptoms, such as tiredness, weight loss, folate deficiency or iron deficiency anaemia. Other symptoms include oral ulceration, dyspepsia and bloating; such non-specific symptomatology is more common in older people (Box 22.42). Unrecognised coeliac disease may present with mild under-nutrition and osteoporosis. Coeliac disease is associated with other HLA-linked autoimmune disorders and with certain other diseases (Box 22.43). In some centres, individuals at higher risk of developing coeliac disease, such as those with type 1 diabetes, undergo periodic antibody screening. This may identify people with asymptomatic or minimally symptomatic disease.

Investigations

These should be performed to confirm the diagnosis and to look for the consequences of malabsorption.

Duodenal biopsy

Endoscopic small bowel biopsy is the gold standard. Normal appearances on endoscopy should not preclude biopsy, as the mucosa usually looks normal. As the histological changes can be patchy, an adequate number of biopsies (four biopsies from the second part of the duodenum plus one from the duodenal bulb) should be taken. The histological features are usually characteristic, but other causes of villous atrophy should be considered (Box 22.44 and Fig. 22.41).

Antibodies

Antibody tests constitute a valuable screening tool in patients with diarrhoea or other suggestive symptoms, but are not a diagnostic substitute for small bowel biopsy at present. Tissue transglutaminase (tTG) is now recognised as the autoantigen for anti-endomysial antibodies. If the antibody screen is positive, adult patients should remain on a gluten-containing diet until duodenal biopsies are taken. High-titre serology in symptomatic children can be considered diagnostic without the need for endoscopy and biopsy. The use of this approach for diagnosis in adults is currently being explored.

Anti-endomysial antibodies of the IgA class are detectable by immunofluorescence in most untreated cases. They are sensitive (85%–95%) and specific (approximately 99%) for the diagnosis, except in very young infants. IgG antibodies, however, must be measured in patients with coexisting IgA deficiency. Measurement of the concentration of tTG antibodies has become the serological test of choice in many countries, as it is easier to perform, is semi-quantitative, has more than 95% sensitivity and specificity, and is more accurate in patients with IgA deficiency.

Haematology and biochemistry

A full blood count may show microcytic or macrocytic anaemia from iron or folate deficiency and features of hyposplenism (target cells, spherocytes and Howell–Jolly bodies). Biochemical tests may reveal reduced concentrations of calcium, magnesium, total protein, albumin or vitamin D. Serum IgA measurement is required to ensure an appropriate IgA response and to allow accurate analysis of serological testing.

Other investigations

Measurement of bone density may be considered in people with a 10-year fracture risk of > 10% but is not routinely required.

Management

The aims are to correct existing deficiencies of micronutrients, such as iron, folate, calcium and/or vitamin D, and to achieve mucosal healing through a life-long gluten-free diet. This requires the exclusion of wheat, rye, barley and initially oats, although oats may be re-introduced safely in most patients after 6–12 months. Initially, frequent dietary counselling is required to make sure the diet is being observed, as the most common reason for failure to improve with dietary treatment is accidental or unrecognised gluten ingestion. Mineral and vitamin supplements can also be given where indicated but are seldom necessary when a strict gluten-free diet is adhered to. Booklets produced by 'coeliac societies' in many countries contain diet sheets and recipes using gluten-free flour and are of great value. Dietetic follow-up is key to management. Patients should be followed up after initiation of a gluten-free diet, with assessment of symptoms, weight and nutritional status, and blood should be taken for measurement of tTG or anti-endomysial antibodies. There are currently

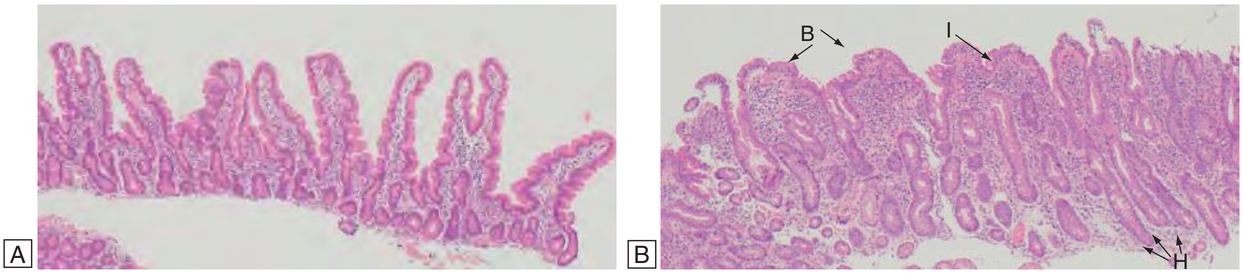

Fig. 22.41 **Jejunal mucosa.** **A** Normal. **B** Subtotal villous atrophy in coeliac disease. There is blunting of villi (B), crypt hyperplasia (H) and inflammatory infiltration of the lamina propria (I).

no effective non-invasive tests to assess small bowel mucosal healing. Repeat small bowel biopsies should be considered in patients whose symptoms fail to improve and those in whom antibody levels remain high. In these circumstances, if the diet is satisfactory, then other conditions, such as pancreatic insufficiency or microscopic colitis, should be sought, as should complications of coeliac disease, such as ulcerative jejunitis or enteropathy-associated T-cell lymphoma. Some patients who fail to respond adequately to a gluten-free diet may require therapy with glucocorticoids or immunosuppressive drugs, and this may be classified as refractory coeliac disease (RCD). RCD can be classified as type 1, characterised as a normal intra-epithelial lymphocyte phenotype, or type 2, characterised by an abnormal expansion of a subset of small intestinal intra-epithelial lymphocytes. Type 2 RCD has a 5-year survival of around 50% due to the increased risk of lymphoma, compared to 90% in type 1 RCD, where deaths can occur due to severe malabsorption.

Complications

A twofold-increased risk of malignancy, particularly of enteropathy-associated T-cell lymphoma, small bowel carcinoma and squamous carcinoma of the oesophagus, has been reported.

A few patients develop ulcerative jejunoileitis. This may present with fever, pain, obstruction or perforation. This diagnosis can be made by barium studies or enteroscopy, but laparotomy and full-thickness biopsy may be required. Treatment is difficult. Glucocorticoids are used with mixed success and some patients require surgical resection and parenteral nutrition. The course is often progressive.

Osteoporosis and osteomalacia may occur in patients with long-standing, poorly controlled coeliac disease. These complications are less common in those who adhere strictly to a gluten-free diet.

Dermatitis herpetiformis

This is characterised by crops of intensely itchy blisters over the elbows, knees, back and buttocks (Ch. 26). Immunofluorescence shows granular or linear IgA deposition at the dermo-epidermal junction. Almost all patients have partial villous atrophy on duodenal biopsy, identical to that seen in coeliac disease, even though they usually have no gastrointestinal symptoms. In contrast, fewer than 10% of coeliac patients have evidence of dermatitis herpetiformis, although both disorders are associated with the same histocompatibility antigen groups. The rash usually responds to a gluten-free diet, but some patients require additional treatment with dapsone (100–150 mg daily).

Tropical sprue

Tropical sprue is defined as chronic, progressive malabsorption in a patient in or from a tropical country, associated with abnormalities of small intestinal structure and function. The disease occurs mainly in the West Indies and in southern India, Malaysia and Indonesia.

Pathophysiology

The epidemiological pattern and occasional epidemics suggest that an infective agent may be involved. Although no single bacterium has been isolated, the condition often begins after an acute diarrhoeal illness. Small bowel bacterial overgrowth with *Escherichia coli*, *Enterobacter* and *Klebsiella* is frequently seen. The changes closely resemble those of coeliac disease.

Clinical features

There is diarrhoea, abdominal distension, anorexia, fatigue and weight loss. In visitors to the tropics, the onset of severe diarrhoea may be sudden and accompanied by fever. When the disorder becomes chronic, the features of megaloblastic anaemia (vitamin B_{12} and folic acid malabsorption) and other deficiencies, including ankle oedema, glossitis and stomatitis, are common. Remissions and relapses may occur. The differential diagnosis in the indigenous tropical population is an infective cause of diarrhoea. The important differential diagnosis in visitors to the tropics is giardiasis (Ch. 14).

Management

Tetracycline (250 mg 4 times daily for 28 days) is the treatment of choice and brings about long-term remission or cure. In most patients, pharmacological doses of folic acid (5 mg daily) improve symptoms and jejunal morphology. In some cases, treatment must be prolonged before improvement occurs and occasionally patients must leave the tropics.

Small intestinal bacterial overgrowth

The normal duodenum and jejunum contain fewer than 10^4/mL organisms and these are usually derived from saliva. The count of coliform organisms never exceeds 10^3/mL. In bacterial overgrowth, there may be 10^8–10^{10}/mL organisms, most of which are normally found only in the colon. Disorders that impair the normal physiological mechanisms controlling bacterial proliferation in the intestine predispose to bacterial overgrowth (Box 22.45). The most important are loss of gastric acidity, impaired intestinal motility and structural abnormalities that allow colonic bacteria to gain access to the small intestine or provide a secluded haven from the peristaltic stream.

Pathophysiology

Bacterial overgrowth can occur in patients with small bowel diverticuli or following surgery that creates ‘blind loops’ of bowel, such as Billroth II or Roux-en-Y reconstructions. Diabetic autonomic neuropathy reduces small bowel motility and affects enterocyte secretion. In systemic sclerosis, bacterial overgrowth arises because the circular and longitudinal layers of the intestinal muscle are fibrosed and motility is abnormal. In idiopathic hypogammaglobulinaemia, bacterial overgrowth occurs because the IgA and IgM levels in serum and jejunal secretions are reduced. Chronic diarrhoea and malabsorption occur because of bacterial overgrowth and recurrent gastrointestinal infections (particularly giardiasis, Ch. 14).

Clinical features

Patients commonly present with bloating, abdominal pain, distension and diarrhoea. Nutritional deficiencies can occur in severe cases. Specifically, vitamin B_{12} deficiency can arise as the result of the bacteria

22.45 Causes of small intestinal bacterial overgrowth

Mechanism	Examples
Hypo- or achlorhydria	Pernicious anaemia Partial gastrectomy Long-term proton pump inhibitor therapy
Impaired intestinal motility	Systemic sclerosis Diabetic autonomic neuropathy
Structural abnormalities	Gastric surgery Jejunal diverticulosis Enterocolic fistulae* Extensive small bowel resection Strictures*
Impaired immune function	Hypogammaglobulinaemia

*Most commonly caused by Crohn disease.

utilising vitamin B_{12}. Nutritional deficiencies are more commonly seen in patients with structural abnormalities, such as 'blind loop syndrome' or systemic sclerosis. Symptoms can commonly overlap with other diagnoses such as IBS and functional dyspepsia. There may also be symptoms from any underlying intestinal cause.

Investigations

Culture of small bowel aspirate, obtained at endoscopy, is the gold standard for diagnosis. However, this is a time-consuming, invasive and expensive technique. Bacterial overgrowth can also be diagnosed non-invasively using hydrogen breath tests, although they lack sensitivity. These simple, non-radioactive tests involve serial measurement of breath samples for hydrogen after oral ingestion of 75 g glucose or 10 g lactulose. If bacteria are present within the small bowel, they rapidly metabolise the glucose/lactulose, causing an early rise in exhaled hydrogen, in advance of that normally resulting from metabolism by colonic flora. Lactulose breath tests have a higher sensitivity than glucose, although may be less specific, as a rise in hydrogen can coincide with the arrival of lactulose in the caecum, leading to a false-positive result.

Management

The underlying cause of small intestinal bacterial overgrowth should be addressed, where possible. A course of broad-spectrum antibiotic for 2 weeks is the first-line treatment, although there is no consensus on agent or dose. Examples include rifaximin (which is not absorbed from the gut after oral administration), as well as systemic antibiotics such as ciprofloxacin, metronidazole and amoxicillin. Around 30%–40% of patients do not respond adequately, and relapse rates are high. Some patients require up to 4 weeks of treatment and, in a few, continuous rotating courses of antibiotics are necessary. Consideration needs to be given to the risk of emerging antimicrobial resistance. Intramuscular vitamin B_{12} supplementation may be needed in chronic cases. Patients with motility disorders, such as diabetes and systemic sclerosis, can sometimes benefit from antidiarrhoeal drugs (diphenoxylate or loperamide orally). Giardiasis should be controlled in patients with hypogammaglobulinaemia, using metronidazole or tinidazole, but if symptoms fail to respond adequately, immunoglobulin infusions may be required.

Whipple disease

This rare condition is characterised by infiltration of small intestinal mucosa by 'foamy' macrophages, which stain positive with periodic acid–Schiff (PAS) reagent. The disease is a multisystem one and almost any organ can be affected, sometimes long before gastrointestinal involvement becomes apparent (Box 22.46).

22.46 Clinical features of Whipple disease

Gastrointestinal (> 70%)

- Diarrhoea (75%)
- Steatorrhoea
- Weight loss (90%)
- Protein-losing enteropathy
- Ascites
- Hepatosplenomegaly (< 5%)

Musculoskeletal (65%)

- Seronegative large joint arthropathy
- Sacroiliitis

Cardiac (10%)

- Pericarditis
- Myocarditis
- Endocarditis
- Coronary arteritis

Neurological (10%–40%)

- Apathy
- Fits
- Dementia
- Myoclonus
- Meningitis
- Cranial nerve lesions

Pulmonary (10%–20%)

- Chronic cough
- Pleurisy
- Pulmonary infiltrates

Haematological (60%)

- Anaemia
- Lymphadenopathy

Other (40%)

- Fever
- Pigmentation

Pathophysiology

Whipple disease is caused by infection with the gram-positive bacillus *Tropheryma whipplei*, which becomes resident within macrophages in the bowel mucosa. Villi are widened and flattened, containing densely packed macrophages in the lamina propria, which obstruct lymphatic drainage and cause fat malabsorption. Between 50% and 70% of individuals have antibodies against *Tropheryma whipplei* worldwide, indicating prior environmental exposure, and yet Whipple disease only occurs in a minority. This is presumably because host, bacterial and environmental factors are contributory in its pathogenesis.

Clinical features

Middle-aged men of European descent are most frequently affected and the clinical presentation depends on the pattern of organ involvement. Low-grade fever is common and most patients have joint symptoms to some degree, often as the first manifestation. Occasionally, neurological manifestations may predominate, due to CNS infection. Endocarditis can also occur, but usually only in a late phase.

Investigations

The diagnosis is made by the characteristic features on small bowel biopsy, with characterisation of the bacillus by polymerase chain reaction (PCR).

Management

Whipple disease is often fatal if untreated but responds well, at least initially, to intravenous ceftriaxone (2 g daily for 2 weeks), followed by oral co-trimoxazole for at least 1 year. Symptoms usually resolve quickly and biopsy changes revert to normal in a few weeks. Long-term follow-up is essential, as clinical relapse occurs in up to one-third of patients, often within the CNS; in this case, the same therapy is repeated or else treatment with doxycycline and hydroxychloroquine is necessary.

Bile acid diarrhoea

Causes of bile acid diarrhoea are shown in Box 22.47. The population prevalence is estimated at around 1% and it is often under-diagnosed. It is now appreciated that up to a third of patients diagnosed with diarrhoea-predominant irritable bowel syndrome have evidence of bile acid diarrhoea. A common scenario is in patients with Crohn disease who have undergone ileal resection, which can also lead to other malabsorptive manifestations (Fig. 22.42). Unabsorbed bile salts pass into the colon, stimulating water and electrolyte secretion and causing diarrhoea. If hepatic synthesis of new bile acids cannot keep pace with faecal losses, fat malabsorption occurs. Another consequence is the formation of lithogenic bile, leading to gallstones. Renal calculi, rich in oxalate, develop. Normally, oxalate in the colon is bound to and precipitated by calcium. Unabsorbed bile salts preferentially bind calcium, leaving oxalate to be absorbed, with development of urinary oxalate calculi.

Patients have urgent watery diarrhoea or mild steatorrhoea. Contrast studies and tests of B$_{12}$ and bile acid absorption, such as the selenium-75 (^{75}Se)-homocholic acid taurine (SeHCAT) test (see Box 22.12), are useful investigations but are not available throughout the world due to the requirement for synthetic radio-labelled compound. An elevated serum 7α-hydroxycholestenone is a useful non-invasive marker of bile acid diarrhoea. Diarrhoea usually responds well to bile acid sequestrants, such as colestyramine or colesevelam, which bind bile salts in the intestinal lumen. A therapeutic trial of bile acid sequestrants can also be used to make a presumptive diagnosis where investigations are unavailable.

Short bowel syndrome

This is discussed in Chapter 5.

Radiation enteropathy

Intestinal damage occurs in 10%–15% of patients undergoing radiotherapy for abdominal or pelvic malignancy. The risk varies with total dose, dosing schedule and the use of concomitant chemotherapy.

22.47 Classification and causes of bile acid diarrhoea

Type	Cause
Type 1	Terminal ileal disease leading to malabsorption of bile acids from terminal ileum, as the result of Crohn disease or terminal ileal resection
Type 2	Primary or idiopathic – no anatomical abnormalities or risk factors present
Type 3	Other conditions that affect gastrointestinal absorption, such as chronic pancreatitis, coeliac disease, small intestinal bacterial overgrowth

Pathophysiology

The rectum, sigmoid colon and terminal ileum are most frequently involved. Radiation causes acute inflammation, shortening of villi, oedema and crypt abscess formation. These usually resolve completely, but some patients develop an obliterative endarteritis affecting the endothelium of submucosal arterioles over 2–12 months. In the longer term, this can provoke a fibrotic reaction, leading to adhesions, ulceration, strictures, obstruction or fistula to adjacent organs.

Clinical features

In the acute phase, there is nausea, vomiting, cramping abdominal pain and diarrhoea. When the rectum and colon are involved, rectal mucus, bleeding and tenesmus occur. The chronic phase develops after 3 or more months in some patients and produces one or more of the problems listed in Box 22.48.

Investigations

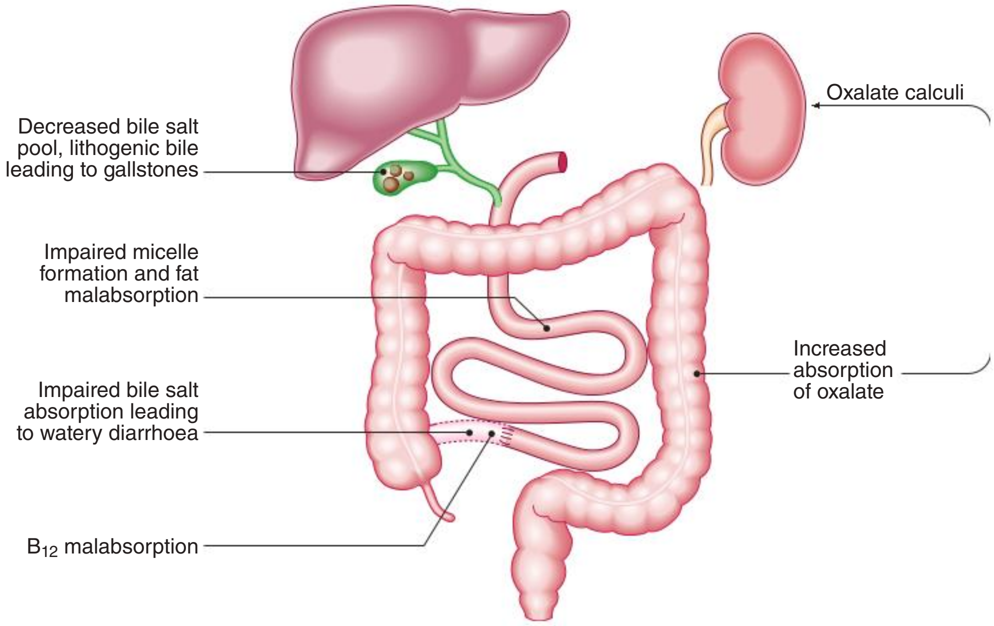
In the acute phase, the rectal changes at sigmoidoscopy resemble ulcerative proctitis (see Fig. 22.62). The extent of the lesion can be assessed by colonoscopy. Barium follow-through or MRI enterography can be of diagnostic value in showing small bowel strictures, ulcers and fistulae.

Management

Diarrhoea in the acute phase should be treated with codeine phosphate, diphenoxylate or loperamide. Antibiotics may be required for bacterial overgrowth. Nutritional supplements are necessary when malabsorption is present. Colestyramine or colesevelam is useful for associated bile acid diarrhoea. In radiation enteropathy, the underlying pathophysiology

22.48 Chronic complications of intestinal irradiation

- Proctocolitis
- Bleeding from telangiectasia
- Small bowel strictures
- Fistulae: rectovaginal, colovesical, enterocolic
- Adhesions
- Malabsorption: bacterial overgrowth, bile acid diarrhoea (ileal damage)



Decreased bile salt pool, lithogenic bile leading to gallstones
Impaired micelle formation and fat malabsorption
Impaired bile salt absorption leading to watery diarrhoea
B12 malabsorption
Oxalate calculi
Increased absorption of oxalate

Fig. 22.42 Consequences of ileal resection.

is tissue ischaemia rather than inflammation; glucocorticoid enemas are therefore not effective. Treatments include sucralfate enema and hyperbaric oxygen. Different endoscopic techniques may also be used, including argon plasma coagulation, radiofrequency ablation and heater probe thermocoagulation. Surgery should be avoided, if possible, because the injured intestine is difficult to resect and anastomose, but may be necessary if there is obstruction, perforation or fistula.

Abetalipoproteinaemia

This rare autosomal recessive disorder is caused by deficiency of apolipoprotein B, which results in failure of chylomicron formation. It leads to fat malabsorption and deficiency of fat-soluble vitamins. Jejunal biopsy reveals enterocytes distended with resynthesised triglyceride and normal villous morphology. Serum cholesterol and triglyceride levels are low. A number of other abnormalities occur in this syndrome, including acanthocytosis, retinitis pigmentosa and a progressive neurological disorder with cerebellar and dorsal column signs. Symptoms may be improved by a low-fat diet supplemented with medium-chain triglycerides and vitamins A, D, E and K.

Miscellaneous disorders of the small intestine

Protein-losing enteropathy

This term is used when there is excessive loss of protein into the gut lumen sufficient to cause hypoproteinaemia. Protein-losing enteropathy occurs in many gut disorders but is most common in those where ulceration occurs (Box 22.49). In other disorders, protein loss can result from increased mucosal permeability or obstruction of intestinal lymphatic vessels. The presentation is with peripheral oedema and hypoproteinaemia (reduced serum albumin and immunoglobulins), in the context of normal liver function and absent proteinuria. The diagnosis can be confirmed by measurement of faecal clearance of α1-antitrypsin or chromium-51 (^{51}Cr)-labelled albumin after intravenous injection. Other investigations should be performed to determine the underlying cause. Treatment is that of the underlying disorder, with nutritional support and measures to control peripheral oedema.

Intestinal lymphangiectasia

This may be primary, resulting from congenital malunion of lymphatics, or secondary to lymphatic obstruction due to lymphoma, filariasis or constrictive pericarditis. Impaired drainage of intestinal lymphatic vessels leads to discharge of protein and fat-rich lymph into the gastrointestinal lumen. The condition presents with peripheral lymphoedema, pleural effusions or chylous ascites, and steatorrhoea. Investigations reveal hypoalbuminaemia, lymphopenia and reduced serum immunoglobulin concentrations. The diagnosis can be made by CT or MRI scanning and by enteroscopy with jejunal biopsy, which shows greatly dilated lacteals. Treatment consists of a low-fat diet with medium-chain triglyceride supplements.

Ulceration of the small intestine

Small bowel ulcers are uncommon and are either idiopathic or secondary to underlying intestinal disorders (Box 22.50). Ulcers are more common in the ileum and cause bleeding, perforation, stricture formation or obstruction. Capsule endoscopy and enteroscopy confirm the diagnosis.

NSAID-associated small intestinal toxicity

NSAIDs cause a spectrum of small intestinal lesions, ranging from erosions and ulcers to mucosal webs, strictures and, rarely, a condition known as 'diaphragm disease', in which intense submucosal fibrosis results in circumferential strictures. The condition can present with pain, obstruction, bleeding or anaemia, and may mimic Crohn disease, carcinoma or lymphoma. Enteroscopy or capsule endoscopy can reveal the diagnosis but sometimes this is discovered only at laparotomy.

i 22.49 Causes of protein-losing enteropathy

With mucosal erosions or ulceration

- Crohn disease
- Ulcerative colitis
- Radiation damage
- Oesophageal, gastric or colonic cancer
- Lymphoma

Without mucosal erosions or ulceration

- Ménétrier disease
- Bacterial overgrowth
- Coeliac disease
- Tropical sprue
- Eosinophilic gastroenteritis
- Systemic lupus erythematosus

With lymphatic obstruction

- Intestinal lymphangiectasia
- Constrictive pericarditis
- Lymphoma
- Whipple disease

i 22.50 Causes of small intestinal ulcers

- Idiopathic
- Inflammatory bowel disease
- Non-steroidal anti-inflammatory drugs
- Ulcerative jejunoileitis
- Lymphoma and carcinoma
- Infections (tuberculosis, typhoid, *Yersinia enterocolitica*)
- Others (radiation, vasculitis)

Eosinophilic gastroenteritis

This disorder of unknown aetiology can affect any part of the gastrointestinal tract, with the stomach and small intestine being the areas most commonly affected; it is characterised by eosinophil infiltration involving the gut wall, in the absence of parasitic infection or eosinophilia of other tissues. It may be mucosal, muscular or subserosal. Peripheral blood eosinophilia is present in around 70% of cases.

Clinical features

There are features of obstruction and inflammation, such as colicky pain, nausea and vomiting, diarrhoea and weight loss. Protein-losing enteropathy occurs and up to 50% of patients have a history of other allergic disorders. Steatorrhoea is present in around 30% of patients. Serosal involvement may produce eosinophilic ascites.

Investigations and management

The diagnosis is made by histological assessment of multiple endoscopic biopsies, although full-thickness biopsies are occasionally required. Other investigations should be performed to exclude parasitic infection and other causes of eosinophilia. Serum IgE concentration is raised in around two-thirds of cases. Dietary manipulations can be considered as an initial strategy, but are rarely effective, although elimination diets (especially of milk) may benefit a few patients. Severe symptoms are treated with prednisolone (20–40 mg daily) and/or sodium cromoglicate, which stabilises mast cell membranes. The prognosis is good in the majority of patients.

Meckel diverticulum

This is the most common congenital anomaly of the gastrointestinal tract and occurs in 0.3%–3% of people, but the vast majority of affected individuals are asymptomatic throughout life. The diverticulum results from failure of closure of the vitelline duct, with persistence of a blind-ending sac arising from the anti-mesenteric border of the ileum; it usually occurs within 100 cm of the ileocaecal valve and is up to 5 cm long.

Approximately 50% contain ectopic gastric mucosa; rarely, colonic, pancreatic or endometrial tissue is present. Complications most commonly occur in the first 2 years of life but are occasionally seen in young adults. Bleeding can result from ulceration of ileal mucosa adjacent to the ectopic parietal cells and presents as recurrent melaena or altered blood per rectum. The diagnosis can be made by scanning the abdomen using a gamma camera following an intravenous injection of ^{99m}Tc-pertechnetate, which is concentrated by ectopic parietal cells. Other complications include intestinal obstruction, diverticulitis, intussusception and perforation. Intervention is unnecessary unless complications occur.

Adverse food reactions

Adverse food reactions are common and are subdivided into food intolerance and food allergy, the former being much more common. In food intolerance, there is an adverse reaction to food that is not immune-mediated and results from pharmacological (histamine, tyramine or monosodium glutamate), metabolic (lactase deficiency) or other mechanisms (toxins or chemical contaminants in food). Food allergies (discussed in Chapter 4) are immune-mediated disorders, most commonly due to type I hypersensitivity reactions with production of IgE antibodies, although type IV delayed hypersensitivity reactions are also seen.

Lactose intolerance

Lactose intolerance is characterised by the occurrence of colicky abdominal pain, distension, increased flatus, borborygmi and diarrhoea after ingesting milk or milk products. It is caused by enterocyte lactase deficiency. Lactase activity normally declines throughout childhood and the enzyme is deficient in up to 90% of adult Africans, Asians and South Americans, but only 5% of northern Europeans.

In cases of genetically determined (primary) lactase deficiency, jejunal morphology is normal. Secondary lactase deficiency can also occur as a consequence of disorders that damage the jejunal mucosa, such as coeliac disease and viral gastroenteritis. Under these circumstances, unhydrolysed lactose enters the colon, where bacterial fermentation produces volatile short-chain fatty acids, hydrogen and carbon dioxide. The diagnosis should be suspected when the gastrointestinal symptoms mentioned above are triggered by ingesting milk or milk products with clinical improvement on lactose withdrawal. The lactose hydrogen breath test is a useful non-invasive investigation. Management is by excluding lactose from the diet, although most affected individuals are able to tolerate small amounts of dairy products without symptoms.

Infections of the small intestine

Infections of the small intestine are discussed in other chapters. For travellers' diarrhoea, giardiasis and amoebiasis, see Chapter 14. Abdominal tuberculosis is discussed on page 559. Cryptosporidiosis and other protozoal infections, including cystoisosporiasis (*Cystoisospora belli*) and microsporidiosis, are covered Chapter 14.

Tumours of the small intestine

The small intestine is rarely affected by neoplasia and fewer than 5% of all gastrointestinal tumours occur at this site.

Benign tumours

The most common are adenomas, GISTs, lipomas and hamartomas. Adenomas are most often found in the periampullary region and are usually asymptomatic, although occult bleeding or obstruction due to intussusception may occur. Transformation to adenocarcinoma is rare. Multiple adenomas are common in the duodenum of patients with familial adenomatous polyposis (FAP), who require regular endoscopic surveillance. Hamartomatous polyps with almost no malignant potential occur in Peutz–Jeghers syndrome (p. 850).

Malignant tumours

These are rare and include, in decreasing order of frequency, neuroendocrine tumours, adenocarcinoma, malignant GIST and lymphoma. The majority occur in middle age or later. Kaposi sarcoma of the small bowel may arise in patients with HIV/AIDS.

Adenocarcinomas

Adenocarcinomas occur with increased frequency in patients with FAP, coeliac disease, small bowel Crohn disease and Peutz–Jeghers syndrome. This rare cancer accounts for fewer than 5% of all gastrointestinal malignancies. The non-specific presentation and rarity of these lesions often lead to a delay in diagnosis. Most are noted during assessment of anaemia or obscure gastrointestinal bleeding. Capsule endoscopy or device-assisted enteroscopy, and small bowel enterography studies (CT or MRI) can be used to identify lesions. Treatment is by surgical resection.

Neuroendocrine tumours

These are discussed in detail on page 732.

Lymphoma

Non-Hodgkin lymphoma (Ch. 24) may involve the gastrointestinal tract as part of more generalised disease or may rarely arise in the gut, the small intestine being most commonly affected. Lymphomas occur with increased frequency in patients with coeliac disease, HIV/AIDS and other immunodeficiency states. Most are of B-cell origin, although lymphoma associated with coeliac disease is derived from T cells (enteropathy-associated T-cell lymphoma).

Colicky abdominal pain, obstruction and weight loss are the usual presenting features but perforation is also seen occasionally. Malabsorption is a feature of diffuse bowel involvement and hepatosplenomegaly is rare.

The diagnosis is made by small bowel biopsy, radiological contrast studies and CT. Staging investigations should be performed as for lymphomas occurring elsewhere (p. 163). Surgical resection, where possible, is the treatment of choice, with radiotherapy and combination chemotherapy reserved for those with advanced disease. The prognosis depends largely on the stage at diagnosis, cell type, patient age and the presence of 'B' symptoms (fever, weight loss, night sweats).

Immunoproliferative small intestinal disease

Immunoproliferative small intestinal disease (IPSID), also known as alpha heavy chain disease, is a rare condition occurring mainly in Mediterranean countries, the Middle East, India, Pakistan and North America. It is a variant of B-cell lymphoma of MALT type and often associated with *Campylobacter jejuni* infection. The condition varies in severity from relatively benign to frankly malignant.

The small intestinal mucosa is diffusely affected, especially proximally, by a dense lymphoplasmacytic infiltrate. Enlarged mesenteric lymph nodes are also common. Most patients are young adults who present with malabsorption, anorexia and fever. Serum electrophoresis confirms the presence of alpha heavy chains (from the Fc portion of IgA). Prolonged remissions can be obtained with long-term antibiotic therapy, but chemotherapy is required for those who fail to respond or who have aggressive disease.

Small intestine motility disorders

Chronic small intestine pseudo-obstruction

Small intestinal motility is disordered in conditions that affect the smooth muscle or nerves of the intestine. Many cases are primary (idiopathic), while others are secondary to a variety of disorders or drugs (Box 22.51).

i 22.51 Causes of chronic intestinal pseudo-obstruction

Primary or idiopathic

- Rare familial visceral myopathies or neuropathies
- Congenital aganglionosis

Secondary

- Drugs (opiates, tricyclic antidepressants, phenothiazines)
- Smooth muscle disorders (systemic sclerosis, amyloidosis, mitochondrial myopathies)
- Myenteric plexus dysfunction due to paraneoplastic neuropathy
- Central nervous system disorders (Parkinson disease, autonomic neuropathy)
- Endocrine and metabolic disorders (hypothyroidism, diabetic autonomic neuropathy, phaeochromocytoma, acute intermittent porphyria)

Clinical features

The presentation is with recurrent episodes of nausea, vomiting, abdominal discomfort and distension, often worse after food. Alternating constipation and diarrhoea occur and weight loss results from malabsorption (due to bacterial overgrowth) and fear of eating. There may also be symptoms of dysmotility affecting other parts of the gastrointestinal tract, such as dysphagia, and features of bladder dysfunction in primary cases. Some patients develop severe abdominal pain for reasons that are poorly understood, and this can be difficult to manage.

Investigations

The diagnosis is often delayed, and a high index of suspicion is needed. Plain X-rays show distended loops of bowel and air–fluid levels, with abdominal CT and small bowel MRI used to exclude mechanical obstruction. Laparotomy is sometimes required to exclude obstruction and to obtain full-thickness biopsies of the intestine. Examination of biopsy material using specialised techniques, such as electron microscopy and immunohistochemistry can diagnose the many rare diseases of enteric smooth muscle and nerves that can cause this syndrome.

Management

This is often difficult. Underlying causes should be addressed and further surgery avoided. Metoclopramide or domperidone may enhance motility and antibiotics are given for bacterial overgrowth. Nutritional and psychological support is also necessary.

Disorders of the colon and rectum

Colorectal polyps

Types of colorectal polyps

In the colon, polyps usually arise from the mucosal layer. These can vary in number and size, from a few millimetres to several centimetres. They are commonly described based on their appearance as sessile, pedunculated, flat, elevated or depressed (Fig. 22.43). In addition, they are classified histologically, as neoplastic or non-neoplastic polyps (Box 22.52). This is important to help predict their malignant potential.

Non-neoplastic polyps include hamartomas, inflammatory polyps and hyperplastic polyps, which have no malignant potential. Hyperplastic polyps are the commonest type of colorectal polyp, and are a subgroup of so-called serrated polyps, often small in size, and frequently found in the distal colon. Hamartomas can occur sporadically, or as part of a polyposis syndrome. Inflammatory polyps are commonly seen in the context of IBD and are due to inflammation within the colon with distorted mucosa.

The most common neoplastic polyps are conventional adenomas, which have malignant potential and are extremely common in the Western world. The prevalence of adenomas increases with age; 50% of people over 60 years of age have colorectal adenomas and in about half of these individuals the polyps are multiple. Adenomas can be found throughout the colon, although larger polyps, harbouring a higher risk of malignancy, tend to be more common in the rectum and distal colon. They can be further subclassified histologically, as either tubular, villous or tubulovillous, according to the glandular architecture. Features associated with a higher risk of subsequent malignancy are listed in Box 22.53. Adenomas are usually asymptomatic and discovered incidentally. Larger adenomas can occasionally cause bleeding and anaemia. Rarely, large villous adenomas can secrete significant amounts of mucus, causing diarrhoea and hypokalaemia (McKittrick–Wheelock syndrome).

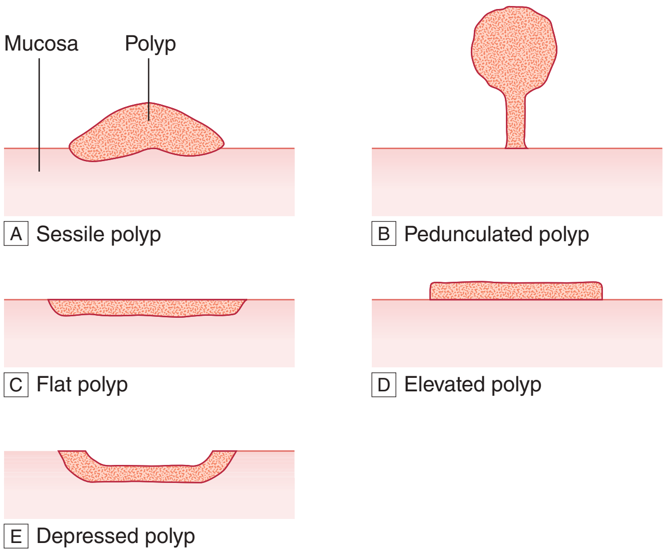


Fig. 22.43 **Polyp morphology.**

i 22.52 Neoplastic and non-neoplastic polyps

Neoplastic polyps	Non-neoplastic polyps
• Conventional adenoma	• Hamartoma
• Sessile serrated lesion	• Inflammatory
• Traditional serrated adenoma	• Hyperplastic

i 22.53 Risk factors for malignant change in colonic polyps

- Large size (> 2 cm)
- Multiple polyps
- Serrated polyps (excluding small rectal hyperplastic polyps)
- Villous architecture
- High-grade dysplasia

Traditionally, it was thought that adenomas were the only type of neoplastic polyp. However, it is now known that sessile serrated lesions and traditional serrated adenomas, have malignant potential. Sessile serrated lesions are more common in the right colon, tend to be flatter than conventional adenomas and are often covered with a mucus cap, making them hard to detect. It is now thought that between 15% and 30% of colorectal cancers arise from sessile serrated lesions. Traditional serrated adenomas are relatively rare, accounting for < 1% of all polyps, and are most commonly found in the distal colon.

Assessment and treatment of colorectal polyps

Colonic polyps are commonly found incidentally during endoscopy. If a polyp is found during sigmoidoscopy, a colonoscopy should be

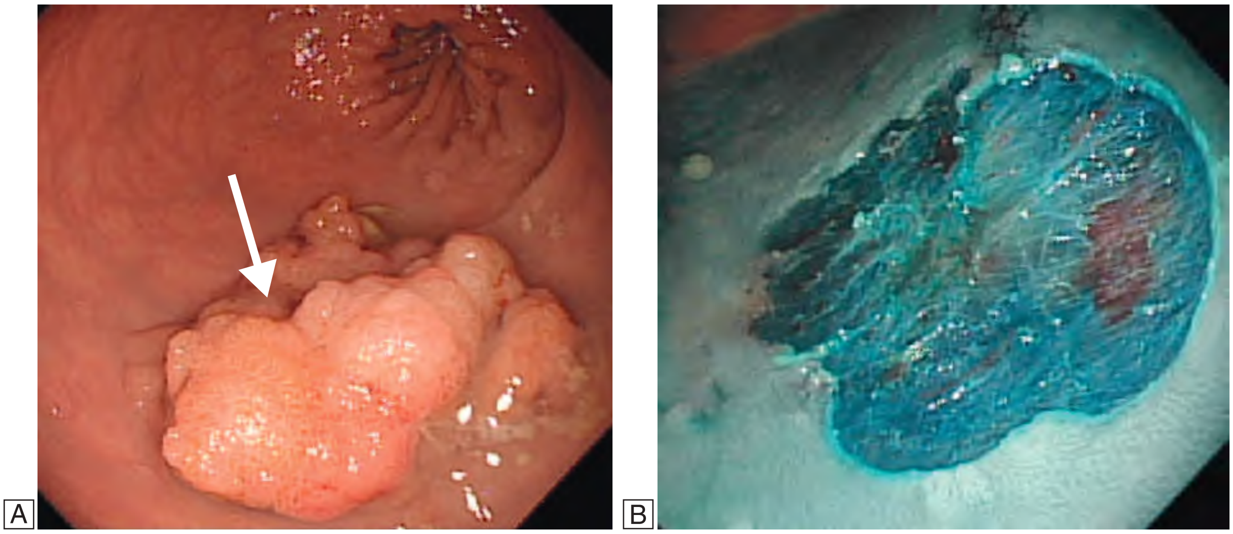

Fig. 22.44 **Large rectal adenomatous polyp.** A Before colonoscopic polypectomy. B After polypectomy.

subsequently performed, as up to 40%–50% of affected individuals have further polyps more proximally in the colon. As neoplastic colonic polyps have malignant potential, these should be removed via colonoscopic polypectomy, as this considerably reduces subsequent colorectal cancer risk (Fig. 22.44). When cancer cells are found within 2 mm of the resection margin of the polyp, when the polyp cancer is poorly differentiated or when lymphatic invasion is present, segmental colonic resection is recommended because residual tumour or lymphatic spread (in up to 10%) may be present. Malignant polyps without these features can be followed up by surveillance colonoscopy.

Very large sessile polyps can sometimes be removed safely by endoscopic mucosal resection (EMR), but many require surgery. Endoscopic submucosal dissection (ESD) can be used for some lesions with a high suspicion of limited submucosal invasion. Once all polyps have been removed, surveillance colonoscopy should be undertaken in individuals with high-risk findings, as new polyps develop in 50% of patients. Surveillance of patients over the age of 75 years should take into consideration of the patient's comorbidities, life expectancy and personal preferences.

Colorectal cancer

Globally, colorectal cancer is the third most commonly diagnosed cancer in males and second in females. High-income countries have the highest incidence of colorectal cancer, while Africa and South Asia have the lowest incidence. The incidence is continuing to increase on a worldwide basis, with the fastest rise in incidence occurring in younger populations, although incidence rates have stabilised in high-income countries. In the UK, the incidence is around 70 per 100 000 of the population. The condition becomes increasingly common over the age of 50 years.

Pathophysiology

Both environmental and genetic factors are important in colorectal carcinogenesis, as outlined in Figure 22.45. More than 200 loci that predispose to colorectal cancer have been identified by genome-wide association studies, but the effect size of the individual genetic variants is small. While the vast majority of colorectal cancers are sporadic, occurring in people without a family history of the disorder, about 3%–5% of individuals have hereditary colorectal cancer due to pathogenic variants in a single gene.

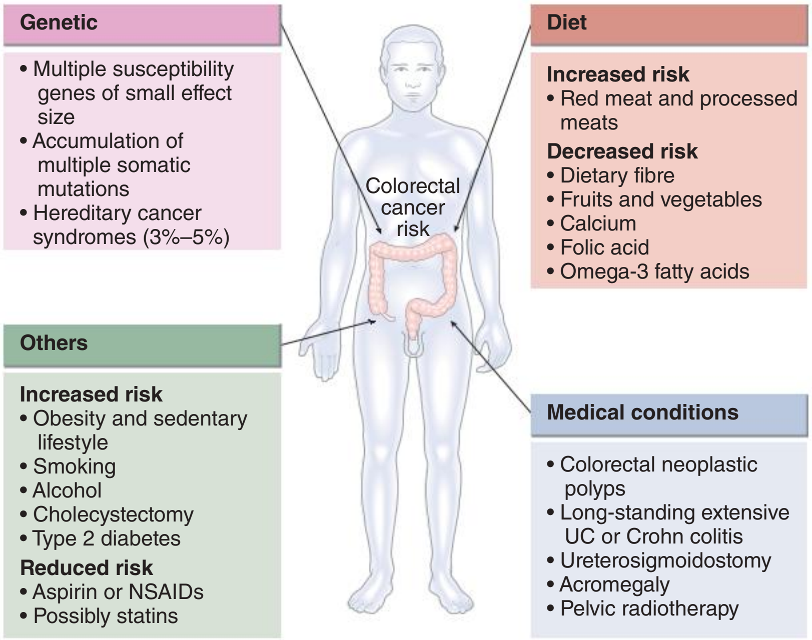
Genetics

The key pathophysiological factors are outlined in Figure 22.46. The development of colorectal cancer results from the accumulation of multiple somatic genetic pathogenic variants, accompanied by chromosomal instability, microsatellite instability and widespread hypermethylation of genes across the genome resulting in silencing of tumour suppressor genes.

There are three main pathways of genetic instability and each is associated with distinct histological, clinical and prognostic features.

- *Chromosomal instability*. Mutations or deletions of portions of chromosomes arise, with loss of heterozygosity (LOH) and inactivation of specific tumour suppressor genes. In LOH, one allele of a gene is deleted, but gene inactivation occurs only when a subsequent pathogenic variant affects the other allele. Chromosomal instability (CIN) occurs in around 85% of colorectal cancers.
- *Microsatellite instability*. This involves germline mutations in one of six genes encoding enzymes involved in repairing errors that occur normally during DNA replication (DNA mismatch repair); these genes are designated *hMSH2, hMSH6, hMLH1, hMLH3, hPMS1* and *hPMS2*. Replication errors accumulate and can be detected in 'microsatellites' of repetitive DNA sequences. They also occur in important regulatory genes, resulting in a genetically unstable phenotype and accumulation of multiple somatic mutations throughout the genome that eventually lead to cancer. Around 15% of sporadic cancers develop this way, as do most cases of hereditary non-polyposis colon cancer (HNPCC).
- *CpG island methylator phenotype (CIMP)*. This phenotype is found in approximately 20%–30% of colorectal cancers and results in widespread gene hypermethylation. The result is functional loss of tumour suppressor genes.

There are two distinct pathways of carcinogenesis: the classical adenoma–carcinoma pathway and the serrated neoplasia pathway. In the classical adenoma–carcinoma pathway, an adenoma is the precursor lesion. Adenomas progress to form carcinomas through the sequential acquisition of mutations, as the result of chromosomal and microsatellite instability (see Fig. 22.46). It is thought to take between 5 and 10 years for an adenoma to develop into a carcinoma. The serrated neoplasia pathway is characterised by a serrated polyp as a precursor lesion. Serrated polyps (hyperplastic, sessile serrated lesions, and traditional serrated adenomas) were previously thought to be non-neoplastic. However, it is now thought that sessile serrated lesions and traditional serrated adenomas are precursor lesions for malignancy. While hyperplastic polyps are generally still viewed as non-neoplastic, some subtypes are thought to be precursors of sessile serrated lesions. There are two pathways of carcinoma formation via the serrated neoplasia pathway, through the traditional serrated and sessile routes, with genetic instability through



Genetic
• Multiple susceptibility genes of small effect size

Normal
Early adenoma
Intermediate adenoma
Late adenoma
Carcinoma

	Normal	Early adenoma	Intermediate adenoma	Late adenoma	Carcinoma
Key gene(s)	*APC* (adenomatous polyposis coli)	*KRAS*	*DCC* (deleted in colon cancer) *SMAD4*	*TP53*
Chromosome	5q	12p	18q	17p
Normal function	Inhibits translocation of β-catenin to nucleus and suppresses cell growth	Transmembrane GTP-binding protein mediating mitogenic signals (p21)	*DCC* regulates apoptosis and has a tumour suppressor function *SMAD4* regulates cell growth	Up-regulated during cell damage to arrest cell cycle and allow DNA repair or apoptosis to occur
Alteration	Truncating mutations	Gain-of-function mutations	Allelic deletion or silencing (*DCC*) Gain-of-function mutations (*SMAD4*)	Allelic deletion; gain-of-function mutations
Effect	Progression to early adenoma development	Cell proliferation	Enhanced tumour growth, invasion and metastasis	Cell proliferation; impaired apoptosis

Further mutations
- Anchorage independence
- Protease synthesis
- Telomerase synthesis
- Multidrug resistance
- Evasion of immune system

Fig. 22.46 The classical adenoma to carcinoma pathway. It is thought that the initiating event is a loss-of-function pathogenic variant in the *APC* gene and this is followed by accumulation of pathogenic mutations in other genes such as *KRAS, DCC, SMAD4* and *TP53* in association with microsatellite instability and CpG island methylator phenotype (see text for details). (GTP = guanosine triphosphate)

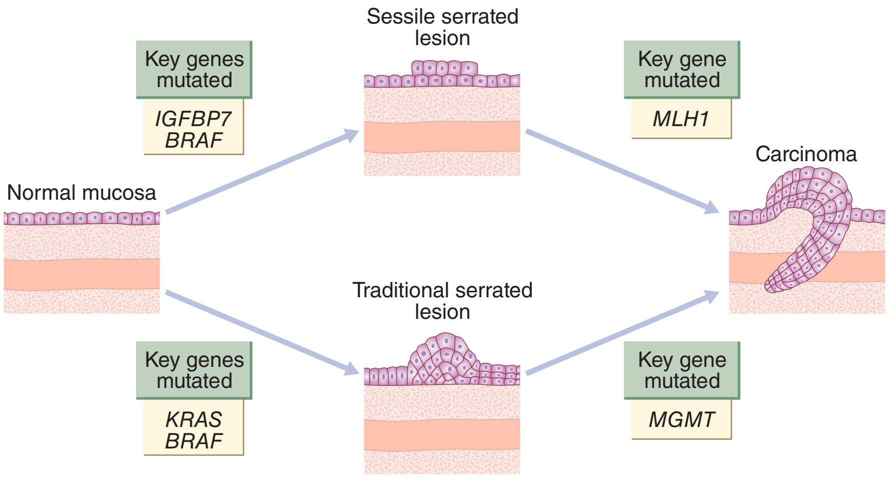
microsatellite instability and CIMP (Fig. 22.47), although molecular pathways are still not well understood. The serrated neoplasia pathway is associated with faster carcinoma development in comparison to the classical adenoma–carcinoma pathway.

Environment

The majority of colorectal cancers are sporadic, and the development of carcinoma is dependent upon genetic predisposition and environmental triggers. In keeping with this, it is thought that up to 50% of cases of colorectal cancer may potentially be preventable by lifestyle modifications. Several risks factors increase the risk of colorectal cancer, such as smoking, alcohol and type 2 diabetes. In addition, dietary factors are also key in the pathophysiology of colorectal cancer, such as low fruit and vegetable intake (see Fig. 22.45).

Clinical features

Symptoms vary, depending on the site of the carcinoma. However, the disease is often asymptomatic until at an advanced stage. In tumours of



Gene	*IGFBP7*	*BRAF*	*KRAS*	*MLH1*	*MGMT*
Chromosome	4q	7q	12p	3p	10q
Normal function	Interacts with insulin-like growth factors that are involved in preventing apoptosis	Regulates cell proliferation, differentiation, migration and apoptosis	Transmembrane GTP-binding protein mediating mitogenic signals (p21)	Mismatch repair gene that repairs errors made during DNA replication	DNA-repair protein involved in defence against mutagenesis and toxicity

Fig. 22.47 The serrated neoplasia pathway. Here the initiating events are thought to be mutations in *KRAS* and/or *BRAF* with *IGFBP7* mutations in sessile serrated lesions. Silencing of the DNA repair genes *MLH1* and *MGMT* subsequently occurs due to hypermethylation, driving progression from adenoma to carcinoma.

the left colon, fresh rectal bleeding is common and obstruction occurs early. Tumours of the right colon present with anaemia from occult bleeding or with altered bowel habit, but obstruction is a late feature. Colicky lower abdominal pain is present in two-thirds of patients and rectal bleeding occurs in 50%. A minority present with features of either obstruction or perforation, leading to peritonitis, localised abscess or fistula formation. Carcinoma of the rectum usually causes early bleeding, mucus discharge or a feeling of incomplete emptying. Between 10% and 20% of patients present with iron deficiency anaemia or weight loss. On examination, there may be a palpable mass, signs of anaemia or hepatomegaly from metastases. Low rectal tumours may be palpable on digital examination.

Investigations

Colonoscopy is the investigation of choice because it is more sensitive and specific than barium enema. Furthermore, lesions can be biopsied and polyps removed. Patients in whom colonoscopy is incomplete and those who are at high risk of complications can be investigated by CT colonography (virtual colonoscopy). This is a sensitive and non-invasive technique for diagnosing tumours and polyps of more than 6 mm diameter. When the diagnosis of colon cancer has been made, CT of the chest, abdomen and pelvis should be performed as a staging investigation, particularly to detect hepatic metastases, with an increasing role of MRI for further characterisation of liver lesions. Pelvic MRI or endoanal ultrasound should be used for local staging of rectal cancer. Measurement of serum carcinoembryonic antigen (CEA) levels is of limited value in diagnosis, since values are normal in many patients, but CEA testing can be helpful during follow-up to monitor for recurrence. FDG PET-CT has a role in the staging of patients with metastatic disease being considered for treatment with curative intent, as well as in patients with previously treated colorectal cancer with rising CEA and negative investigations to look for occult disease. Tumour stage (TNM) at diagnosis (Fig. 22.48) is the most important determinant of prognosis, determining the overall stage of the cancer.

Management

Endoscopy

Early colorectal cancers may be amenable to endoscopic treatment, using techniques such as endoscopic mucosal resection, endoscopic submucosal dissection and endoscopic full-thickness resection. Endoscopic submucosal dissection and endoscopic full-thickness resection tend to be used when there is suspicion of superficial submucosal invasion. In addition to such a procedure, surgical mesenteric lymphadenectomy may be required.

Curative therapy

In the absence of metastases, or when metastases are limited to the liver, surgery remains the cornerstone of curative treatment. Outcomes are improved by the judicious use of chemotherapy and/or radiotherapy in addition to surgery and all patients should be discussed in a multidisciplinary team meeting. Rectal cancers can be complex to operate on due to the anatomy of the pelvis and positive margins result in poor outcomes for patients. Neoadjuvant radiotherapy, chemoradiotherapy or chemotherapy should be offered to individuals with high-risk rectal cancers to increase the subsequent chance of a complete (R0) surgical resection and to reduce risk of future recurrence. Perioperative or adjuvant post-operative chemotherapy with 5-fluorouracil (or capecitabine) +/− oxaliplatin is indicated for T3–4 N0–2 M0 colon cancers to reduce risk of recurrence in those fit enough for it. There is increasing interest in the use of immunotherapy/checkpoint inhibitor treatment for the 15% of patients who have mismatch repair deficient (dMMR) cancers, where a high rate of complete responses can be seen with neoadjuvant immunotherapy treatment. Some patients with metastatic colorectal cancer can also be cured or have prolonged survival and should be discussed in appropriate multidisciplinary meetings. When metastatic disease is confined to the liver, hepatic surgery and/or ablative techniques should be considered, with a chance of cure. Patients with a small

number of metastases limited to the lung can be considered for surgical resection, radiofrequency ablation or radiotherapy. Some individuals with non-aggressive metastatic disease limited to the peritoneum can benefit from cytoreductive surgery and hyperthermic intraperitoneal chemotherapy. Post-operatively, patients should undergo colonoscopy after 1 year and then 3 years later to search for local recurrence or development of new lesions.

Palliative management

Surgical resection, laser therapy or expandable metal stenting of the primary tumour is appropriate for some patients with metastases to treat bleeding, pain or obstruction. Palliative radiotherapy is sometimes useful for pain or bleeding from pelvic disease or bone or lung metastases. Palliative chemotherapy can improve symptoms, quality of life and survival in patients who are fit enough to benefit. Colorectal cancers should be tested for dMMR and pathogenic variants in *NRAS*, *KRAS* or *BRAF* V600E. This molecular stratification helps in assessment of prognosis for patients with inoperable metastatic disease (median <1 year for *BRAF* mutated cancers to median 3 years with *RAS*/*BRAF* wild type cancers) and predicts the response to targeted treatments. Initial palliative chemotherapy includes combinations of 5-fluorouracil, leucovorin, capecitabine, oxaliplatin, and/or irinotecan. Chemotherapy is often given with monoclonal antibody therapies bevacizumab (vascular endothelial growth factor inhibitor) or panitumumab/cetuximab (epidermal growth factor inhibitors for *RAS* and *BRAF* wild type cancers). For patients with dMMR tumours, checkpoint inhibitor therapy can result in impressive responses.

Prevention and screening

Secondary prevention aims to detect and remove lesions at an early or pre-malignant stage by screening the asymptomatic general population. Several potential methods exist:

- Population-based screening of people between the age of 50 and 74 years by regular *faecal immunochemical testing (FIT)* reduces colorectal cancer mortality and increases the proportion of early cancers detected. Serial stool testing with or without subsequent colonoscopy is the screening method of choice in the UK.
- *Colonoscopy* remains the gold standard and allows preventative polypectomy, but is expensive, requires bowel preparation and carries risks (perforation approximately 1:1000). Many countries lack the resources to offer this form of screening.
- *CT colonography* is fast and low-risk, and offers equivalent sensitivity to colonoscopy. Disadvantages include reduced sensitivity to detect polyps of less than 6 mm, the requirement for bowel preparation, exposure to ionising radiation and its inability to offer therapeutic intent.

Hereditary syndromes predisposing to colorectal cancer

Whilst hereditary syndromes are rare, collectively accounting for 3%–5% of colorectal carcinomas, they are important to identify, as the risk of colorectal carcinoma is high in these individuals.

Non-polyposis syndromes

Hereditary non-polyposis colorectal cancer (HNPCC), also known as Lynch syndrome, has an autosomal dominant mode of inheritance, with a positive family history of colon cancer occurring at a young age. It is the commonest hereditary cancer syndrome, accounting for 1%–3% of all colorectal cancer cases. The lifetime risk in affected individuals is 80%, with a mean age at cancer development of 45 years. In contrast to sporadic colon cancer, two-thirds of tumours occur proximally. The clinical diagnostic criteria are listed in Box 22.54. However, over recent years, the diagnosis has shifted from clinical criteria to genetic testing for pathogenic variants in *MLH1*, *MSH2*, *MSH6*, *PMS2* and *EPCAM* genes, and testing of tumour material for microsatellite instability by polymerase chain reaction and by immunohistochemistry for mismatch repair proteins. In a subset of patients, there is also an increased incidence of cancers of the endometrium, ovary, urinary tract, stomach, pancreas, small intestine and

CNS, related to inheritance of different mismatch repair gene mutations. Those who fulfil the criteria for HNPCC should be referred for pedigree assessment, genetic testing (see above) and colonoscopy. These should begin at either 25 years or 35 years (dependent upon the specific genetic abnormalities detected). Colonoscopy needs to be repeated every 2 years, but despite this, interval cancers can still occur. Regular daily use of aspirin is thought to reduce colorectal cancer risk.

Polyposis syndromes

A summary of the clinical features of polyposis syndromes is shown in Box 22.55. It is important to note that, while the hamartomatous polyps in Peutz–Jeghers syndrome and juvenile polyposis are not themselves neoplastic, both disorders are associated with an increased risk of malignancy of the breast, colon, ovary and thyroid.

Familial adenomatous polyposis

Familial adenomatous polyposis (FAP) is a rare autosomal dominant disorder affecting about 1 in 14 000 of the population and accounting for 0.07% of colorectal cancers. It results from germline pathogenic variant of the tumour suppressor *APC* gene, followed by acquired pathogenic variant of the remaining allele (Ch. 3). The *APC* gene is large and over 1400 different pathogenic variants have been reported, but most are loss-of-function variants resulting in a truncated APC protein. This protein normally binds to and sequesters β-catenin, but is unable to do so when truncated, allowing β-catenin to translocate to the nucleus, where it up-regulates the expression of many genes. Pathogenic variants are detected in around 95% of FAP cases. Around 25% of cases arise as new mutations and have no family history.

Hundreds to thousands of adenomatous colonic polyps develop in 80% of patients by age 15 (Fig. 22.49), with symptoms such as rectal bleeding beginning a few years later. In those affected, cancer will develop within 10–15 years of the appearance of adenomas and 90% of patients will develop colorectal cancer by the age of 50 years. Despite surveillance, approximately 1 in 4 patients with FAP have cancer by the time they undergo colectomy. There appears to be phenotypic variability in FAP, with an attenuated form resulting in fewer than 100 adenomatous polyps and later onset of polyposis and cancer.

A second gene involved in base excision repair (MutY homolog, *MUTYH*) has been identified and may give rise to colonic polyposis. *MUTYH* displays autosomal recessive inheritance and leads to tens to hundreds of polyps and proximal colon cancer. This variant is referred to as *MUTYH*-associated polyposis (MAP).

In FAP, non-neoplastic cystic fundic gland polyps occur in the stomach, but adenomatous polyps also arise uncommonly. Duodenal adenomas are found in over 90% and are most common around the ampulla of Vater. Malignant transformation to adenocarcinoma takes place in 10% and is the leading cause of death in those who have had prophylactic colectomy. Many extra-intestinal features are also seen (Box 22.56).

Desmoid tumours occur in up to one-third of patients and usually arise in the mesentery or abdominal wall. Although benign, they may become very large, causing compression of adjacent organs, intestinal obstruction or vascular compromise and are difficult to remove. They sometimes respond to hormonal therapy with tamoxifen, and the NSAID sulindac may bring about regression in some, by unknown mechanisms.

i 22.54 Modified Amsterdam criteria* for hereditary non-polyposis colon cancer

- Three or more relatives with colon cancer (with at least one affected first-degree relative)
- Colorectal cancer in two or more generations
- At least one member affected under 50 years of age
- Familial adenomatous polyposis excluded

*These criteria are strict and may miss some families with hereditary non-polyposis colon cancer. The diagnosis should also be considered in individuals with colorectal or endometrial cancer under 45 years of age.

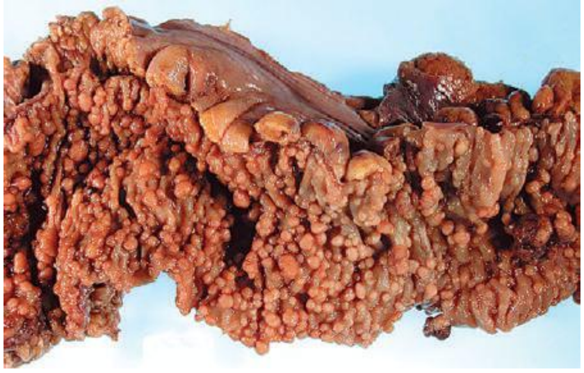

Fig. 22.49 Familial adenomatous polyposis. There are hundreds of adenomatous polyps throughout the colon.

i 22.55 Clinical features of polyposis syndromes

	Neoplastic			Non-neoplastic*		
	Familial adenomatous polyposis	**Peutz–Jeghers syndrome**	***MUTYH*-associated polyposis**	**Juvenile polyposis**	**Cronkhite–Canada syndrome**	**Cowden syndrome**
Inheritance	Autosomal dominant	Autosomal dominant	Autosomal recessive	Autosomal dominant in one-third	None	Autosomal dominant
Key genes involved	*APC*	*STK11*	*MUTYH*	*SMAD4, BMPR1A*	No specific single gene	*PTEN*
Oesophageal polyps	–	–	–	–	+	+

Other features	Colorectal cancer, bleeding, extra-intestinal features (see Box 22.56)	Pigmentation, bleeding, intussusception, bowel and other cancers	Ampullary and duodenal adenomas	Colorectal cancer	Hair loss, pigmentation, nail dystrophy, malabsorption	Many congenital anomalies, oral and cutaneous hamartomas, thyroid and breast tumours

*The polyps themselves are not neoplastic, but cancer risk is increased in juvenile polyposis and Cowden syndrome.
(– = absent; + = may occur; ++ = common; +++ = very common)

i 22.56 Extra-intestinal features of familial adenomatous polyposis

- Congenital hypertrophy of the retinal pigment epithelium (CHRPE, 70%–80%)
- Epidermoid cysts (extremities, face, scalp)* (50%)
- Benign osteomas, especially skull and angle of mandible* (50%–90%)
- Dental abnormalities (15%–25%)*
- Desmoid tumours (10%–15%)
- Other malignancies (brain, thyroid, liver, adrenal; 1%–3%)

*Gardner syndrome.

Congenital hypertrophy of the retinal pigment epithelium (CHRPE) occurs in some cases and is seen as dark, round, pigmented retinal lesions. When present in an at-risk individual, these are 100% predictive of the presence of FAP. A variant, Turcot syndrome, is characterised by FAP with primary CNS tumours (astrocytoma or medulloblastoma).

Early identification of affected individuals before symptoms develop is essential. The diagnosis can be excluded if sigmoidoscopy is normal. In newly diagnosed cases, genetic testing should be carried out to confirm the diagnosis and identify the causal pathogenic variant. Subsequently, all first-degree relatives should undergo genetic testing (Ch. 3). In families with known FAP, adolescents should undergo genetic testing at 13–14 years of age and patients who are found to have the pathogenic variant should be offered colectomy after school or college education has been completed. The operation of choice is total proctocolectomy with ileal pouch–anal anastomosis. Ileoanal pouch construction may be associated with reduced fertility in women, which may be due to Fallopian tube scarring post-surgery. Therefore, colectomy with ileorectal anastomosis can be used, but is associated with a risk of cancer in the retained rectum. Periodic upper gastrointestinal endoscopy every 1–3 years is recommended to detect and monitor duodenal and periampullary adenomas. If large, these may be amenable to endoscopic resection.

Peutz–Jeghers syndrome

Peutz–Jeghers syndrome occurs in around 1 in 120 000 of the population, accounting for less than 0.01% of colorectal cancer cases. Multiple hamartomatous polyps occur in the small intestine and colon, as well as melanin pigmentation of the lips, mouth and digits (Fig. 22.50). Most cases are asymptomatic, although chronic bleeding, anaemia or intussusception can occur. There is a significant risk of small bowel or colonic adenocarcinoma and of cancer of the pancreas, lung, testis, ovary, breast and endometrium. Peutz–Jeghers syndrome is an autosomal dominant disorder with high penetrance, most commonly resulting from truncating pathogenic variants in a serine–threonine kinase gene on chromosome 19p (*STK11*). The diagnosis requires two of the three following features:

- small bowel polyposis
- mucocutaneous pigmentation
- a family history suggesting autosomal dominant inheritance.

The diagnosis can be made by genetic testing, but this may be inconclusive, since pathogenic variants in genes other than *STK11* can cause the disorder. Affected people should undergo regular upper endoscopy, colonoscopy and small bowel and pancreatic imaging. Polyps greater than 1 cm in size should be removed. Testicular examination is essential for men, while women should undergo pelvic examination, cervical smears and regular mammography (lifetime risk of breast cancer of 50%). Asymptomatic relatives of affected patients should also undergo screening.

Juvenile polyposis

In juvenile polyposis, tens to hundreds of mucus-filled hamartomatous polyps are found in the colorectum. One-third of cases are inherited in an autosomal dominant manner and up to one-fifth develop colorectal cancer before the age of 40. The criteria for diagnosis are:

- ten or more colonic juvenile polyps
- juvenile polyps elsewhere in the gut, *or*
- any polyps in those with a family history.

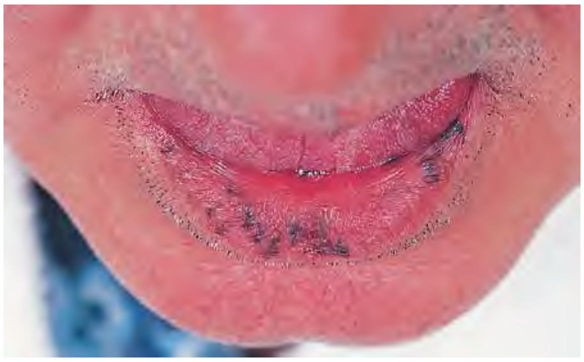

Fig. 22.50 Peutz–Jeghers syndrome. Typical lip pigmentation.

Germline pathogenic variants in the *SMAD4* gene are often found, as well as pathogenic variants in the *BMPR1A* gene. *SMAD4* variants may have a more aggressive clinical phenotype, while *BMPR1A* is particularly implicated in European populations. Colonoscopy with polypectomy should be performed every 1–2 years and colectomy considered for extensive involvement. Periodic upper gastrointestinal endoscopy should be performed every 1–2 years, in view of the risk of gastric and duodenal cancer.

Cronkhite–Canada syndrome

Cronkhite–Canada syndrome is a rare non-hereditary polyposis syndrome characterised by cystic polyps in the gastrointestinal tract, alopecia, nail dystrophy, and skin hyperpigmentation. Symptoms include abdominal pain and diarrhoea. It is thought to have an inflammatory basis but the pathogenesis is poorly understood. It may respond to corticosteroid therapy.

Cowden syndrome

Cowden syndrome is characterised by the occurrence of benign hamartomas in the gastrointestinal tract along with other congenital anomalies. It is caused by loss-of-function pathogenic variants in the *PTEN* tumour suppressor gene. The risk of breast cancer, endometrial cancer and thyroid cancer is increased.

Diverticulosis

Diverticula are acquired and are most common in the sigmoid and descending colon of middle-aged people. Asymptomatic diverticula (diverticulosis) are present in over 50% of people above the age of 70 years. Symptomatic diverticular disease supervenes in 10%–25% of cases, while complicated diverticulosis (acute diverticulitis, pericolic abscess, bleeding, perforation or stricture) is uncommon.

Pathophysiology

A life-long refined diet with a relative deficiency of fibre is thought to be responsible, and the condition is rare in populations with a high dietary fibre intake, such as in Asia, where it more often affects the right side of the colon. It is postulated that small-volume stools require high intracolonic pressures for propulsion and this leads to herniation of mucosa between the taeniae coli (Fig. 22.51). Whilst the pathophysiology of diverticular disease is thought to be mainly due to environmental risk factors, recent evidence suggests the involvement of predisposing genetic factors. Diverticula consist of protrusions of mucosa covered by peritoneum. There is commonly hypertrophy of the circular muscle coat. Inflammation is thought to result from impaction of diverticula with faecoliths. This may resolve spontaneously or progress to cause haemorrhage, perforation, local abscess formation, fistula and peritonitis. Repeated attacks of inflammation lead to thickening of the bowel wall, narrowing of the lumen and eventual obstruction.

Clinical features

Symptoms are usually the result of associated constipation or spasm. Colicky pain is suprapubic or felt in the left iliac fossa. The sigmoid colon

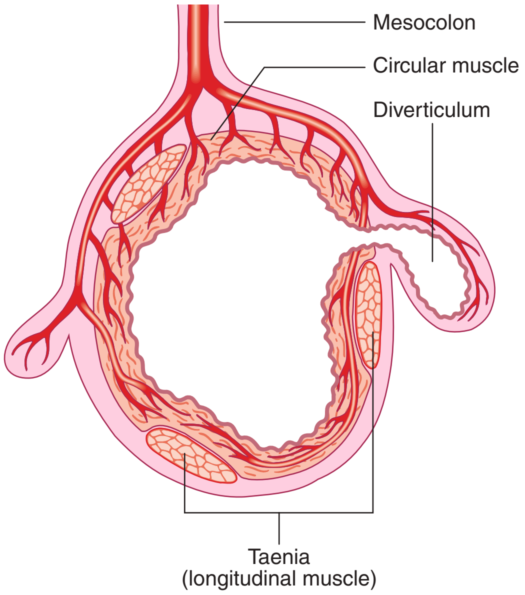

Fig. 22.51 The human colon in diverticulosis. The colonic wall is weak between the taeniae. The blood vessels that supply the colon pierce the circular muscle and weaken it further by forming tunnels. Diverticula usually emerge through these points of least resistance.

may be palpable and, in attacks of diverticulitis, there is local tenderness, guarding, rigidity ('left-sided appendicitis') and sometimes a palpable mass. During these episodes, there may be diarrhoea, rectal bleeding or fever. The differential diagnosis includes colorectal cancer, ischaemic colitis, IBD and infection. Diverticular disease may be complicated by perforation, pericolic abscess, fistula formation (usually colovesical), acute lower gastrointestinal bleeding and obstruction. These complications are more common in patients who take NSAIDs or aspirin. After one attack of diverticulitis, the recurrence rate is around 3% per year. Over 10–30 years, perforation, obstruction or bleeding may occur, each affecting 5% of patients.

Investigations

Investigations are usually performed to exclude colorectal neoplasia. Diverticula can be seen during colonoscopy or on imaging modalities such as CT scan, CT colonography or barium enema (see Fig. 22.12C). In severe diverticulosis, colonoscopy requires expertise and carries a risk of perforation. CT is used to assess complications, such as perforation or pericolic abscess.

Management

Diverticular disease that is asymptomatic and discovered coincidentally requires no treatment. Constipation can be relieved by a high-fibre diet, with or without a bulking laxative (ispaghula husk, 1–2 sachets daily), taken with plenty of fluids. Stimulant laxatives (Box 22.57) should be avoided. Antispasmodics may sometimes help. Acute attacks of diverticulitis may require the use of antibiotics active against gram-negative and anaerobic organisms. Severe cases require intravenous fluids, intravenous antibiotics, analgesia and nasogastric suction, but randomised trials show no benefit from acute resection compared to conservative management. Emergency surgery is reserved for severe haemorrhage or perforation. Percutaneous drainage of acute paracolic abscesses can be effective and avoids the need for emergency surgery. Patients who have repeated attacks of obstruction should undergo elective surgery once the acute episode has settled, in order to resect the affected segment of bowel with restoration of continuity by primary anastomosis.

22.57 Laxatives

Class	Examples
Bulk-forming laxatives	Ispaghula husk, methylcellulose
Stimulants	Bisacodyl, dantron (only for terminally ill patients), docusate, senna
Faecal softeners	Docusate, arachis oil enema
Osmotic laxatives	Lactulose, lactitol, magnesium salts
Serotonergic agents	Prucalopride
Prosecretory agents	Linaclotide, lubiprostone, plecanatide
Opioid receptor antagonists	Naloxegol, naldemedine, methylnaltrexone
Others	Polyethylene glycol (PEG)* phosphate enema*

*Also used for bowel preparation prior to investigation or surgery.

22.58 Constipation in old age

- **Evaluation**: particular attention should be paid to immobility, dietary fluid and fibre intake, drugs and depression.
- **Immobility**: predisposes to constipation by increasing the colonic transit time; the longer this is, the greater the fluid absorption and the harder the stool.
- **Bulking agents**: can make matters worse in patients with slow transit times and should be avoided.
- **Overflow diarrhoea**: if faecal impaction develops, paradoxical overflow diarrhoea may occur. If antidiarrhoeal agents are given, the underlying impaction may worsen and result in serious complications, such as stercoral ulceration and bleeding.

Colonic motility disorders

The clinical approach to patients with constipation and its aetiology have been described on page 821.

Simple constipation

Simple constipation is extremely common and does not signify underlying organic disease. It usually responds to increased dietary fibre or the use of bulking agents; an adequate fluid intake is also essential. Many types of laxative are available, and these are listed in Box 22.57.

Severe idiopathic constipation

This occurs almost exclusively in young women and often begins in childhood or adolescence. The cause is unknown, but some have 'slow transit' with reduced motor activity in the colon. Others have 'dyssynergic defaecation', resulting from inappropriate contraction of the external anal sphincter and puborectalis muscle (anismus). The condition is often resistant to treatment. Bulking agents may exacerbate symptoms, but prokinetic agents or balanced solutions of polyethylene glycol 3350 benefit some patients with slow transit. Glycerol suppositories and biofeedback techniques are used for those with dyssynergic defaecation. Others benefit from agents such as prucalopride or linaclotide. Rarely, subtotal colectomy may be necessary as a last resort.

Faecal impaction

In faecal impaction, a large, hard mass of stool fills the rectum. This tends to occur in disabled, immobile or institutionalised patients, especially frail older adults or those with dementia (Box 22.58). Constipating drugs, autonomic neuropathy and painful anal conditions also contribute. Megacolon, intestinal obstruction and urinary tract infections may supervene. Perforation and bleeding from pressure-induced ulceration are occasionally seen. Overflow diarrhoea may also be a presenting feature, sometimes leading to worsening of symptoms with the incorrect use of antidiarrhoeal medication. Treatment should involve adequate hydration and careful digital disimpaction after softening the impacted stool with arachis oil enemas. Stimulant laxatives should be avoided.

Melanosis coli and laxative misuse syndromes

Long-term consumption of stimulant laxatives leads to accumulation of lipofuscin pigment in macrophages in the lamina propria. This imparts a brown discoloration to the colonic mucosa, often described as resembling 'tiger skin'. The condition is benign and resolves when the laxatives are stopped. Prolonged laxative use may rarely result in megacolon or 'cathartic colon', in which barium enema demonstrates a featureless mucosa, loss of haustra and shortening of the bowel. Surreptitious laxative misuse is a psychiatric condition seen in young women, some of whom have a history of bulimia or anorexia nervosa (Ch. 29). They complain of refractory watery diarrhoea. Laxative use is usually denied and may continue, even when patients are undergoing investigation. Screening of urine for laxatives may reveal the diagnosis.

Hirschsprung disease

This disease is characterised by constipation and colonic dilatation (megacolon) due to congenital absence of ganglion cells in the large intestine. Incidence is approximately 1:5000. About one-third of patients have a positive family history and, in these families, the disease is inherited in an autosomal dominant manner with incomplete penetrance. About 50% of familial cases and 15% of sporadic cases have pathogenic variants affecting the *RET* proto-oncogene, which is also implicated in multiple endocrine neoplasia (MEN) types 2a and 2b (p. 742). Unlike MEN 2a and 2b, which are caused by activating *RET* variants, Hirschsprung disease is caused by loss-of-function variants. In some kindreds, Hirschsprung disease and MEN can actually co-segregate and this presumably represents both 'switch off' and 'switch on' of *RET* in different tissues. Although *RET* is the most important susceptibility gene, some patients with *RET* variants do not develop clinical Hirschsprung disease and pathogenic variants in other genes have been identified that interact to cause the disease. All of the genes implicated in Hirschsprung disease are involved in the regulation of enteric neurogenesis and the mutations cause failure of migration of neuroblasts into the gut wall during embryogenesis. Ganglion cells are absent from nerve plexuses, most commonly in a short segment of the rectum and/or sigmoid colon. As a result, the internal anal sphincter fails to relax. Constipation, abdominal distension and vomiting usually develop immediately after birth, but a few cases do not present until childhood or adolescence. The rectum is empty on digital examination.

A plain abdominal X-ray or barium enema shows a small rectum and colonic dilatation above the narrowed segment. Full-thickness biopsies are required to demonstrate nerve plexuses and confirm the absence of ganglion cells. Histochemical stains for acetylcholinesterase are also used. Anorectal manometry demonstrates failure of the internal sphincter to relax with balloon distension. Treatment involves resection of the affected segment.

Acquired megacolon

This may develop in childhood as a result of voluntary withholding of stool during toilet training and can present with faecal impaction and soiling. In such cases, it presents after the first year of life and is distinguished from Hirschsprung disease by the urge to defaecate and the presence of stool in the rectum. It usually responds to osmotic laxatives.

In adults, acquired megacolon has several causes. It is seen in patients with depression or dementia, either as part of the condition or as a side-effect of antidepressant drugs. Prolonged misuse of stimulant laxatives may cause degeneration of the myenteric plexus, while interruption of sensory or motor innervation may be responsible in a number of neurological disorders. Patients taking large doses of opioid analgesics can develop a megacolon: so-called 'narcotic bowel syndrome'. Systemic sclerosis and hypothyroidism are other recognised causes.

22.59 Causes of acute colonic pseudo-obstruction

- Trauma, burns
- Recent surgery
- Drugs (opiates, phenothiazines)
- Respiratory failure
- Electrolyte and acid–base disorders (hypokalaemia, hypomagnesaemia)
- Diabetes mellitus – autonomic dysfunction
- Uraemia

Most patients can be managed conservatively by treatment of the underlying cause, high-residue diets, laxatives and the judicious use of enemas. Prokinetics are helpful in a minority of patients. Opioid-induced constipation can be treated with the specific peripheral opioid receptor antagonists, such as naloxegol, methylnaltrexone and naldemedine. Subtotal colectomy is a last resort for the most severely affected patients.

Acute colonic pseudo-obstruction

Acute colonic pseudo-obstruction (Ogilvie syndrome) has many causes (Box 22.59) and is characterised by sudden onset of painless, massive enlargement of the proximal colon; there are no features of mechanical obstruction. Bowel sounds are normal or high-pitched, rather than absent. Left untreated, it may progress to perforation, peritonitis and death.

Abdominal X-rays show colonic dilatation with air extending to the rectum. Caecal diameter greater than 10 cm is associated with a high risk of perforation. CT with contrast demonstrates the absence of mechanical obstruction.

Management consists of treating the underlying disorder and correcting any biochemical abnormalities. The anticholinesterase neostigmine is effective in enhancing parasympathetic activity and gut motility. Decompression, with either a rectal tube or colonoscope, may be effective but needs to be repeated until the condition resolves. In severe cases, surgical or fluoroscopic defunctioning caecostomy is necessary.

Anorectal disorders

Haemorrhoids

Haemorrhoids (commonly known as piles) arise from congestion of the internal and/or external venous plexuses around the anal canal. They are extremely common in adults. The aetiology is unknown, although they are associated with constipation and straining, and may develop for the first time during pregnancy. First-degree piles bleed, while second-degree piles prolapse but retract spontaneously. Third-degree piles are those that require manual replacement after prolapsing. Bright red rectal bleeding occurs after defaecation. Other symptoms include pain, pruritus ani and mucus discharge; thrombosis can occur in prolapsed piles, which can be very painful (Fig. 22.52). Treatment involves measures to prevent constipation and straining. Band ligation is effective for many, but a minority of patients require haemorrhoidectomy, which is usually curative. Alternatively, Doppler-guided haemorrhoidal artery ligation and mucopexy may be required.

Pruritus ani

This is common and can stem from many causes (Box 22.60), most of which result in contamination of the perianal skin with faecal contents.

Itching may be severe and results in an itch–scratch–itch cycle that exacerbates the problem. When no underlying cause is found, all local barrier ointments and creams must be stopped. Good personal hygiene is essential, with careful washing after defaecation. The perineal area must be kept dry and clean. Bulk-forming laxatives may reduce faecal soiling.

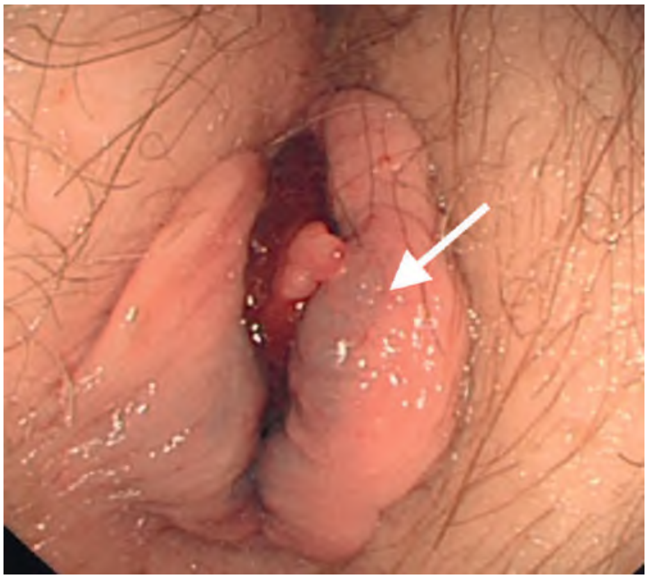

Fig. 22.52 Thrombosed prolapsed haemorrhoids (arrow).

22.60 Causes of pruritus ani

Local anorectal conditions	
• Haemorrhoids • Fistula, fissures	• Poor hygiene
Infections	
• Threadworms	• Candidiasis
Skin disorders	
• Contact dermatitis • Psoriasis	• Lichen planus
Other	
• Diarrhoea or incontinence of any cause	• Irritable bowel syndrome • Anxiety

Solitary rectal ulcer syndrome

This is most common in young adults and occurs on the anterior rectal wall. It is thought to result from localised chronic trauma and/or ischaemia associated with disordered puborectalis function and mucosal prolapse. The ulcer is seen at sigmoidoscopy, and biopsies show a characteristic accumulation of collagen.

Symptoms include minor bleeding and mucus per rectum, tenesmus and perineal pain. Treatment is often difficult, but avoidance of straining at defaecation is important and treatment of constipation may help. Marked mucosal prolapse is treated surgically.

Anal fissure

In this common problem, traumatic or ischaemic damage to the anal mucosa results in a superficial mucosal tear, most commonly in the midline posteriorly. Spasm of the internal anal sphincter exacerbates the condition. Severe pain occurs on defaecation and there may be minor bleeding, mucus discharge and pruritus. The skin may be indurated and an oedematous skin tag, or 'sentinel pile', adjacent to the fissure is common.

Avoidance of constipation with bulk-forming laxatives and increased fluid intake is important. Relaxation of the internal sphincter is normally mediated by nitric oxide and 0.2% glyceryl trinitrate, which donates nitric oxide and improves mucosal blood flow, is effective in 60%–80% of patients. Diltiazem cream (2%) can be used as an alternative. Resistant cases may respond to injection of botulinum toxin into the internal anal sphincter to induce relaxation. Manual dilatation under anaesthesia leads to long-term incontinence and should not be considered. The majority of cases can be treated without surgery, but where these measures fail, healing can be achieved surgically by lateral internal anal sphincterotomy or advancement anoplasty.

22.61 Causes of faecal incontinence

- Obstetric trauma: childbirth, hysterectomy
- Severe diarrhoea
- Faecal impaction
- Congenital anorectal anomalies
- Anorectal disease: haemorrhoids, rectal prolapse, Crohn disease
- Neurological disorders: spinal cord or cauda equina lesions, dementia

Anorectal abscesses and fistulae

Perianal abscesses develop between the internal and external anal sphincters and may point at the perianal skin. Ischiorectal abscesses occur lateral to the sphincters in the ischiorectal fossa. They usually result from infection of anal glands by normal intestinal bacteria. Crohn disease (see below) is sometimes responsible.

Patients complain of extreme perianal pain, fever and/or discharge of pus. Spontaneous rupture may lead to the development of fistulae. These may be superficial or track through the anal sphincters to reach the rectum. Abscesses are drained surgically and fistulae are carefully managed according to their anatomy.

Faecal incontinence

The normal control of anal continence is described on page 806. Common causes of faecal incontinence are listed in Box 22.61. High-risk patients include frail older people, women after childbirth and those with severe neurological/spinal disorders, learning disabilities or cognitive impairment.

Patients are often embarrassed to admit to incontinence and may complain only of 'diarrhoea'. A careful history and examination, especially of the anorectum and perineum, may help to establish the underlying cause. Endoanal ultrasound is valuable for defining the integrity of the anal sphincters, while anorectal physiology and MR proctography are also useful investigations.

Management

This is often very difficult. Underlying disorders should be treated and diarrhoea managed with loperamide, diphenoxylate or codeine phosphate. Attention must be paid to a proper diet and adequate fluid intake. Pelvic floor exercises, biofeedback and bowel retraining techniques help some patients, and those with confirmed anal sphincter defects may benefit from sphincter repair operations. Where sphincter repair is not appropriate, a trial of sacral nerve stimulation is undertaken with a view to insertion of a permanent stimulator but, if unsuccessful, creation of a neo-sphincter may be possible, by graciloplasty or by an artificial anal sphincter.

Inflammatory bowel disease

Ulcerative colitis and Crohn disease are chronic inflammatory bowel diseases that pursue a protracted relapsing and remitting course, usually extending over many years. The diseases have many similarities and it is sometimes impossible to differentiate between them. One crucial distinction is that ulcerative colitis involves only the colonic mucosa, while Crohn disease can involve any part of the gastrointestinal tract from mouth to anus. A comparison of the main features of ulcerative colitis and Crohn disease is provided in Box 22.62.

22.62 Comparison of ulcerative colitis and Crohn disease

	Ulcerative colitis	Crohn disease
Age group	Any	Any
Gender	M = F	Slight female preponderance
Incidence	Stable	Increasing
Ethnic group	Any	Any
Genetic factors	_HLA-DR*103_; colonic epithelial barrier function (*HNF4α*, *LAMB1*, *CDH1*)	Defective innate immunity and autophagy (*NOD2*, *ATG16L1*, *IRGM*)
Risk factors	More common in non-/ex-smokers Appendicectomy protects	More common in smokers
Anatomical distribution	Colon only; begins at anorectal margin with variable proximal extension	Any part of gastrointestinal tract; perianal disease common; patchy distribution, skip lesions
Extra-intestinal manifestations	Common	Common
Presentation	Bloody diarrhoea	Variable; pain, diarrhoea, weight loss all common
Histology	Inflammation limited to mucosa; crypt distortion, cryptitis, crypt abscesses, loss of goblet cells	Submucosal or transmural inflammation common; deep fissuring ulcers, fistulae; patchy changes; granulomas
Management	5-ASA; glucocorticoids; azathioprine; advanced therapy (anti-TNF, anti-α4β7 integrin, cytokine inhibitor, Janus kinase inhibitor, S1P modulators); colectomy is curative	Glucocorticoids; azathioprine; methotrexate; advanced therapy (anti-TNF, anti-α4β7 integrin, cytokine inhibitor, Janus kinase inhibitor); nutritional therapy; smoking cessation; surgery for complications is not curative; 5-ASA is not effective

(5-ASA = 5-aminosalicylic acid; TNF = tumour necrosis factor)

The incidence of inflammatory bowel disease (IBD) varies widely between populations. The highest incidence is in North America, Europe and Oceania. A rapid increase in incidence in the 21st century has been seen in newly industrialised countries in Asia, Africa and South America, with the adoption of an increasingly Westernised lifestyle.

Both diseases most commonly start in the second and third decades of life, with a second smaller incidence peak in the seventh decade. The number of people with IBD over the age of 65 years, however, is increasing, and it is becoming more common in younger children. Approximately 620 000 people are affected by IBD in the UK, with a population prevalence of 0.5%–1%. Life expectancy in patients with IBD is similar to that of the general population. Although many patients require surgery and admission to hospital for other reasons, with substantial associated morbidity, the majority have an excellent work record and pursue a normal life.

Pathophysiology

Both environmental and genetic factors contribute to the pathogenesis of IBD (Box 22.63), and evidence from genome-wide association studies suggests that genetic variants that predispose to Crohn disease may have undergone positive selection by protecting against infectious diseases, including tuberculosis. It is thought that IBD develops because these genetically susceptible individuals mount an abnormal inflammatory response to environmental triggers, such as intestinal bacteria. This leads to inflammation of the intestine with involvement of a wide array of innate and adaptive immune cell responses, with release of inflammatory mediators, including tumour necrosis factor alpha (TNF-α), interleukin (IL)-12 and IL-23, which cause tissue damage (Fig. 22.53). There appears to be an association between microbial dysbiosis and IBD. For example, there is a reduced diversity, primarily of *Firmicutes* and *Bacteroides*, and a relative increase in *Enterobacteriaceae*. Functional changes in the bacteria are important and include a reduction of anti-inflammatory metabolites, such as butyrate and other short-chain fatty acids. While microbial dysbiosis has been recognised in IBD, a causal role has yet to be established. There is emerging evidence that the virome and mycobiome (fungal species) may be important in the development of IBD. In both diseases, the intestinal wall is infiltrated with acute and chronic inflammatory cells, but there are important differences between the conditions in the distribution of lesions and in histological features (Fig. 22.54).

22.63 Factors associated with the development of inflammatory bowel disease

Genetic

- Both CD and UC are common in Ashkenazi Jews
- 10% have first-degree relative/one or more close relative with IBD
- High concordance in identical twins (40%–50% CD; 20%–25% UC)
- Multiple susceptibility loci identified at genome-wide levels of significance; most confer susceptibility to both CD and UC; many are also susceptibility loci for other inflammatory conditions (especially ankylosing spondylosis and psoriasis)
- UC and CD are both associated with polymorphic variants at HLA locus, and with multiple genes involved with immune signalling (especially IL-23 and IL-10 pathways)
- CD is associated with polymorphic variants close to genes involved in innate immunity and autophagy (*NOD2*, *ATG16L1* and *IRGM*)
- UC is associated with genetic defects in barrier function
- Variants at *NOD2* locus associated with ileal and stricturing disease, and hence a need for resectional surgery
- _HLA-DR*103_ is associated with severe UC

Environmental

- UC is more common in non-smokers and ex-smokers
- CD is more common in smokers (relative risk = 3)
- CD is associated with a low-residue, high-refined-sugar diet
- Commensal gut microbiota are altered (dysbiosis) in CD and UC
- Appendicectomy protects against UC

(CD = Crohn disease; HLA = human leucocyte antigen; IBD = inflammatory bowel disease; IL = interleukin; UC = ulcerative colitis)

Ulcerative colitis

Inflammation invariably involves the rectum (proctitis) and spreads proximally in a continuous manner to involve the entire colon in some cases (pancolitis). In long-standing pancolitis, the bowel can become shortened and post-inflammatory ‘pseudopolyps’ develop; these are normal or hypertrophied residual mucosa within areas of atrophy (Fig. 22.55). The inflammatory process is limited to the mucosa and spares the deeper layers of the bowel wall (Fig. 22.56). Both acute and chronic inflammatory cells infiltrate the lamina propria and the crypts (‘cryptitis’). Crypt abscesses are typical. Goblet cells lose their mucus and, in long-standing cases, glands become distorted. Dysplasia, characterised by heaping of cells within crypts, nuclear atypia and increased mitotic rate, may herald the development of colon cancer.

Crohn disease

The sites most commonly involved, in order of frequency, are the terminal ileum and right side of the colon, the small intestine, the colon alone, and the perianal region (see Fig. 22.54). The entire wall of the bowel is oedematous and thickened, and there are deep ulcers that often appear as linear fissures; because of this, the mucosa between them is described as 'cobblestone'. These ulcers may penetrate through the bowel wall to initiate abscesses or fistulae involving the bowel, bladder, uterus, vagina and skin of the perineum. The mesenteric lymph nodes are enlarged and the mesentery is thickened. Crohn disease has a patchy distribution and the inflammatory process is interrupted by islands of normal mucosa, resulting in 'skip lesions'. On histological examination, the bowel wall is thickened with a chronic inflammatory infiltrate throughout all layers (Fig. 22.57).

Fig. 22.53 Pathogenesis of inflammatory bowel disease. (1) Bacterial antigens are taken up by specialised M cells, pass between leaky epithelial cells or enter the lamina propria through ulcerated mucosa. (2) After processing, they are presented to type 1 T-helper cells by antigen-presenting cells (APCs) in the lamina propria. (3) T-cell activation and differentiation results in a Th1 T cell–mediated cytokine response (4) with secretion of cytokines, including interferon gamma (IFN-γ). Further amplification of T cells perpetuates the inflammatory process with activation of non-immune cells and release of other important cytokines, including interleukin (IL)-12, IL-23, IL-1, IL-6 and tumour necrosis factor alpha (TNF-α). These pathways occur in all normal individuals exposed to an inflammatory insult and this is self-limiting in healthy subjects. In genetically predisposed persons, dysregulation of innate immunity may trigger inflammatory bowel disease.

Clinical features

Ulcerative colitis

The cardinal symptoms are rectal bleeding with passage of mucus and bloody diarrhoea. The presentation varies, depending on the site

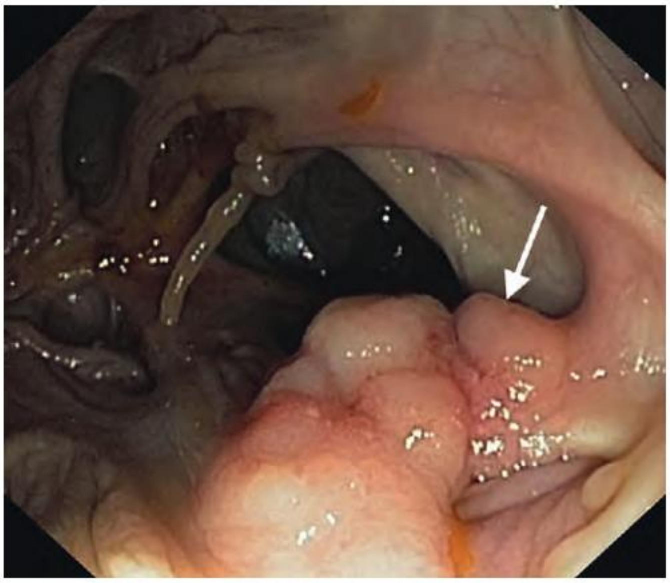

Fig. 22.55 Pseudopolyposis in ulcerative colitis. One of the more prominent pseudopolyps is indicated by an arrow.

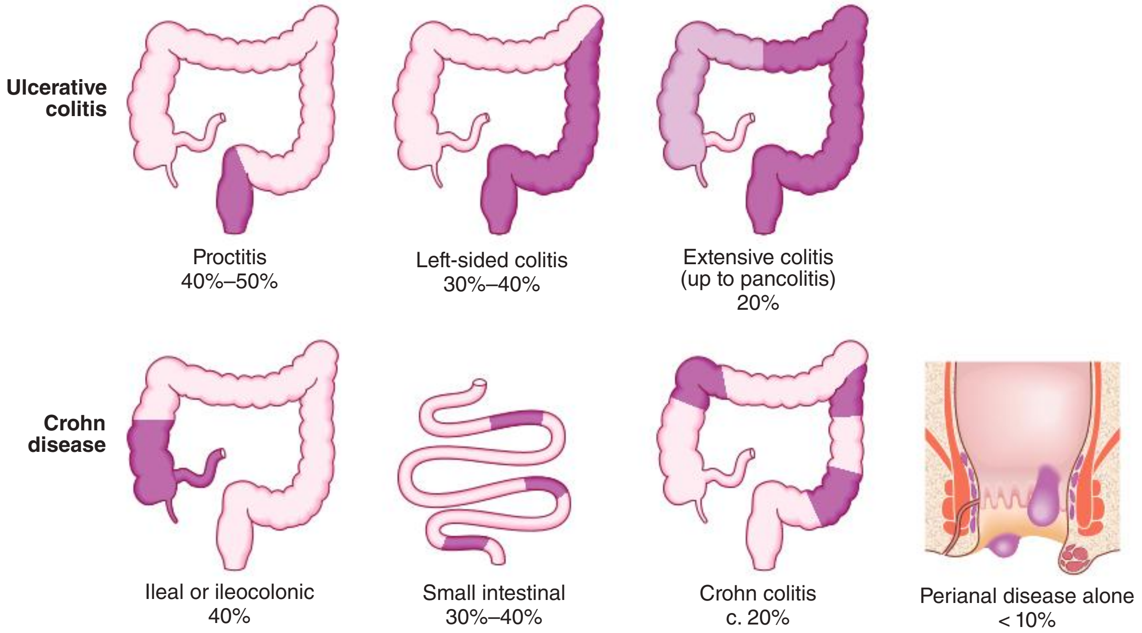

Ulcerative colitis
Proctitis 40%–50%
Left-sided colitis 30%–40%
Extensive colitis (up to pancolitis) 20%
Crohn disease
Ileal or ileocolonic 40%
Small intestinal 30%–40%
Crohn colitis c. 20%
Perianal disease alone < 10%

Fig. 22.54 Common patterns of disease distribution in inflammatory bowel disease.

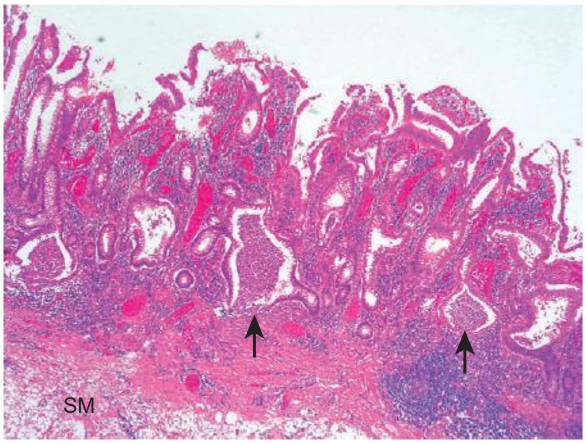

Fig. 22.56 Histology of ulcerative colitis. There is surface ulceration and inflammation is confined to the mucosa with excess inflammatory cells in the lamina propria, loss of goblet cells and crypt abscesses (arrows). (SM = submucosa)

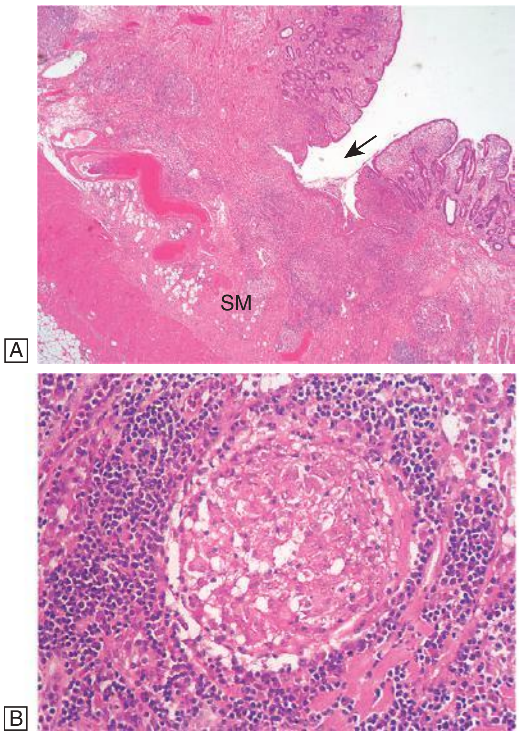

Fig. 22.57 Histology of Crohn disease. **A** Inflammation is 'transmural'; there is fissuring ulceration (arrow), with inflammation extending into the submucosa (SM). **B** At higher power, a characteristic non-caseating granuloma is seen.

and severity of the disease (see Fig. 22.54), as well as the presence of extra-intestinal manifestations. The first attack is usually the most severe and is followed by relapses and remissions. Emotional stress, intercurrent infection, gastroenteritis, antibiotics or NSAID therapy may all provoke a relapse. Proctitis causes rectal bleeding and mucus discharge, accompanied by tenesmus. Some patients pass frequent, small-volume fluid stools, while others pass pellety stools due to constipation upstream of the inflamed rectum. Left-sided and extensive colitis causes bloody diarrhoea with mucus, often with abdominal cramps. In severe cases, anorexia, malaise, weight loss and abdominal pain occur and the patient is toxic, with fever, tachycardia and signs of peritoneal inflammation (Box 22.64).

Crohn disease

The major symptoms are abdominal pain, diarrhoea and weight loss. Ileal Crohn disease (Figs. 22.58 and 22.59) may cause subacute or even acute intestinal obstruction. Occasionally, the presentation is with a perforated abscess. Abdominal pain is often associated with diarrhoea, which is usually watery and does not contain blood or mucus. Patients may lose weight because they avoid food, since eating provokes pain. Weight loss may also be due to malabsorption and some patients present with features of fat, protein or vitamin deficiencies. Crohn colitis presents in an identical manner to ulcerative colitis, but rectal sparing and the presence of perianal disease favour a diagnosis of Crohn disease. Many present with symptoms of both small bowel and colonic disease. A few present with isolated perianal disease, vomiting from jejunal strictures or severe oral ulceration.

Physical examination often reveals evidence of weight loss and anaemia with the inflamed area. An abdominal mass may be palpable and is due to matted loops of thickened bowel or an intra-abdominal abscess. Perianal skin tags, fissures or fistulae are found in at least 50% of those affected.

Differential diagnosis

Conditions that can mimic UC or CD are summarised in Box 22.65. The most important issue is to distinguish the first attack of UC from infection. In general, diarrhoea lasting longer than 10 days in Western countries is unlikely to be the result of infection, whereas a history of foreign travel, antibiotic exposure (*Clostridioides difficile*/pseudomembranous colitis) or homosexual contact increases the possibility of infection, which should be excluded by the appropriate investigations (see below). The diagnosis of Crohn disease is usually more straightforward based on imaging findings and clinical presentation, but terminal ileal disease can be mistaken for an appendix abscess, colonic carcinoma, pelvic inflammatory disease, lymphoma, tuberculosis, *Yersinia enterocolitica infection*, actinomycosis or mesenteric adenitis. In atypical cases, biopsy or surgical resection may be necessary to confirm or exclude the diagnosis of CD.

Complications

Life-threatening colonic inflammation

This can occur in both ulcerative colitis and Crohn colitis. In the most extreme cases, the colon dilates (toxic megacolon) and bacterial toxins pass freely across the diseased mucosa into the portal and then systemic circulation. This complication arises most commonly during the first attack of colitis and is recognised by the features described in Box 22.64. An abdominal X-ray should be taken daily because, when the transverse colon is dilated to more than 6 cm (Fig. 22.60), there is a high risk of colonic perforation, although this complication can also occur in the absence of toxic megacolon. Severe colonic inflammation with toxic dilatation is a surgical emergency and often requires colectomy.

Haemorrhage

Haemorrhage due to erosion of a major artery is rare but can occur in both conditions. This is more common in Crohn disease, where deep ulceration can erode into larger vessels.

Fistulae

These are specific to Crohn disease. Enteroenteric fistulae can cause diarrhoea and malabsorption due to blind loop syndrome. Enterovesical fistulation causes recurrent urinary infections and pneumaturia. An enterovaginal fistula causes a faeculent vaginal discharge. Fistulation from the bowel may also cause perianal or ischiorectal abscesses, fissures and fistulae.

Cancer

The risk of dysplasia and colorectal cancer increases with the duration and extent of uncontrolled colonic inflammation in colitis. Patients who have long-standing, extensive colitis are at highest risk. There is evidence

22.64 Assessment of disease severity in ulcerative colitis

	Mild	Moderate	Severe
Daily bowel frequency	< 4	4–6	≥ 6
Blood in stools	+/–	+/++	+++
Stool volume	< 200 g/24 hrs	200–400 g/24 hrs	> 400 g/24 hrs
Pulse	< 90 beats/min	< 90 beats/min	≥ 90 beats/min
Temperature	Normal	Normal	≥ 37.8°C
Haemoglobin	Normal	Normal	< 100 g/L (< 10 g/dL)
Inflammatory markers	Normal	Normal	ESR > 30 mm/hr (or C-reactive protein > 12 mg/mL)
Serum albumin	> 35 g/L (> 3.5 g/dL)		< 30 g/L (< 3 g/dL)
Abdominal X-ray	Normal	Normal	Dilated bowel, mucosal islands, thumb-printing of mucosa, or absence of features
Sigmoidoscopy	Normal or erythema/granular mucosa		Severe mucosal inflammatory changes; ulceration; blood in lumen

The Truelove–Witts criteria for acute severe ulcerative colitis are ≥ 6 bloody stools/24 hrs plus one or more of: anaemia, fever, tachycardia and high inflammatory markers.

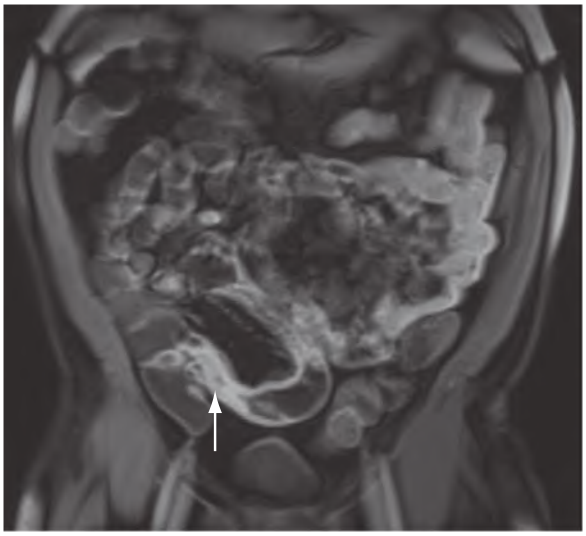

Fig. 22.58 Ileal Crohn disease. Small bowel magnetic resonance image showing a terminal ileum that is thickened, narrowed and enhancing (arrow), with dilatation immediately proximal to this.

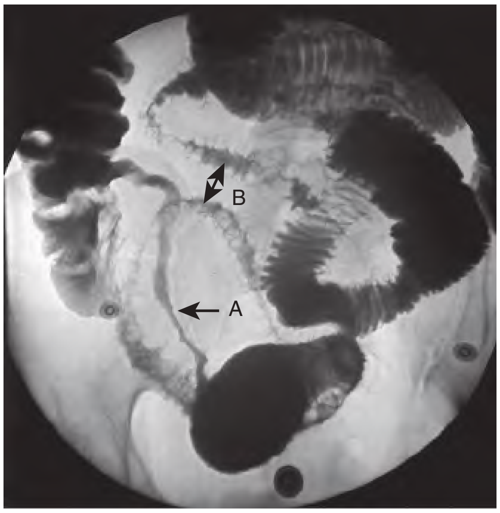

Fig. 22.59 Barium follow-through showing terminal ileal Crohn disease. A long stricture is present (arrow A), and more proximally there is ulceration with characteristic ‘rose thorn’ ulcers (arrow B).

22.65 Conditions that can mimic ulcerative colitis or Crohn disease

Infective

Bacterial

- *Salmonella*
- *Shigella*
- *Campylobacter jejuni*
- *Escherichia coli* 0157
- *Yersinia*
- Gonococcal proctitis
- Pseudomembranous colitis
- Chlamydia proctitis
- Appendix abscess
- Tuberculosis

Viral

- Herpes simplex proctitis
- Cytomegalovirus
- Mesenteric adenitis

Protozoal

- Amoebiasis

Non-infective

- Ischaemic colitis
- Collagenous colitis
- Pelvic inflammatory disease
- Non-steroidal anti-inflammatory drugs
- Diverticulitis
- Radiation proctitis
- Behçet disease
- Colonic carcinoma
- Lymphoma

that 5-aminosalicylic acid (5-ASA) therapy may reduce the risk of dysplasia and neoplasia in ulcerative colitis. Thiopurines also seem to reduce the risk of colorectal cancer in ulcerative colitis, but not Crohn disease. However, these benefits must be weighed against the very small increase in lymphoma, especially in older patients and with long duration of use. The cumulative incidence for IBD-associated colorectal cancer has been reported at 1% at 10 years after diagnosis, which increases to 7% after 30 years. For unknown reasons, the risk is particularly high in patients who have concomitant primary sclerosing cholangitis. Tumours develop in areas of dysplasia and may be multiple. Patients with long-standing colitis are therefore entered into surveillance programmes beginning 8 years after diagnosis, with patients with primary sclerosing cholangitis having annual surveillance colonoscopy from diagnosis. Targeted biopsies of areas that show abnormalities on staining with indigo carmine or methylene blue increase the chance of detecting dysplasia (termed pancolonic chromo-endoscopy) or, if not performed, colonoscopy with random biopsies taken every 10 cm can be performed in screening for malignancy. The procedure allows patients to be stratified into high-, medium- or low-risk groups to determine the interval between surveillance procedures. Family history of colorectal cancer is also an important factor to consider. If high-grade dysplasia is found, panproctocolectomy is usually recommended because of the high risk of colorectal cancer.

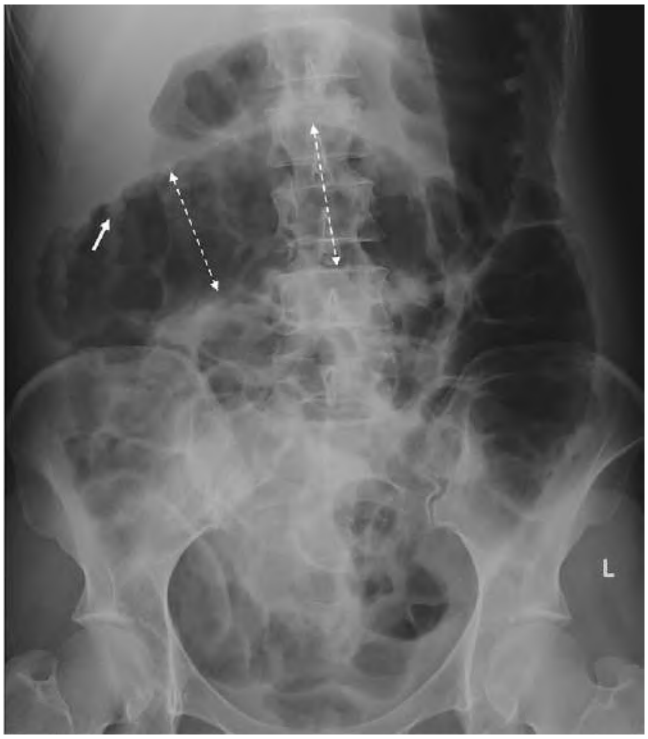

Fig. 22.60 Plain abdominal X-ray showing a grossly dilated colon (interrupted arrows) due to severe ulcerative colitis. There is also marked mucosal oedema and 'thumb-printing' (solid white arrow).

Extra-intestinal complications

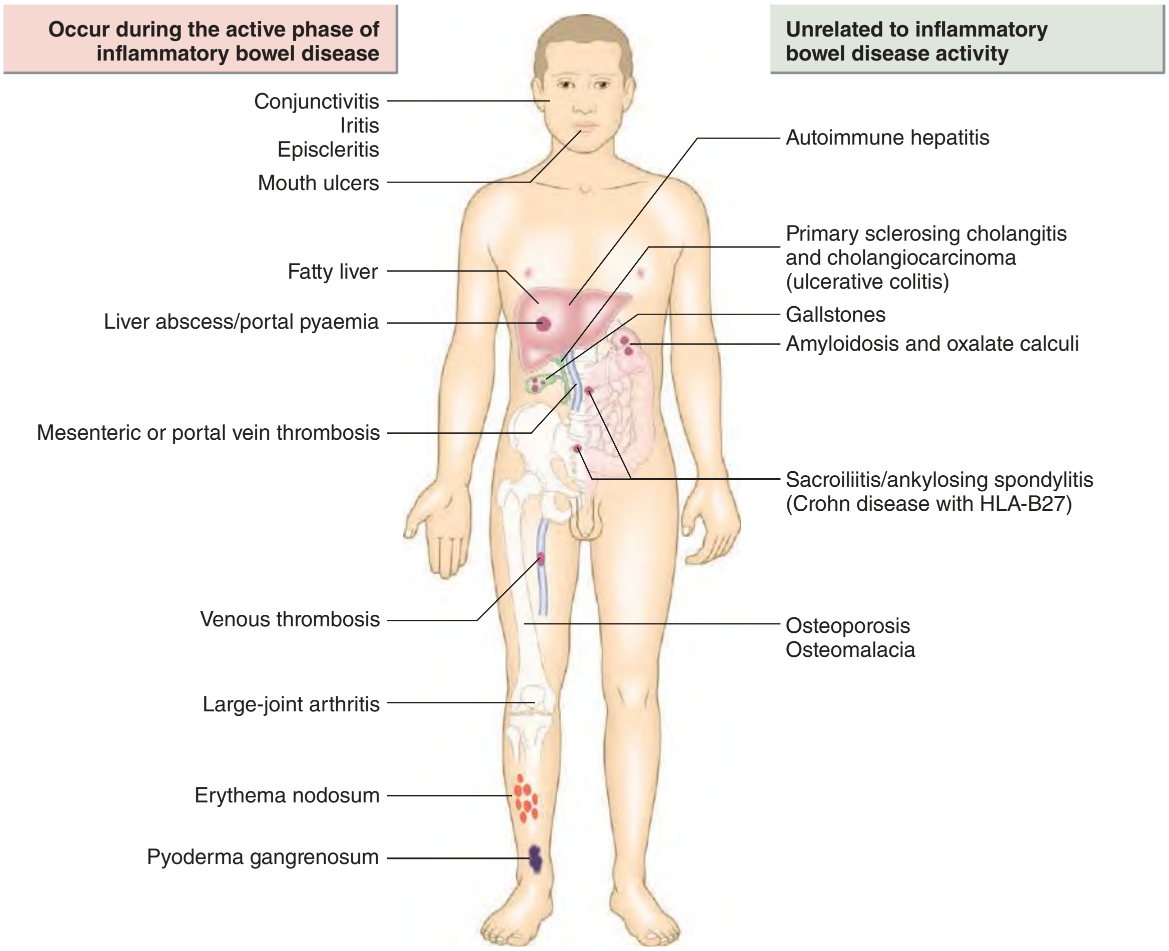
Extra-intestinal complications are common in IBD and may dominate the clinical picture (Fig. 22.61). Some of these occur during relapse of intestinal disease, whereas others are unrelated to current activity of intestinal disease.

Investigations

Investigations are necessary to confirm the diagnosis, define disease distribution and activity, and identify complications. Full blood count may show anaemia resulting from bleeding or malabsorption of iron, folic acid or vitamin B_{12}. Platelet count can also be high as a marker of chronic inflammation. Serum albumin concentration falls as a consequence of protein-losing enteropathy, inflammatory disease or poor nutrition. The ESR and CRP are elevated in exacerbations and in response to abscess formation. Faecal calprotectin has a high sensitivity for detecting gastrointestinal inflammation and may be elevated, even when the CRP is normal. It is particularly useful for distinguishing inflammatory bowel disease from irritable bowel syndrome at diagnosis, and for subsequent monitoring of disease activity.

Bacteriology

At initial presentation, stool microscopy, culture and examination for *Clostridioides difficile* toxin or for ova and cysts, blood cultures and serological tests should be performed. These investigations should be repeated in established disease to exclude superimposed enteric infection in patients who present with exacerbations of IBD. During acute flares necessitating hospital admission, three separate stool samples should be sent for bacteriology to maximise sensitivity. In addition, biopsies for cytomegalovirus should be considered at time of endoscopy in patients with refractory colitis.



Occur during the active phase of inflammatory bowel disease
Conjunctivitis
Iritis
Episcleritis
Mouth ulcers
Fatty liver
Liver abscess/portal pyaemia
Mesenteric or portal vein thrombosis
Venous thrombosis
Large-joint arthritis
Erythema nodosum
Pyoderma gangrenosum
Unrelated to inflammatory bowel disease activity
Autoimmune hepatitis
Primary sclerosing cholangitis and cholangiocarcinoma (ulcerative colitis)
Gallstones
Amyloidosis and oxalate calculi
Sacroiliitis/ankylosing spondylitis (Crohn disease with HLA-B27)
Osteoporosis
Osteomalacia

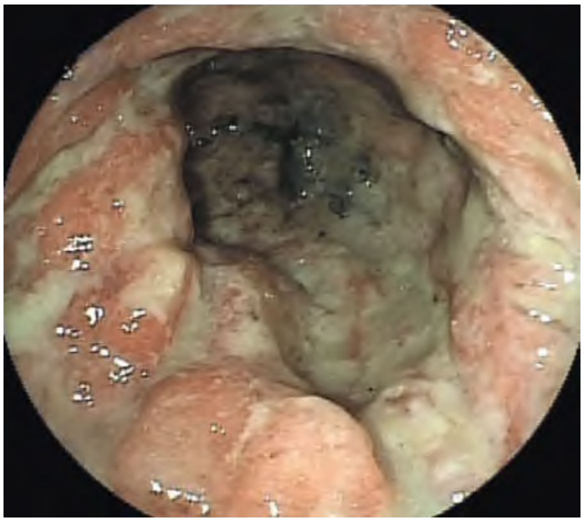

Fig. 22.62 **Sigmoidoscopic view of moderately active ulcerative colitis.** Mucosa is erythematous and friable with contact bleeding. Submucosal blood vessels are no longer visible. The pale yellow mucosa represent areas of ulceration.

Endoscopy

Patients who present with diarrhoea plus raised inflammatory markers or alarm features, such as weight loss, rectal bleeding and anaemia, should undergo ileocolonoscopy. Flexible sigmoidoscopy is occasionally performed to make a diagnosis, especially during acute severe presentations when ileocolonoscopy may confer an unacceptable risk; ileocolonoscopy should still be performed at a later date, however, in order to evaluate disease extent. In ulcerative colitis, there is loss of vascular pattern, granularity, friability and contact bleeding, with or without ulceration (Fig. 22.62). In Crohn disease, patchy inflammation, with discrete, deep ulcers, strictures and perianal disease (fissures, fistulae and skin tags), is typically observed, often with rectal sparing. In established disease, colonoscopy may show active inflammation with pseudopolyps or a complicating carcinoma. Biopsies should be taken from each anatomical segment (terminal ileum, right colon, transverse colon, left colon and rectum) to confirm the diagnosis and define disease extent, and also to seek dysplasia in patients with long-standing colitis guided by pancolonic chromo-endoscopy. In Crohn disease, wireless capsule endoscopy has a greater sensitivity for detecting small bowel disease in comparison to radiological techniques and is useful when there is a high suspicion of Crohn disease despite normal imaging. A dissolvable patency capsule should be performed prior if there are concerns for small bowel strictures. Enteroscopy may be required to make a histological diagnosis of small bowel Crohn disease, when the inflamed segment is out of reach of standard endoscopes, or for a therapeutic indication, such as dilatation of strictures. In individuals with upper gastrointestinal symptoms, an upper gastrointestinal endoscopy may be useful. However, this is not routinely performed in adults with suspected or proven Crohn disease.

Radiology

Where colonoscopy is incomplete, a CT colonography is preferred. Small bowel imaging is essential to complete staging of Crohn disease. Imaging with MRI may reveal thickening of the bowel wall and stricture (see Fig. 22.58) as well as providing information on pelvic and perineal involvement. These MRI studies use an orally administered small bowel–distending agent and intravenous contrast to provide transmural imaging that can usefully distinguish between predominantly inflammatory strictures (that should respond to anti-inflammatory medical strategies) and fibrotic strictures (that require a mechanical solution, such as surgical resection, stricturoplasty or endoscopic balloon dilatation). Traditional X-rays using barium follow-through may also be used (see Fig. 22.59), but these have largely been superseded by MRI imaging. A plain abdominal X-ray is essential in the management of patients who present with severe active disease. Dilatation of the colon (see Fig. 22.60), mucosal oedema (thumb-printing) or evidence of perforation may be found. Patients with proctitis may have features of proximal faecal loading. In small bowel Crohn disease, there may be evidence of intestinal obstruction or displacement of bowel loops by a mass. Ultrasound is a very powerful tool to detect small bowel inflammation and stricture formation, but it is operator-dependent. The role of CT is limited to screening for complications, such as perforation or abscess formation, in the acutely unwell.

i 22.66 Conventional immunosuppressives used in the treatment of inflammatory bowel disease

Class	Drug	Indication
Aminosalicylates	Mesalazine Olsalazine Sulfasalazine Balsalazide	Induce remission or maintenance in mild/moderate ulcerative colitis
Glucocorticoids	Prednisolone Hydrocortisone Budesonide Beclomethasone Methylprednisolone	Induce remission in acute ulcerative colitis or Crohn disease
Anti-metabolites	Azathioprine Mercaptopurine Methotrexate	Maintenance therapy in ulcerative colitis or Crohn disease
Calcineurin inhibitors	Ciclosporin	Severe ulcerative colitis refractory to glucocorticoids
Antibiotics	Ciprofloxacin Metronidazole	Peri-anal Crohn disease and pouchitis

Management

Medical therapy plays an important role in the management of IBD. However, optimal management depends on establishing a multidisciplinary team-based approach involving physicians, surgeons, radiologists, nurse specialists, pharmacists and dietitians. Both ulcerative colitis and Crohn disease are life-long conditions and have important psychosocial implications; specialist nurses, counsellors and patient support groups have key roles in education, reassurance and coping. The key aims of medical therapy are to:

- treat acute attacks (induce remission)
- prevent relapses (maintain remission)
- prevent bowel damage
- detect dysplasia and prevent carcinoma
- select appropriate patients for surgery.

Medical therapy

Several medical treatment options exist in the management for IBD. Whilst traditional management for IBD has been through the use of conventional immunosuppressives, there has been a rapid expansion in the use of advanced medical therapies, with common treatments described below.

Conventional immunosuppressive therapies

Conventional immunosuppressives used in IBD are summarised in Box 22.66.

Aminosalicylates (5-ASA) 5-ASAs are more commonly used in ulcerative colitis than in Crohn disease. 5-ASAs are thought to have multiple anti-inflammatory effects, including inhibition of mediators of lipoxygenase and cyclooxygenase, modulating cytokine release from the mucosa. Several types are available, with different means of delivery to the colon; pH-dependent (Asacol, Salofalk), time-dependent (Pentasa) or bacterial breakdown by colonic bacteria from a carrier molecule (sulfasalazine, balsalazide). While sulfasalazine was the first 5-ASA to be used in IBD, side-effects are common, such as headache, nausea, diarrhoea and blood dyscrasias. Other 5-ASAs are better tolerated. 5-ASAs can be administered orally or topically (suppositories or enema). Patients commencing a 5-ASA should have their urea and electrolytes checked at baseline, after 2–3 months and then annually, as nephrotoxicity can rarely occur (1 in 4000 patient years).

Glucocorticoids Glucocorticoids such as prednisolone, hydrocortisone, budesonide and beclomethasone can be used to induce clinical remission in both ulcerative colitis and Crohn disease but have no role in preventing relapse. They can be administered orally, topically (suppositories or enema) or intravenously and have powerful anti-inflammatory effects. When administered, it is important to have high vigilance for complications, such as osteoporosis, diabetes and weight gain. Simultaneous calcium and vitamin D supplementation should be given for bone protection. Budesonide is a potent glucocorticoid, which is efficiently cleared from circulation by the liver, thereby minimising adrenocortical suppression and side-effects. It is commonly used in the treatment of active ileitis and ileocolitis.

Thiopurines Thiopurines used in IBD are azathioprine and mercaptopurine. They are immunomodulators that induce T-cell apoptosis. Azathioprine and mercaptopurine are administered orally and metabolised to thioguanine nucleotides (TGNs). Thiopurine methyltransferase (TPMT) methylates thiopurine metabolites away from TGNs and affects drug levels. Leucopenia can occur in 3%, particularly in those with genetic variants in TPMT that are associated with reduced TPMT activity. Because of this, TPMT genotyping is generally performed prior to starting treatment, and thiopurines are often avoided if this reveals variants with reduced TMPT activity due to the risk of myelosuppression. Genetic variations in *NUDT15* similarly influence thiopurine metabolism and variations in this gene can also be tested where available. Thiopurines take around 6 weeks after starting treatment to be effective. Around 20% of patients will have complications leading to drug withdrawal. Complications include influenza-like syndrome with myalgia, nausea and vomiting. Other adverse effects include hepatotoxicity and pancreatitis. Patients should be counselled on the increased lymphoma (approximately two- to threefold) and non-melanoma skin cancer (life-long sun protection advised) risk. Caution should be exercised in prescribing thiopurines in patients presenting over the age of 60 years due to the increased risk of malignancy.

Methotrexate Methotrexate can be used for maintenance therapy in Crohn disease but has no role in ulcerative colitis. It is commonly used in individuals who have failed to respond with thiopurines. It is a folic acid antagonist, which inhibits dihydrofolate reductase, preventing DNA synthesis. The bioavailability of oral methotrexate is variable when compared to parenteral administration, with the subcutaneous route being preferred. Nausea, stomatitis, diarrhoea, hepatotoxicity and pneumonitis can occur with methotrexate. Folic acid should be given concurrently to reduce gastrointestinal and liver toxicity. Women of child-bearing potential must use a robust contraceptive method and should be counselled to plan pregnancy with a 3-month methotrexate-free period prior to conception as it is teratogenic.

Ciclosporin Ciclosporin is a calcineurin inhibitor, which inhibits T-cell signalling and prevents lymphocyte activation. It is used in ulcerative colitis that has responded poorly to glucocorticoids but has no role in Crohn disease. Major adverse effects include nephrotoxicity, infections and neurotoxicity (including seizures). Others include tremor, paraesthesiae, abnormal liver function tests and hirsutism. In severe UC, ciclosporin is usually administered intravenously, and responders to treatment are subsequently converted to oral administration. This may be continued for several months as a bridging therapy before starting a thiopurine for longer-term control of disease activity.

Antibiotics Antibiotics are useful in perianal Crohn disease and pouchitis. There is little evidence comparing different antibiotics for acute pouchitis, although ciprofloxacin is better tolerated with fewer adverse effects than metronidazole. The major concern is peripheral neuropathy with long-term metronidazole, with tendon inflammation and damage potentially occurring with ciprofloxacin. Combination antibiotics may be needed for chronic pouchitis. Antibiotics tend to be used in combination with thiopurines and anti-TNF therapy in perianal disease.

22.67 Biologics and targeted immunosuppressives used in the treatment of inflammatory bowel disease

Class	Medicine	Route	Standard maintenance dose
Anti-TNF antibodies	Infliximab	IV or SC	5 mg/kg every 8 weeks (IV) 120 mg every 2 weeks (SC)
	Adalimumab	SC	40 mg every 2 weeks
	Golimumab	SC	50 mg or 100 mg every 4 weeks
	Certolizumab	SC	400 mg every 4 weeks
Anti-α4β7 integrin antibodies	Vedolizumab	IV or SC	300 mg every 8 weeks (IV) 10 mg every 2 weeks (SC)
JAK inhibitors	Tofacitinib	PO	5 mg twice daily
	Filgotinib	PO	200 mg once daily
	Upadacitinib	PO	15 mg or 30 mg daily
Anti IL-12/23 antibodies	Ustekinumab	IV induction, SC maintenance	90 mg every 8 to 12 weeks (SC)
Anti IL-23 antibodies	Risankizumab	IV induction, SC maintenance	360 mg every 8 weeks (SC) for Crohn disease 180 mg every 8 weeks (SC) for ulcerative colitis
	Mirikizumab	IV induction, SC maintenance	200 mg every 4 weeks (SC)
S1P receptor modulators	Ozanimod	PO	0.92 mg once daily
	Etrasimod	PO	2 mg once daily

(IV = intravenous; PO = oral; SC = subcutaneous; S1P = sphingosine-1-phosphate)

Biologics and other targeted immunosuppressives

Several classes of targeted immunosuppressive are used in the management of IBD, as summarised in Box 22.67. In general, these medicines are used in patients with moderate to severe IBD that has not responded adequately to conventional therapy, although the precise licensed indication for individual drugs varies. At present, sphingosine-1-phosphate receptor (S1PR) modulators, ozanimod and etrasimod are only approved for use in UC whereas the other drugs can be used in either UC or CD. Their sites of action are shown in Figure 22.63. Before commencing these therapies, screening for active and latent infection is important, with screening including a chest X-ray and interferon gamma release assay (IGRA) for tuberculosis; serology for hepatitis B, C and HIV is also necessary. Some centres also screen for infection with cytomegalovirus (CMV), varicella zoster virus (VZV) and Epstein–Barr virus (EBV) and delay treatment in those with evidence of recent infection. Live vaccines should be avoided during treatment with all of these agents, but immunisation to protect against VZV, COVID-19 and influenza are all recommended for people on these medications.

Anti-TNF antibodies These include infliximab, adalimumab, golimumab and certolizumab. They are monoclonal antibodies typically given by subcutaneous injection, which bind to and neutralise TNF-α, reducing inflammation in the gut. Etanercept, a decoy receptor for TNF-α, is not effective in IBD. They are generally well tolerated but acute (anaphylactic) and delayed (serum sickness) infusion reactions can occur after multiple infusions of infliximab. Anti-drug antibody titres and drug levels can also be

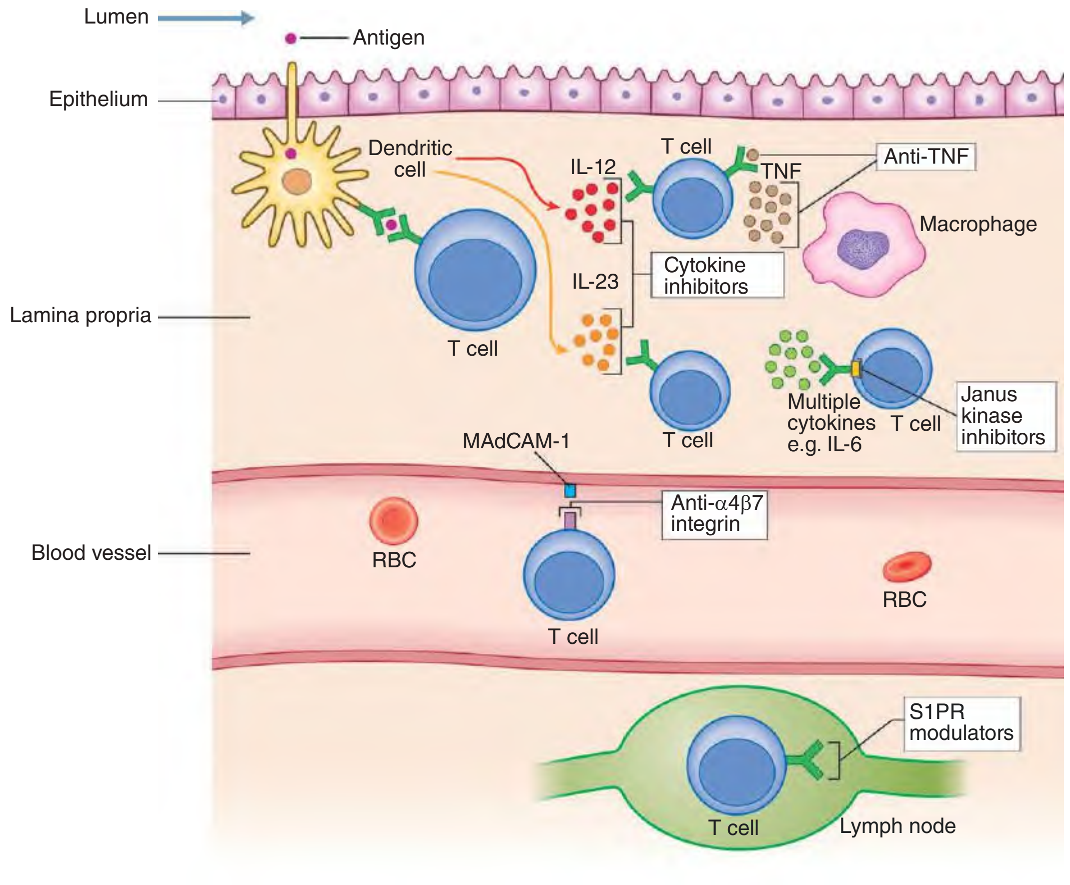

Fig. 22.63 **Site of action of biologics.** (IL = interleukin; RBC = red blood cell; S1PR = sphingosine-1-phosphate receptors; TNF = tumour necrosis factor)

measured to assess efficacy. Anti-TNF antibodies are contraindicated in active infection and in patients with pre-existing moderate to severe heart failure. There is a possible increased risk of malignancy, and demyelinating disease is a rare adverse effect. Treatment should continue so long as efficacy is maintained with reassessment of response every 12 months.

Anti-α4β7 integrin Vedolizumab is a monoclonal antibody that blocks α4β7 integrin expressed on leucocytes and inhibits leucocyte interaction with a gut-specific receptor on endothelium, reducing leucocyte migration into gut mucosa. It is a gut-selective biologic used in both ulcerative colitis and Crohn disease. Side-effects include nasopharyngitis, arthralgia and headache. Treatment should be discontinued if there is no improvement after 14 weeks but otherwise should be continued so long as efficacy is maintained with reassessment of response every 12 months.

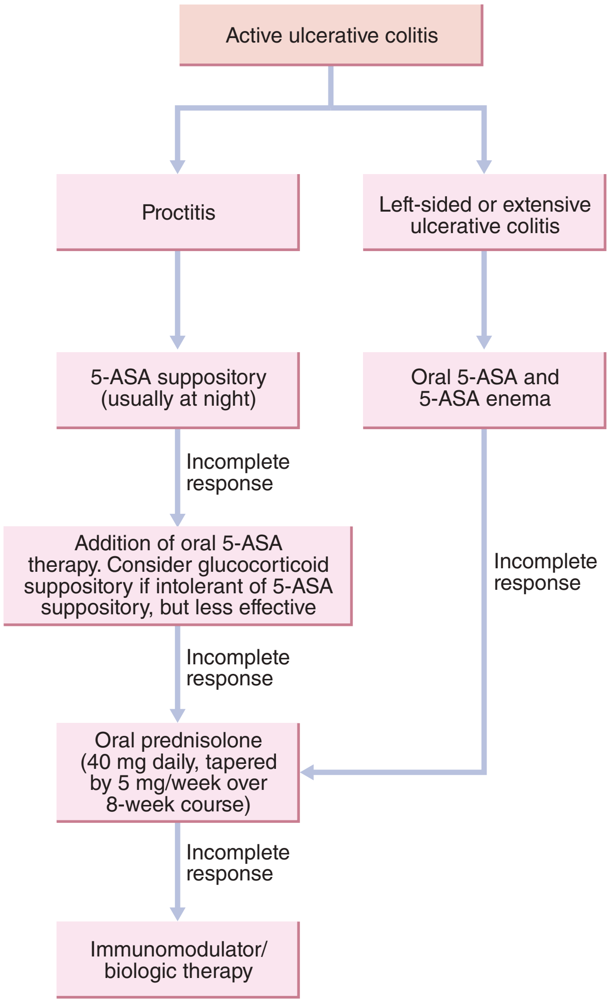
Janus kinase inhibitors These include tofacitinib, upadacitinib and filgotinib. These Janus kinase (JAK) inhibitors selectively inhibit different isoforms of Janus kinases. Tofacitinib has greater selectivity for JAK1 and JAK3, whereas upadacitinib and filgotinib have greater selectively for JAK1. They have the advantage of oral administration. High doses should be avoided in patients at risk of venous thrombo-embolism and treatment is contraindicated in pregnancy. In addition, caution should be used in individuals with cardiovascular disease and risk factors for malignancy, as well as in individuals above the age of 65 years. Herpes zoster infection is a relatively common adverse event. Because of this, zoster vaccination is currently recommended for all patients on these medicines. Treatment should continue so long as efficacy is maintained, with reassessment of response every 12 months.

Interleukin 12 and interleukin 23 inhibitors Ustekinumab, risankizumab and mirikizumab are monoclonal antibodies used in IBD. Ustekinumab binds to the p40 subunit of both IL-12 and IL-23, thereby inhibiting the actions of both cytokines, whereas risankizumab and mirikizumab are specific IL-23 inhibitors binding to the p19 subunit of this cytokine. All of these drugs inhibit T-cell activation, thereby exerting an anti-inflammatory effect. Adverse effects include nasopharyngitis, headache and arthralgia. Treatment should continue so long as efficacy is maintained, with reassessment of response every 12 months.

Sphingosine-1-phosphate receptor modulators Ozanimod and etrasimod bind to sphingosine-1-phosphate receptors (S1PRs), preventing their activation by sphigosine-1-phosphate (S1P). Ozanimod specifically binds to S1P receptors 1 and 5, whereas etrasimod binds to S1P receptors 1, 4 and 5. This prevents the movement of T lymphocytes from lymph nodes into the circulation, thereby reducing inflammation. Like Janus kinase inhibitors, they have the advantage of oral administration. Side-effects include nasopharyngitis, lymphopenia, headache, bradycardia, blurred vision and hypertension. In addition, S1PR modulators may increase the risk of skin cancer, with adequate skin care protection being advised. Treatment should continue so long as efficacy is maintained, with reassessment of response every 12 months.

Therapeutic drug monitoring

Up to one-third of patients do not respond to targeted immunosuppressives (primary non-response), and up to half discontinue after an initial positive response due to secondary loss of response or adverse effects. There is evidence that the outcomes are most favourable when drug concentrations are within the therapeutic range, whereas suboptimal drug concentrations may be due to inadequate dosing or the development of anti-drug antibodies, leading to treatment failure. Therapeutic drug monitoring is used most often in patients on anti-TNF therapy, to ensure that patients have adequate drug levels, pre-emptively preventing flares.



Active ulcerative colitis
Proctitis
Left-sided or extensive ulcerative colitis
5-ASA suppository (usually at night)
Oral 5-ASA and 5-ASA enema
Incomplete response
Addition of oral 5-ASA therapy. Consider glucocorticoid suppository if intolerant of 5-ASA suppository, but less effective
Incomplete response
Incomplete response
Oral prednisolone (40 mg daily, tapered by 5 mg/week over 8-week course)
Incomplete response
Immunomodulator/ biologic therapy

Fig. 22.64 Medical management of active ulcerative colitis. (5-ASA = 5-aminosalicylic acid)

Combination treatment of anti-TNF therapy with thiopurines or methotrexate can be used to reduce the risk of anti-drug antibodies developing. Therapeutic drug monitoring can also be performed with thiopurines, by measurement of thiopurine metabolites measured to tailor dosing.

Ulcerative colitis

Active ulcerative colitis Patients with active ulcerative colitis can be initially treated with topical or oral 5-aminosalicylate acid (5-ASA) therapy. Patients with left-sided or extensive ulcerative colitis should continue oral 5-ASA in the long term to prevent relapse and minimise the risk of dysplasia. Individuals with an incomplete response to 5-ASA treatment may require treatment with systemic glucocorticoids, conventional or targeted immunosuppressive therapy. Glucocorticoids should never be used for maintenance therapy. An algorithm for the management of active ulcerative colitis is shown in Figure 22.64.

Severe ulcerative colitis Patients who present with acute severe colitis (meeting the Truelove–Witts criteria, see Box 22.64) are best managed in hospital and should be monitored jointly by a physician and surgeon:

- *clinically*: for the presence of abdominal pain, temperature, pulse rate, stool blood and frequency
- *by laboratory testing*: haemoglobin, white cell count, albumin, electrolytes, ESR and CRP, stool culture, including *Clostridioides difficile* toxin assay
- *radiologically*: for colonic dilatation on plain abdominal X-rays.

22.68 Medical management of fulminant ulcerative colitis

- Admit to hospital for intensive therapy and monitoring
- Give IV fluids and correct electrolyte imbalance
- Consider transfusion if haemoglobin is < 100 g/L (< 10 g/dL)
- Give IV methylprednisolone (60 mg daily) or hydrocortisone (100 mg four times daily)
- Give antibiotics until enteric infection is excluded
- Arrange nutritional support
- Give subcutaneous low-molecular-weight heparin for prophylaxis of venous thromboembolism
- Avoid opiates and antidiarrhoeal agents
- Consider infliximab (5 mg/kg) or ciclosporin (2 mg/kg) in patients not responding to 3–5 days of glucocorticoids

(IV = intravenous)

All patients should be given supportive treatment with intravenous fluids to correct dehydration and enteral nutritional support should be provided for malnourished patients (Box 22.68). Intravenous glucocorticoids (methylprednisolone 60 mg every 24 hours or hydrocortisone 100 mg four times daily) should be given by infusion or bolus injection. Patients should receive prophylactic low-molecular weight heparin, as the risk of venous thromboembolism is significantly increased. Topical and oral aminosalicylates have no role to play in the acute severe attack. Response to therapy is judged over the first 3 days. Patients who do not respond promptly to glucocorticoids should be considered for medical rescue therapy with infliximab (5 mg/kg) or ciclosporin (2 mg/kg daily by intravenous infusion followed by 5 mg/kg daily, then orally after 7 days), which can avoid the need for urgent colectomy in approximately 60% of cases.

Patients who develop colonic dilatation (> 6 cm), those whose clinical and laboratory measurements deteriorate and those who do not respond after 7–10 days' maximal medical treatment usually require urgent surgery. Subtotal colectomy with end ileostomy is the operation of choice and can be performed open or laparoscopically, dependent upon local expertise. The surgical and medical teams should liaise early in the disease course and, if possible, the patient should have the opportunity to speak with the stoma nurse prior to colectomy.

Maintenance of remission Life-long maintenance therapy is recommended for all patients with left-sided or extensive disease but may not be necessary in those with proctitis, although up to 20% of these patients may develop a proximal extension of disease over their lifetime. Once-daily oral 5-aminosalicylates are the preferred first-line agents. Sulfasalazine has a higher incidence of side-effects but is equally effective and can be considered in patients with coexistent arthropathy. Patients who frequently relapse despite aminosalicylate drugs have in the past always been offered thiopurines (azathioprine or 6-mercaptopurine). While thiopurines still have a role for treatment, other immunosuppressive drugs should also be considered early. Targeted immunosuppressive therapy with anti-TNF antibodies (infliximab, adalimumab or golimumab) can be considered for maintenance treatment in patients with moderate to severe ulcerative colitis. Combination therapy with infliximab and a thiopurine should be used where possible, as it is more effective than monotherapy with infliximab. In patients where anti-TNF treatment has failed, anti-α4β7 integrin antibodies (vedolizumab), Janus kinase inhibitors (tofacitinib, filgotinib, upadacitinib), IL-12/IL-23 inhibitors (ustekinumab, risankizumab, mirikizumab) and S1PR modulators (ozanimod, etrasimod) can all be used to maintain remission.

Crohn disease

Principles of management Crohn disease is a progressive condition that may result in stricture or fistula formation if suboptimally treated. It is therefore important to agree long-term treatment goals with the patient; these are to induce remission and then maintain glucocorticoid-free remission with a normal quality of life. Treatment should focus on

22.69 Monitoring of patients with Crohn disease

- Assess symptoms, including extra-intestinal manifestations
- Examine for abdominal mass or perianal disease
- Perform full blood count, urea and electrolytes, liver function tests, albumin, C-reactive protein (CRP)
- Check haematinics (vitamin B_{12}, folate, iron studies) at least annually
- Check faecal calprotectin (to monitor each disease flare/change in therapy and assess response)
- Perform stool cultures (at each flare to exclude infection)
- Assess mucosal healing: surrogate markers (CRP/calprotectin), small bowel capsule, ileocolonoscopy and/or small bowel magnetic resonance imaging
- Enroll patient in a dedicated IBD clinic (monitoring of stable, uncomplicated patients may be carried out by a nurse or phone clinic)
- Arrange IBD multidisciplinary meeting for acutely ill or complex patients
- Check vaccinations are up to date; live vaccinations may be given at least 4 weeks before starting immunosuppressive therapy and at least 3 months after stopping immunosuppressive therapy. Patients on immunosuppressive therapy should receive influenza and pneumococcal vaccination
- Ensure surveillance colonoscopy is scheduled where appropriate

(IBD = inflammatory bowel disease)

monitoring the patient carefully for evidence of disease activity and complications (Box 22.69) and ensuring that mucosal healing is achieved.

Induction of remission in mild to moderate disease Glucocorticoids can be used as treatment for active Crohn disease. The drug of first choice in patients with ileal disease is budesonide, since it undergoes 90% first-pass metabolism in the liver and has very little systemic toxicity. A typical regimen is 9 mg once daily for 4 weeks, with a stepwise reduction of 3 mg every 4 weeks until therapy is stopped. If there is no response to budesonide within 2 weeks, the patient should be switched to prednisolone, which has greater efficacy. This is typically given in a dose of 40 mg daily, reducing by 5 mg/week over 8 weeks, at which point treatment is stopped. Oral prednisolone in the dose regimen described above is the treatment of choice for inducing remission in colonic Crohn disease.

As an alternative to glucocorticoid therapy, enteral nutrition with either an elemental (constituent amino acids) or polymeric (liquid protein) diet may induce remission. Both types of diet are equally effective, but the polymeric one is more palatable when taken by mouth, and this improves adherence. It is particularly effective in children, in whom equal efficacy to glucocorticoids has been demonstrated, and in extensive ileal disease in adults. As well as resting the gut and providing excellent nutritional support, it also has a direct anti-inflammatory effect. It is an effective bridge to urgent staging investigations at first presentation and can be given by mouth or by nasogastric tube. With sufficient explanation, encouragement and motivation, most patients will tolerate it well.

Induction and maintenance of remission in severe disease Patients with severe disease can be treated with systemic glucocorticoids short term, but early introduction of targeted immunosuppressives should be considered in these individuals providing that complications, such as perforation or abscess, have been excluded. Anti-TNF, anti-α4β7 integrin, anti-IL-12/23 and JAK inhibitors can all be considered to maintain remission in such patients. Combination therapy of infliximab with a thiopurine is more effective than monotherapy with infliximab. Combination therapy of infliximab with methotrexate may also be used to reduce the risk of anti-drug antibodies developing. In patients who still require glucocorticoids despite optimising treatment with targeted immunosuppressives, other options must be considered, including surgery.

Cigarette smokers with Crohn disease should be strongly advised to stop. Those that do not stop smoking fare much worse, with increased rates of relapse and surgical intervention. The adverse effects of smoking are more pronounced in women than in men. Careful monitoring of disease activity (see Box 22.69) is the key to maintaining sustained remission and preventing the accumulation of bowel damage in Crohn disease.

22.70 Indications for surgery in ulcerative colitis

Impaired quality of life
- Loss of occupation or education
- Disruption of family life

Failure of medical therapy
- Dependence on oral glucocorticoids
- Resistant to drug therapy
- Intolerable side-effects of drug therapy

Fulminant colitis
- Life-threatening bleeding

Toxic megacolon
- Perforation

Colon cancer or severe dysplasia

Fistulae and perianal disease

Fistulae may develop in relation to active Crohn disease and are often associated with sepsis. The first step is to define the site by imaging (usually MRI of the pelvis). Endoanal ultrasound is another option for assessment, but is limited in patients with luminal stenoses, as well as by local expertise. Surgical exploration by examination under anaesthetic is usually then required, to delineate the anatomy and drain abscesses. Seton sutures can be inserted through fistula tracts to ensure adequate drainage and to prevent future sepsis. Glucocorticoids are ineffective but use of antibiotics, such as metronidazole and/or ciprofloxacin, can aid healing. Thiopurines can be used in chronic disease, but do not usually result in fistula healing. Anti-TNF therapy can heal fistulae and perianal disease in many patients and are indicated when the measures described above have been ineffective. Higher trough infliximab drug levels are aimed for in perianal Crohn disease. The evidence of benefit in perianal fistulating disease for the newer targeted immunosuppressives is presently unclear. Other options for refractory perianal disease are proctectomy or faecal diversion with an upstream stoma.

Surgical management

Ulcerative colitis

Up to 30% of patients with extensive ulcerative colitis eventually require surgery. The indications are listed in Box 22.70. Impaired quality of life, with its impact on occupation and social and family life, is the most important of these. Surgery involves removal of the entire colon and rectum and cures the patient. Around 10% of patients with colitis undergo colectomy within 5 years of diagnosis. Before surgery, patients should be counselled by doctors, stoma nurses and patients who have undergone similar surgery. The procedure of choice is usually an initial subtotal colectomy with ileostomy and a subsequent ileorectal anastomosis, or a proctocolectomy and ileal pouch–anal anastomosis. The companion text to this book, *Principles and Practice of Surgery*, should be consulted for further details.

Crohn disease

Operations are often necessary to deal with fistulae, abscesses and perianal disease, and may also be required to relieve small or large bowel obstruction. In contrast to ulcerative colitis, surgery is not curative and disease recurrence is the rule. The only method that has consistently been shown to reduce post-operative recurrence is smoking cessation. Antibiotics are effective in the short term only. Use of thiopurines post-surgery should be considered if there are indicators of a high chance of recurrence, such as more than one resection or evidence of penetrating disease, such as fistulae or abscess. Otherwise, it is common to undertake colonoscopy 6 months after surgery to inspect and biopsy the anastomosis and neo-terminal ileum. Patients with endoscopic recurrence should be prescribed immunomodulators or biologics to prevent further complications.

Surgery should be as conservative as possible in order to minimise the loss of viable intestine and to avoid the creation of a short bowel syndrome (Ch. 5). Obstructing or fistulating small bowel disease may require resection of affected tissue. Patients who have localised segments of Crohn colitis may be managed by segmental resection and/or multiple stricturoplasties, in which the stricture is not resected but instead incised in its longitudinal axis and sutured transversely. Others who have extensive colitis require total colectomy, but ileal pouch formation should be avoided because of the high risk of recurrence within the pouch and subsequent fistulae, abscess formation and pouch failure.

Historical datasets show that around 80% of Crohn disease patients undergo surgery at some stage and 70% of these require more than one operation during their lifetime. Clinical recurrence following resectional surgery is present in 50% of all cases at 10 years. Emerging data demonstrate that aggressive medical therapy, coupled with intense monitoring, probably reduces the requirement for surgery substantially.

IBD in special circumstances

Childhood

Children developing IBD tend to have more extensive disease than adults. Chronic ill health in childhood or adolescence may result in impaired growth, metabolic bone disease and delayed puberty. Loss of schooling and social contact, as well as frequent hospitalisations, can have important psychosocial consequences. Treatment is similar to that described for adults and may involve glucocorticoids, immunosuppressive drugs, biologic agents and surgery. However, exclusive enteral nutrition can also be used to induce disease remission in Crohn disease, as well as aiding with growth and nutritional status. Monitoring of height, weight and sexual development is crucial. Children with IBD should be managed by specialised paediatric gastroenterologists and transitioned to adult care in dedicated clinics (Box 22.71).

Pregnancy

Pregnant women with IBD are best managed with a multidisciplinary team approach involving an IBD physician and an obstetrician. A woman's ability to become pregnant is adversely affected by active IBD. Pre-conceptual counselling should focus on optimising disease control. During pregnancy, roughly one-third of women improve, one-third get worse and one-third remain stable with active disease. In the post-partum period, these changes sometimes reverse spontaneously; for example, women who improve during pregnancy may relapse post-partum. Drug therapy, including aminosalicylates, glucocorticoids, thiopurines and biologics can be safely continued throughout pregnancy, but methotrexate, Janus kinase inhibitors and S1PR modulators must be avoided (Box 22.72). Biologics such as infliximab, adalimumab, vedolizumab and ustekinumab cross the placenta, especially in the last trimester and infants of these women should avoid live vaccines for 6–12 months. Some women who are in deep remission may therefore choose to omit their biologics in the last trimester. Biologics can be safely continued throughout the pregnancy, especially in women with ongoing active disease, at high risk of relapse or when treatment options are limited. Breastfeeding is recommended in all women and the use of thiopurines and biologics does not preclude women from breastfeeding. Thiopurine drug levels in breastmilk are very low, with negligible levels measured in breast-fed infants of mothers on thiopurines. Levels of biologics are also very low in breastmilk and lead to negligible levels in the breastfed infant due to normal gut digestion. The mode of delivery should be discussed with pregnant women. A vaginal delivery is safe in most patients provided there is no evidence of active rectal or perianal fistulating disease, where a caesarean section is recommended.

Metabolic bone disease

Patients with IBD are prone to developing osteoporosis due to the effects of chronic inflammation, glucocorticoids, weight loss, malnutrition and

22.71 Inflammatory bowel disease in adolescence

- **Delayed growth and pubertal development**: chronic active inflammation, malabsorption, malnutrition and long-term glucocorticoids contribute to short stature and delayed development, with physical and psychological consequences.
- **Metabolic bone disease**: more common with chronic disease beginning in childhood, resulting from chronic inflammation, dietary deficiency and malabsorption of calcium and vitamin D.
- **Drug side-effects and adherence issues**: young people are more likely to require azathioprine or biologic therapy than adults. Poor adherence to therapy is more common than with adults, as younger patients may feel well, lack self-motivation to adhere and believe that drugs are ineffective or cause side-effects.
- **Loss of time from education**: physical illness, surgery, fatigue in chronic inflammatory bowel disease, privacy and dignity issues, and social isolation may all contribute.
- **Emotional difficulties**: may result from challenges in coping with illness, problems with forming interpersonal relationships, and issues relating to body image or sexual function.

22.72 Pregnancy and inflammatory bowel disease

Pre-conception

- Outcomes are best when pregnancy is carefully planned and disease is in remission
- Methotrexate should be stopped 3 months prior to conception
- Janus kinase inhibitors and S1PR modulators should be stopped 2 weeks prior to conception
- Aminosalicylates, azathioprine and glucocorticoids can be continued
- Certolizumab can be continued throughout pregnancy
- TNF inhibitors, vedolizumab, ustekinumab, risankizumab and mirikizumab are probably safe and can be continued if necessary provided the benefits outweigh any potential risk to both the mother and fetus. However, if continued into the third trimester, the neonate should avoid live vaccines for 6–12 months
- Folic acid (5 mg/day) is recommended pre-conception and high-dose supplements may be required in small bowel Crohn disease

During pregnancy

- Two-thirds of patients in remission will remain so in pregnancy
- Active disease is likely to remain active and severe disease carries an increased risk of premature delivery and low birth weight
- Perform endoscopy if required for clinical decision-making (ideally in second trimester)
- X-rays can be performed if clinically indicated. Ultrasound safe but is operator-dependent. MRI small bowel can be performed without intravenous gadolinium and oral contrast

Labour

- Mode of delivery needs careful discussion between patient, gastroenterologist and obstetrician
- Normal labour and vaginal delivery are possible for most
- Caesarean section may be preferred for patients with perianal Crohn disease or an ileoanal pouch to reduce risks of pelvic floor damage, fistulation and late incontinence
- Venous thromboembolism prophylaxis is important and a risk assessment should be performed following delivery, daily in hospital and before discharge

Breastfeeding

- This is safe and does not exacerbate IBD
- Data on the risk to babies from drugs excreted in breastmilk are limited; most of these drugs are probably safe
- Patients should discuss breastfeeding and drug therapy with their doctor

(IBD = inflammatory bowel disease; S1PR = sphingosine-1-phosphate receptor) malabsorption. Osteomalacia can also occur in Crohn disease that is complicated by malabsorption but is less common than osteoporosis. The risk of osteoporosis increases with age and with the dose and duration of glucocorticoid therapy. Patients should have their fracture risk assessed prior to glucocorticoid therapy. Individuals who receive prolonged (>3 months) or repeated courses of oral glucocorticoid therapy should have bone density measured. If osteopenia or osteoporosis is detected, treatment should be offered as described in Chapter 25.

Microscopic colitis

Microscopic colitis, which comprises two related conditions called lymphocytic colitis and collagenous colitis, has no known cause. Both forms are commoner in women, with a mean age of presentation of around 60 years. The presentation is with chronic non-bloody watery diarrhoea. The colonoscopic appearances are normal, but histological examination of biopsies shows a range of abnormalities. It is therefore recommended that biopsies of the right and left colon plus the terminal ileum should be undertaken in all patients undergoing colonoscopy for diarrhoea. An increased number of intra-epithelial and lamina propria lymphocytes is noted in both forms of microscopic colitis, with a thickened subepithelial collagen band also noted in collagenous colitis. Microscopic colitis may be associated with autoimmune diseases such as coeliac disease, rheumatoid arthritis and thyroid disease, and some drug therapies, such as NSAIDs and PPIs. Bile acid diarrhoea has also been reported to be more prevalent in this group. Treatment with budesonide is usually effective for inducing remission. Up to 70% of individuals can relapse and require further treatment, but others can remain symptom free.

Functional bowel disorders

Functional gastrointestinal disorders are a common diagnosis in gastroenterology, accounting for around 40% of all referrals to secondary care. They are thought to be disorders of brain–gut interaction, with alterations in motility, visceral hypersensitivity, gut microbiota, immune and mucosal function, as well as alterations in central nervous system processing.

Functional dyspepsia

Functional dyspepsia can be diagnosed in patients presenting with dyspepsia where organic disease has been excluded. Patients are usually young (<40 years) and women are affected twice as commonly as men. There are subtypes of this condition, with individuals being classified as having post-prandial distress syndrome, epigastric pain syndrome or a mixture of both.

Pathophysiology

The cause is poorly understood, but probably covers a spectrum of mucosal, motility and psychological factors.

Clinical features

Symptoms such as bloating, early satiety, loss of appetite, nausea, vomiting or retching may suggest a diagnosis of post-prandial distress syndrome, whereas symptoms of epigastric pain or epigastric burning may suggest a diagnosis of epigastric pain syndrome. Symptoms seen in functional dyspepsia can significantly overlap with symptoms of an organic disease, and alarm features should be sought (see Box 22.15). While patients with functional dyspepsia can experience vomiting, persistent vomiting suggests an underlying organic disorder. Peptic ulcer disease must be considered, while in older people intra-abdominal malignancy is a prime concern. There are no diagnostic signs, although there may be tenderness on abdominal palpation. A drug history should be taken and the possibility of a depressive illness should be considered. Pregnancy should be ruled out in young women before radiological studies are undertaken. Alcohol misuse should be suspected when early-morning nausea and retching are prominent.

Investigations

The history will often suggest the diagnosis. All patients should be checked for *H. pylori* infection and patients with alarm features should undergo endoscopy to exclude mucosal disease. While an ultrasound scan may detect gallstones, these are rarely responsible for dyspeptic symptoms, unless the patient has features to suggest biliary pathology.

Management

If *H. pylori* infection is detected, eradication therapy should be offered. This removes a major risk factor for peptic ulcers and gastric cancer, at the cost of a small risk of side-effects and worsening symptoms of underlying gastro-oesophageal reflux disease. Idiosyncratic and restrictive diets are of little benefit but smaller portions and fat restriction may help.

Drug treatment should be targeted on the subtype of functional dyspepsia. Prokinetic drugs like metoclopramide, fundus-relaxing drugs like buspirone or centrally acting neuromodulators like mirtazapine can all be used in post-prandial distress syndrome. Proton pump inhibitors and tricyclic antidepressants like amitriptyline can be used in epigastric pain syndrome. Patients with major psychological disorders that result in persistent or recurrent symptoms may require behavioural or other formal psychotherapy (Ch. 29).

Functional causes of vomiting

Cyclical vomiting syndrome (CVS) is an increasingly recognised cause of functional vomiting. It is characterised by distinct phases. There tends to be a prodrome phase, where symptoms of nausea, pallor and sweating can occur. This is then followed by an intense vomiting phase, with other associated symptoms such as abdominal pain, which can last up to a week. After this, patients enter a recovery phase, with improvement and resolution of symptoms. There is then a period of time without symptoms. Triggers can include stress, fatigue and menstruation. The cause of CVS is unknown, although an association with migraine headaches is recognised. A subset of adults with CVS have symptoms triggered by chronic cannabis use, known as cannabinoid hyperemesis syndrome. Patients with CVS are managed with general lifestyle advice, with avoidance of triggers such as cannabis. Acute episodes can be managed with medications, such as anxiolytics and antiemetics. Prophylactic treatment includes the use of tricyclic antidepressants and antiepileptic medications like levetiracetam.

In all patients it is essential to exclude other common causes of vomiting (see Box 22.16). Patients who do not have characteristic symptoms seen in CVS, with nausea or vomiting occurring weekly, in the absence of organic disease may be diagnosed as having chronic nausea and vomiting syndrome (CNVS). These patients may respond to treatments including antiemetics such as ondansetron and tricyclic antidepressants such as amitriptyline.

Irritable bowel syndrome

Irritable bowel syndrome (IBS) has an estimated worldwide prevalence of around 11%. It is characterised by recurrent abdominal pain in association with abnormal defaecation in the absence of a structural abnormality of the gut. IBS accounts for frequent absenteeism from work and impaired quality of life. Young women are affected more often than men.

Pathophysiology

The cause of IBS is incompletely understood but biopsychosocial factors are thought to play an important role, along with luminal factors, such as diet and the gut microbiota, as discussed below.

Behavioural and psychosocial factors

Early learning difficulties or emotionally challenging interactions during childhood may contribute to IBS in later life. Most patients seen in general practice do not have psychological problems but about 50% of patients referred to hospital have a psychiatric illness, such as anxiety, depression, somatisation and neurosis. Panic attacks are also common. Acute psychological stress and overt psychiatric disease are known to alter visceral perception and gastrointestinal motility. There is an increased prevalence of abnormal illness behaviour, with frequent consultations for minor symptoms and reduced coping ability (Ch. 29). These factors contribute to but do not cause IBS.

Physiological factors

The pathophysiology of IBS is still not fully understood. IBS is thought to be a disorder of the brain–gut axis, with alterations in visceral hypersensitivity. There is some evidence that IBS may be a serotoninergic (5-HT) disorder, as evidenced by increased release of 5-HT in diarrhoea-predominant IBS (IBS-D) and reduced release of 5-HT with constipation-predominant IBS (IBS-C). Accordingly, 5-HT$_3$ receptor antagonists are effective in IBS-D, while 5-HT$_4$ agonists improve bowel function in IBS-C. There is some evidence that IBS may represent a state of low-grade gut inflammation or immune activation, not detectable by tests, with raised numbers of mucosal mast cells that sensitise enteric neurons by releasing histamine and tryptase. Some patients respond positively to mast cell stabilisers, such as ketotifen, which supports a pathogenic role of mast cells in at least some patients. Immune activation may be associated with altered CNS processing of visceral pain signals. This is more common in women and in IBS-D, and may be triggered by a prior episode of gastroenteritis with *Salmonella* or *Campylobacter* species.

Luminal factors

Both quantitative and qualitative alterations in intestinal bacterial microbiota have been reported. Small intestinal bacterial overgrowth (SIBO) may be present in some patients and lead to symptoms. This 'gut dysbiosis' may explain the response to probiotics or the non-absorbable antibiotic rifaximin.

Dietary factors are also important. Some patients have chemical food intolerances (not allergy) to poorly absorbed, short-chain carbohydrates (lactose, fructose and sorbitol, among others), collectively known as FODMAPs (fermentable oligo-, di- and monosaccharides, and polyols). Whilst fermentation of these substances in the colon is normal, this can lead to to bloating, pain, wind and altered bowel habit in patients with IBS, thought to be due to visceral hypersensitivity. Gluten exposure seems to cause symptoms in some IBS patients and there is an overlap with the diagnosis of non-coeliac gluten sensitivity (negative coeliac serology and normal duodenal biopsies).

Clinical features

The key symptoms of IBS include recurrent abdominal pain and altered bowel habit (Box 22.73). Abdominal pain is usually colicky or cramping in nature, felt in the lower abdomen and related to defaecation. The bowel habit is variable, with IBS stratified by predominant bowel habit: those with mainly constipation (IBS-C), mainly diarrhoea (IBS-D), mixed bowel habit (IBS-M) or unsubtyped (IBS-U). Those with constipation tend to pass infrequent pellety stools, usually in association with abdominal pain or proctalgia. Those with diarrhoea have frequent defaecation but produce low-volume stools and rarely have nocturnal symptoms. Passage of mucus is common but rectal bleeding does not occur. Patients do not lose weight and are constitutionally well. The diagnosis is made through a careful history, exploring diet, medical, surgical and psychological history. The presence of other functional gastrointestinal disorders may also support the diagnosis, in addition to non-gastrointestinal symptoms such as migraine headaches, dyspareunia and interstitial cystitis. Onset after gastroenteritis may point towards a diagnosis of post-infectious IBS. Physical examination is generally unremarkable, with the exception of variable tenderness to palpation.

Investigations

The diagnosis is clinical in nature and can be made confidently in most patients using the Rome IV criteria, combined with the absence of alarm symptoms (Box 22.74) and without resorting to complicated tests.

22.73 Rome IV criteria for diagnosis of irritable bowel syndrome

Recurrent abdominal pain at least 1 day per week on average in the last 3 months (onset at least 6 months before diagnosis), associated with *two or more* of the following:

- Related to defaecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool

22.74 Alarm features in suspected irritable bowel syndrome

- Age > 50 years
- Unintentional weight loss
- Nocturnal symptoms
- Recent change in bowel habit
- Palpable abdominal mass or lymphadenopathy
- Family history of colon cancer or inflammatory bowel disease
- Anaemia
- Evidence of overt gastrointestinal bleeding (melaena or fresh blood in the stools)

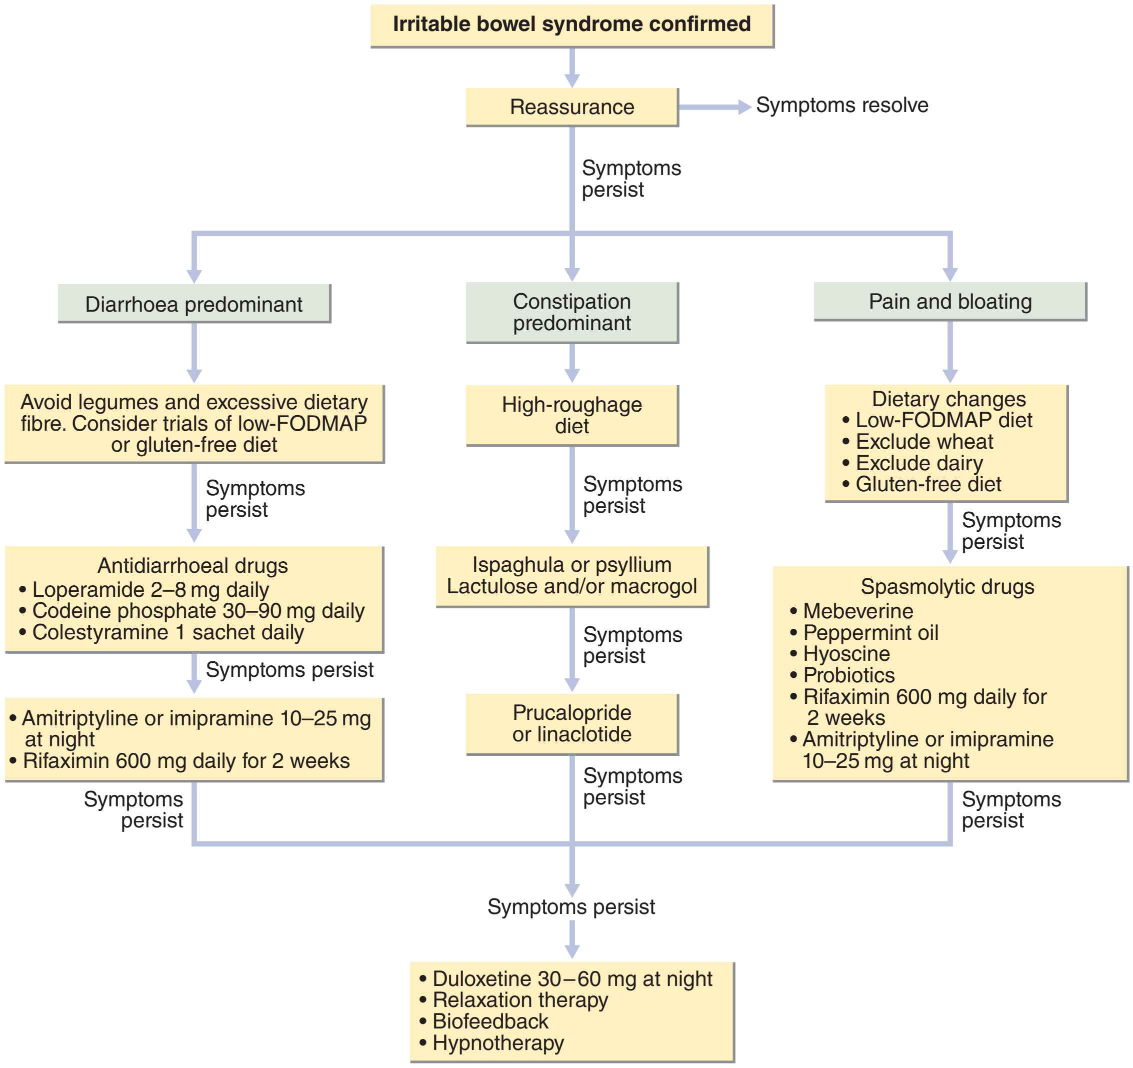
Limited laboratory tests are normally performed prior to making a diagnosis of IBS, including full blood count, faecal calprotectin and C-reactive protein, which are all normal. Colonoscopy should be undertaken when patients present with alarm features, to exclude other diagnoses such as colorectal cancer and inflammatory bowel disease. Those who present atypically require investigations to exclude other gastrointestinal diseases. Diarrhoea-predominant patients justify investigations to exclude coeliac disease, microscopic colitis, lactose intolerance, bile acid diarrhoea (see earlier in this chapter), thyrotoxicosis (Ch. 20) and, in relevant countries, parasitic infection.

Management

The most important steps are to make a positive diagnosis, as well as educating and reassuring the patient. Communicating diagnostic certainty is crucial, to prevent further unwarranted testing. Many people are concerned that they have developed cancer. A cycle of anxiety leading to colonic symptoms, which further heighten anxiety, can be broken by explaining that symptoms are not due to a serious underlying disease, but instead are the result of behavioural, psychosocial, physiological and luminal factors. In individuals who fail to respond to reassurance, treatment is traditionally tailored to the predominant symptoms (Fig. 22.65).

A large proportion of people with IBS report symptoms triggered by food, with diet being shown to be an effective management option for many patients (Box 22.75). Dietary advice should be implemented under the expert guidance of a dietitian, to prevent potential nutritional deficiencies of restrictive diets. General dietary advice is the first-line option recommended in the UK, with advice on regular meals, adjustment of fibre intake, adequate fluid intake, assessment of alcohol and caffeine intake, decreasing fat intake and assessing components of spicy meals which may be contributing to symptoms. If these measures fail, a low FODMAP diet may help some patients, as may a trial of a gluten-free diet. Up to 30% may benefit from a wheat-free diet, some may respond to lactose exclusion and excess intake of artificial sweeteners, such as sorbitol, should be addressed. Probiotics, in capsule form, may be effective if taken for several months, although the optimum combination of bacterial strains and dose have yet to be clarified.

Patients with intractable symptoms sometimes benefit from several months of therapy with a tricyclic antidepressant, such as amitriptyline or imipramine. Side-effects include dry mouth and drowsiness, but these are usually mild and the drug is generally well tolerated, although patients with features of somatisation tolerate the drug poorly and lower doses should be used. It may act by reducing visceral sensation and by altering gastrointestinal motility. Anxiety and affective disorders may also require specific treatment (Ch. 29). The 5-HT$_4$ agonist prucalopride, the guanylate cyclase-C receptor agonist linaclotide and chloride channel activators such as lubiprostone can be effective in IBS-C.



Irritable bowel syndrome confirmed
Reassurance
Symptoms resolve

Fig. 22.65 **Management of irritable bowel syndrome.** (FODMAP = fermentable oligo-, di- and monosaccharides, and polyols)

i 22.75 Dietary management of irritable bowel syndrome

- Eat regularly and avoid missing meals
- Take time to eat
- Ensure adequate hydration and avoid carbonated and caffeinated drinks
- Reduce alcohol intake
- Reduce intake of 'resistant' starch and insoluble fibre
- Avoid foods with artificial sweeteners
- Consider a low FODMAP diet
- Consider a gluten-free diet
- Consider a lactose exclusion diet

(FODMAPs = fermentable oligo-, di- and monosaccharides, and polyols)

Systemic and non-absorbable antibiotics, such as rifaximin, that act strictly on the gut lumen are sometimes used to manage symptoms, although the mechanism of action remains uncertain.

Psychological interventions, such as cognitive behavioural therapy, relaxation and gut-directed hypnotherapy, should be reserved for the most difficult cases. Cognitive behavioural therapy is the most widely studied psychotherapy treatment for IBS and may improve bowel symptoms, quality of life and psychological distress. A range of complementary and alternative therapies exist; most lack a good evidence base but are popular and help some patients (Box 22.76).

i 22.76 Complementary and alternative therapies for irritable bowel syndrome

Manipulative and body-based

- Massage, chiropractic, yoga*

Mind–body interventions

- Meditation, hypnosis*, cognitive behavioural therapy

Biologically based

- Herbal products*, dietary additives, probiotics*

Alternative medical systems

- Ayurveda, homeopathy, traditional Chinese medicine

*Some evidence for benefit exists for these interventions from randomised controlled trials.

Most patients have a relapsing and remitting course. Exacerbations often follow stressful life events, occupational dissatisfaction and difficulties with interpersonal relationships.

Ischaemic gut injury

Ischaemic gut injury is usually the result of arterial occlusion. Severe hypotension and venous insufficiency are less frequent causes. The presentation is variable, depending on the different vessels involved and the acuteness of the event. Diagnosis is often difficult.

Acute small bowel ischaemia

An embolus from the heart or aorta to the superior mesenteric artery is responsible for 40%–50% of cases, thrombosis of underlying atheromatous disease for approximately 25% and non-occlusive ischaemia due to hypotension complicating myocardial infarction, heart failure, arrhythmias or sudden blood loss for approximately 25%. Vasculitis and venous occlusion are rare causes. The clinical spectrum ranges from transient alteration of bowel function to transmural haemorrhagic necrosis and gangrene. Patients usually have evidence of cardiac disease and arrhythmia. Almost all develop abdominal pain that is more impressive than the physical findings. In the early stages, the only physical signs may be a silent, distended abdomen or diminished bowel sounds, with peritonitis developing only later.

Leucocytosis, lactic acidosis, hyperphosphataemia and hyperamylasaemia are typical. Plain abdominal X-rays show 'thumb-printing' due to mucosal oedema. CT with contrast has replaced percutaneous angiography as the gold standard for diagnosis and may demonstrate features such as occlusion of the mesenteric vessels and bowel wall thickening. Laparoscopy may also be used for diagnosis. Resuscitation, management of cardiac disease and intravenous broad-spectrum antibiotic therapy, followed by laparotomy, are key steps. If treatment is instituted early, embolectomy and vascular reconstruction may salvage some small bowel. In these rare cases, a 'second look' laparotomy should be undertaken 24 hours later and further necrotic bowel resected. While laparotomy is the established approach, endovascular techniques may be considered, such as thrombolysis or percutaneous transluminal angioplasty. The results of therapy depend on early intervention; patients treated late have a 75% mortality rate. Survivors often have nutritional failure from short bowel syndrome (Ch. 5) and require intensive nutritional support, including home parenteral nutrition and anticoagulation. Small bowel transplantation can be considered in selected patients. Patients with mesenteric venous thrombosis also require surgery if there are signs of peritonitis but are otherwise treated with anticoagulation. Investigations for underlying prothrombotic disorders should be performed (Ch 24).

Acute colonic ischaemia

The splenic flexure and descending colon have little collateral circulation and lie in 'watershed' areas of arterial supply. The spectrum of injury ranges from reversible colopathy to transient colitis, colonic stricture, gangrene and fulminant pancolitis. Arterial thromboembolism is usually responsible, but colonic ischaemia can also follow severe hypotension, colonic volvulus, strangulated hernia, systemic vasculitis or hypercoagulable states. Ischaemia of the descending and sigmoid colon is also a complication of abdominal aortic aneurysm surgery (where the inferior mesenteric artery is ligated). The patient is usually an older adult who presents with sudden onset of cramping, left-sided, lower abdominal pain and rectal bleeding. Symptoms usually resolve spontaneously over 24–48 hours and healing occurs in 2 weeks. Some may develop a fibrous stricture or segment of colitis. A minority develop gangrene and peritonitis. CT with contrast is the imaging of choice for diagnosis, with early colonoscopy within 48 hours of presentation recommended; otherwise, mucosal ulceration may have resolved. Resection is required for peritonitis; colonoscopy should not be performed in this circumstance.

Chronic mesenteric ischaemia

This results from atherosclerotic stenosis of the coeliac axis, superior mesenteric artery and inferior mesenteric artery. At least two of the three vessels must be affected for symptoms to develop. The typical presentation is with dull but severe mid- or upper abdominal pain developing about 30 minutes after eating. Weight loss is common because patients are reluctant to eat and some experience diarrhoea. Physical examination shows evidence of generalised arterial disease. An abdominal bruit is sometimes audible but is non-specific. The diagnosis is made by mesenteric angiography. Treatment is by vascular reconstruction or percutaneous angioplasty and stenting, if the patient's clinical condition permits. The condition is frequently complicated by intestinal infarction, if left untreated.

Diseases of the pancreas

Acute pancreatitis

Acute pancreatitis accounts for 3% of all cases of abdominal pain admitted to hospital. It affects 2–28 per 100 000 of the population and is increasing in incidence. It is a potentially serious condition with an overall mortality of 10%. About 80% of all cases are mild and have a favourable outcome. Approximately 98% of deaths from pancreatitis occur in the 20% of patients with severe disease and about one-third of these arise within the first week, usually from multi-organ failure. After this time, the majority of deaths result from sepsis, especially that complicating an infected necrotic pancreas. At admission, it is possible to predict patients at risk of these complications (Box 22.77). Individuals with features of severe pancreatitis (Box 22.78) and those with necrosis or other complications should be managed in a specialist centre with an intensive care unit and multidisciplinary hepatobiliary specialists.

Pathophysiology

Acute pancreatitis occurs as a consequence of premature intracellular trypsinogen activation, releasing proteases that digest the pancreas and surrounding tissue. Triggers for this are many, including alcohol,

22.77 Glasgow criteria for prognosis in acute pancreatitis

- Age > 55 years
- PO_2 < 8 kPa (60 mmHg)
- White blood cell count > 15×10^9/L
- Albumin < 32 g/L (3.2 g/dL)
- Serum calcium < 2 mmol/L (8 mg/dL) (corrected)
- Glucose > 10 mmol/L (180 mg/dL)
- Urea > 16 mmol/L (BUN > 45 mg/dL) (after rehydration)
- Alanine aminotransferase > 200 U/L
- Lactate dehydrogenase > 600 U/L

Note: Severity increases and prognosis worsens as the number of these factors increases. More than three implies severe disease.

22.78 Features that predict severe pancreatitis

Initial assessment

- Clinical impression of severity
- Body mass index > 30 kg/m^2
- Pleural effusion on chest X-ray
- APACHE II score > 8 (see Box 10.54)

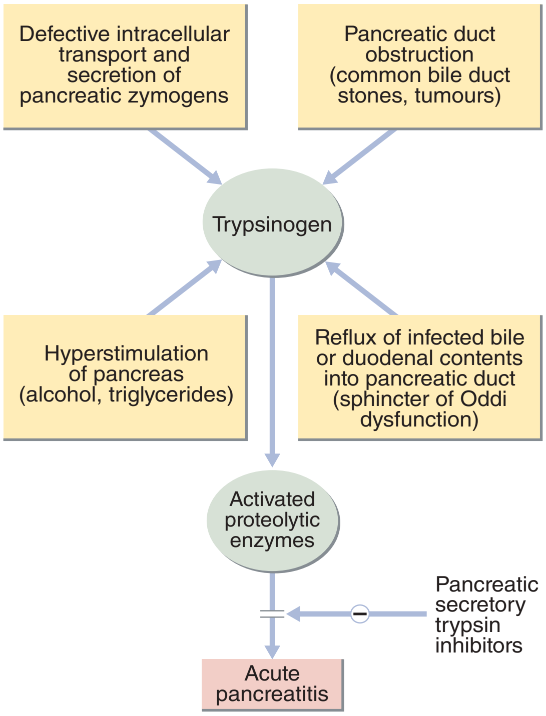
24 hours after admission

- Clinical impression of severity
- APACHE II score > 8
- Glasgow score > 3 (see Box 22.77)
- Persisting organ failure, especially if multiple
- CRP > 150 mg/L

48 hours after admission

- Clinical impression of severity
- Glasgow score > 3
- CRP > 150 mg/L
- Persisting organ failure for 48 hours
- Multiple or progressive organ failure

(CRP = C-reactive protein)



Defective intracellular transport and secretion of pancreatic zymogens
Pancreatic duct obstruction (common bile duct stones, tumours)
Trypsinogen
Hyperstimulation of pancreas (alcohol, triglycerides)
Reflux of infected bile or duodenal contents into pancreatic duct (sphincter of Oddi dysfunction)
Activated proteolytic enzymes
Pancreatic secretory trypsin inhibitors
−
Acute pancreatitis

Fig. 22.66 **Pathophysiology of acute pancreatitis.**

gallstones and pancreatic duct obstruction (Fig. 22.66). Of note, in around 30% of cases an aetiological factor cannot be identified (idiopathic pancreatitis). There is simultaneous activation of nuclear factor kappa B (NFκB), leading to mitochondrial dysfunction, autophagy and a vigorous inflammatory response. The normal pancreas has only a poorly developed capsule, and adjacent structures, including the common bile duct, duodenum, splenic vein and transverse colon, are commonly involved in the inflammatory process. The severity of acute pancreatitis is dependent on the balance between the activity of released proteolytic enzymes and antiproteolytic factors. The latter comprise an intracellular pancreatic trypsin inhibitor protein and circulating β_2-macroglobulin, α1-antitrypsin and C1-esterase inhibitors. The causes of acute pancreatitis are listed in Box 22.79. Acute pancreatitis is often self-limiting, but in some patients with severe disease, local complications, such as necrosis, pseudocyst or abscess, occur, as well as systemic complications that lead to multi-organ failure.

Clinical features

The typical presentation is with severe, constant upper abdominal pain, with increasing intensity over 15–60 minutes, which radiates to the back. Nausea and vomiting are common. There is marked epigastric tenderness, but in the early stages (and in contrast to a perforated peptic ulcer), guarding and rebound tenderness are absent because the inflammation is principally retroperitoneal. Bowel sounds become quiet or absent as paralytic ileus develops. In severe cases, the patient becomes hypoxic and develops hypovolaemic shock with oliguria. Discoloration of the flanks (Grey Turner sign) or the periumbilical region (Cullen sign) is a feature of severe pancreatitis with haemorrhage. The differential diagnosis includes a perforated viscus, acute cholecystitis and myocardial infarction. Various complications may occur and these are listed in Box 22.80.

22.79 Causes of acute pancreatitis

Common (90% of cases)

- Gallstones
- Alcohol
- Idiopathic causes
- Post-ERCP

Rare

- Post-surgical (abdominal, cardiopulmonary bypass)
- Trauma
- Drugs (azathioprine/mercaptopurine, thiazide diuretics, sodium valproate)
- Metabolic (hypercalcaemia, hypertriglyceridaemia)
- Pancreas divisum (p. 873)
- Sphincter of Oddi dysfunction
- Infection (mumps, Coxsackie virus)
- Hereditary factors
- Renal failure
- Organ transplantation (kidney, liver)
- Severe hypothermia
- Petrochemical exposure
- Scorpion sting

(ERCP = endoscopic retrograde cholangiopancreatography)

22.80 Complications of acute pancreatitis

Complication	Cause
Systemic	
Systemic inflammatory response syndrome (SIRS)	Increased vascular permeability from cytokine, platelet-aggregating factor and kinin release
Hypoxia	Acute respiratory distress syndrome (ARDS) due to microthrombi in pulmonary vessels
Hyperglycaemia	Disruption of islets of Langerhans with altered insulin/glucagon release
Hypocalcaemia	Sequestration of calcium in fat necrosis, fall in ionised calcium
Reduced serum albumin concentration	Increased capillary permeability
Pancreatic	
Necrosis	Non-viable pancreatic tissue and peripancreatic tissue death; frequently infected
Abscess	Circumscribed collection of pus close to the pancreas and containing little or no pancreatic necrotic tissue
Pseudocyst	Disruption of pancreatic ducts
Pancreatic ascites or pleural effusion	Disruption of pancreatic ducts
Gastrointestinal	
Upper gastrointestinal bleeding	Gastric or duodenal erosions
Variceal haemorrhage	Splenic or portal vein thrombosis
Erosion into colon	Erosion by pancreatic pseudocyst
Duodenal obstruction	Compression by pancreatic mass
Obstructive jaundice	Compression of common bile duct

A collection of fluid and debris may develop in the lesser sac, following inflammatory rupture of the pancreatic duct; this is known as a pancreatic fluid collection. It is initially contained within a poorly defined, fragile wall of granulation tissue, which matures over a 6-week period to form a fibrous capsule (Fig. 22.67). Such ‘pseudocysts’ are common and usually asymptomatic, resolving as the pancreatitis recovers. Pseudocysts greater than 6 cm in diameter seldom disappear spontaneously and can cause constant abdominal pain and compress or erode surrounding structures, including blood vessels, to form pseudoaneurysms. Large pseudocysts can be detected clinically as a palpable abdominal mass.

Pancreatic ascites occurs when fluid leaks from a disrupted pancreatic duct into the peritoneal cavity. Leakage into the thoracic cavity can result in a pleural effusion or a pleuro-pancreatic fistula.

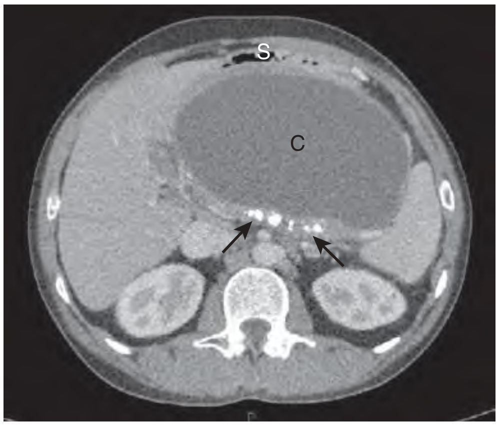


Fig. 22.67 Computed tomogram showing large pancreatic pseudocyst (C) compressing the stomach (S). The pancreas is atrophic and calcified (arrows).

Investigations

The diagnosis is based on finding a serum amylase or lipase concentrations and ultrasound or CT evidence of pancreatic swelling. Plain X-rays should be taken to exclude other diagnoses, such as perforation or obstruction and to identify pulmonary complications. Amylase is efficiently excreted by the kidneys and concentrations may have returned to normal if measured 24–48 hours after the onset of pancreatitis. A persistently elevated serum amylase concentration suggests pseudocyst formation. Peritoneal amylase concentrations are massively elevated in pancreatic ascites. Serum amylase concentrations are also elevated (but less so) in intestinal ischaemia, perforated peptic ulcer and ruptured ovarian cyst, while the salivary isoenzyme of amylase is elevated in parotitis. If available, serum lipase measurements are preferable to amylase, as they have greater diagnostic accuracy for acute pancreatitis.

Ultrasound scanning can confirm the diagnosis, although in the earlier stages the gland may not be grossly swollen. An ultrasound scan is also useful because it may show gallstones, biliary obstruction or pseudocyst formation.

Contrast-enhanced pancreatic CT performed at least 48 hours after admission can be useful in assessing viability of the pancreas if persisting organ failure, sepsis or clinical deterioration is present, since these features may indicate that pancreatic necrosis has occurred. However, this is not recommended earlier due to the possible underestimation of degree of pancreatic necrosis. Necrotising pancreatitis is associated with decreased pancreatic enhancement on CT, following intravenous injection of contrast material. The presence of gas within necrotic material (Fig. 22.68) suggests infection and impending abscess formation, in which case percutaneous aspiration of material for bacterial culture should be carried out and appropriate antibiotics prescribed. Involvement of the colon, blood vessels and other adjacent structures by the inflammatory process is best seen on CT.

Certain investigations stratify the severity of acute pancreatitis and have important prognostic value at the time of presentation (see Boxes 22.77 and 22.78). In addition, serial assessment of CRP is a useful indicator of progress. A peak CRP of > 210 mg/L in the first 4 days predicts severe acute pancreatitis with 80% accuracy. It is worth noting that the serum amylase concentration has no prognostic value.

Management

Management comprises several related steps:

- establishing the diagnosis and disease severity
- early resuscitation, according to whether the disease is mild or severe
- detection and treatment of complications
- treatment of the underlying cause.

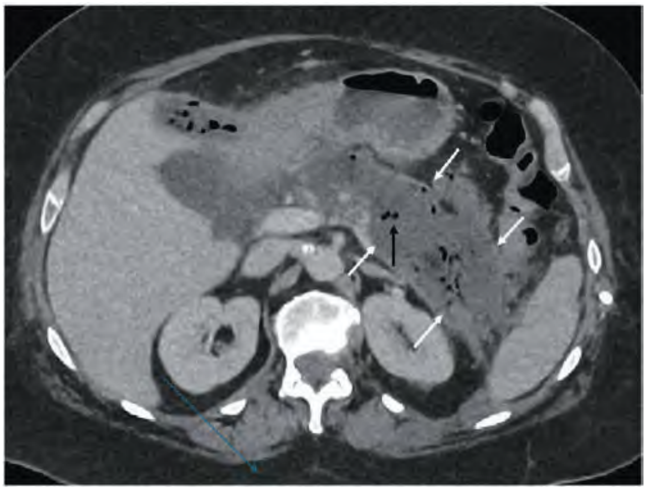

Fig. 22.68 Pancreatic necrosis. Contrast-enhanced CT demonstrating non-enhancing necrotic pancreatic tissue replacing the body and tail of the pancreas (white arrows). Focal areas of gas (black arrow) are present within the necrosis indicating possible associated infection.

Opiate analgesics should be given to treat pain and hypovolaemia should be corrected using Ringer's lactate solution or Hartmann's solution. All severe cases should be managed in a high-dependency or intensive care unit. A urinary catheter should be inserted in patients with shock, with a central venous line inserted if required. Oxygen should be given to hypoxic patients, and those who develop systemic inflammatory response syndrome (SIRS) may require ventilatory support. Hyperglycaemia should be corrected using insulin and hypocalcaemia by intravenous calcium injection.

Nasogastric aspiration is required only if paralytic ileus is present. Enteral feeding should be commenced as soon as abdominal pain has settled in mild pancreatitis. Enteral feeding should be considered in severe pancreatitis but only after the patient has been kept nil by mouth for about 48 hours and fully resuscitated. This is important as individuals are usually in a severely catabolic state and require nutritional support. Enteral feeding decreases endotoxaemia and so may reduce systemic complications. Nasogastric feeding is just as effective as feeding by the nasojejunal route. Prophylaxis of thromboembolism with subcutaneous low-molecular-weight heparin is also advisable. The use of prophylactic, broad-spectrum intravenous antibiotics to prevent infection of pancreatic necrosis is not indicated, but an infected necrotic pancreas should be treated with antibiotics that penetrate necrotic tissue, such as carbapenems or quinolones, and metronidazole.

Patients who present with cholangitis in association with severe acute pancreatitis should undergo urgent ERCP to diagnose and treat choledocholithiasis. In less severe cases of gallstone pancreatitis, biliary imaging (using MRCP or EUS) can be carried out after the acute phase has resolved. If the liver function tests return to normal and ultrasound has not demonstrated a dilated biliary tree, laparoscopic cholecystectomy with an on-table cholangiogram is appropriate because any common bile duct stones have probably passed. When the operative cholangiogram detects residual common bile duct stones, these should be removed by laparoscopic exploration of the duct or by post-operative ERCP. Cholecystectomy should be undertaken within 2 weeks of resolution of pancreatitis – and preferably during the same admission – to prevent further potentially fatal attacks of pancreatitis. Patients with infected pancreatic necrosis or pancreatic abscess may require endoscopic drainage or minimally invasive retroperitoneal pancreatic (MIRP) necrosectomy to debride all cavities of necrotic material. Pancreatic pseudocysts may resolve spontaneously. Drainage into the stomach or duodenum may be required in the case of complications such as infection or if symptomatic with pain. This is usually performed after an interval of at least 6 weeks, once a pseudocapsule has matured, by surgical or endoscopic cystogastrostomy.

Chronic pancreatitis

Chronic pancreatitis is a chronic inflammatory disease characterised by fibrosis and destruction of exocrine pancreatic tissue. Diabetes mellitus occurs in advanced cases because the islets of Langerhans are involved (Ch. 21).

Pathophysiology

Around 80% of cases in Western countries result from alcohol misuse, with idiopathic chronic pancreatitis being the second most common cause. In southern India, severe chronic fibrocalcific pancreatitis occurs in non-alcoholics, possibly as a result of malnutrition, deficiency of trace elements and micronutrients, and cassava consumption. Other causes are listed in Box 22.81. The pathophysiology of chronic pancreatitis is shown in Figure 22.69.

22.81 Causes of chronic pancreatitis*

Toxic–metabolic

- Alcohol
- Tobacco
- Hypercalcaemia
- Chronic kidney disease

Idiopathic

- Tropical
- Early-/late-onset types

Genetic

- Hereditary pancreatitis (cationic trypsinogen pathogenic variant)
- *SPINK-1* pathogenic variant
- Cystic fibrosis

Autoimmune

- In isolation or as part of multi-organ problem

Recurrent and severe acute pancreatitis

- Recurrent acute pancreatitis
- Post-necrotic

Obstructive

- Ductal adenocarcinoma
- Intraductal papillary mucinous neoplasia
- Pancreas divisum
- Sphincter of Oddi stenosis

*These can be memorised by the mnemonic 'TIGARO'. Gallstones do not cause chronic pancreatitis but may be observed as an incidental finding.

Clinical features

Chronic pancreatitis predominantly affects middle-aged men with alcohol dependence. More than 80% present with abdominal pain. In 50%, this occurs as episodes of 'acute pancreatitis', although each attack results in a degree of permanent pancreatic damage. Relentless, slowly progressive chronic pain without acute exacerbations affects 35% of patients, while the remainder have no pain but present with diarrhoea. Pain is due to a combination of increased pressure within the pancreatic ducts and direct involvement of peripancreatic nerves by the inflammatory process. Pain may be relieved by leaning forwards or by drinking alcohol. Approximately one-fifth of patients chronically consume opiate analgesics. Weight loss is common and results from a combination of anorexia, avoidance of food because of post-prandial pain, malabsorption and/or diabetes. Steatorrhoea occurs when more than 90% of the exocrine tissue has been destroyed; protein malabsorption develops only in the most advanced cases. Overall, 30% of patients have (secondary) diabetes, but this figure rises to 70% in those with chronic fibrocalcific pancreatitis. Physical examination reveals a thin, malnourished patient with epigastric tenderness. Skin pigmentation over the abdomen and back is common and results from chronic use of a hot water bottle (erythema ab igne). Many patients have features of other alcohol- and smoking-related diseases. Complications are listed in Box 22.82.

22.82 Complications of chronic pancreatitis

- Pseudocysts and pancreatic ascites, which occur in both acute and chronic pancreatitis
- Obstructive jaundice due to benign stricture of the common bile duct as it passes through the diseased pancreas
- Duodenal stenosis
- Portal or splenic vein thrombosis leading to segmental portal hypertension and gastric varices
- Peptic ulcer
- Secondary diabetes mellitus
- Pancreatic cancer
- Pancreatic exocrine insufficiency
- Osteopenia or osteoporosis

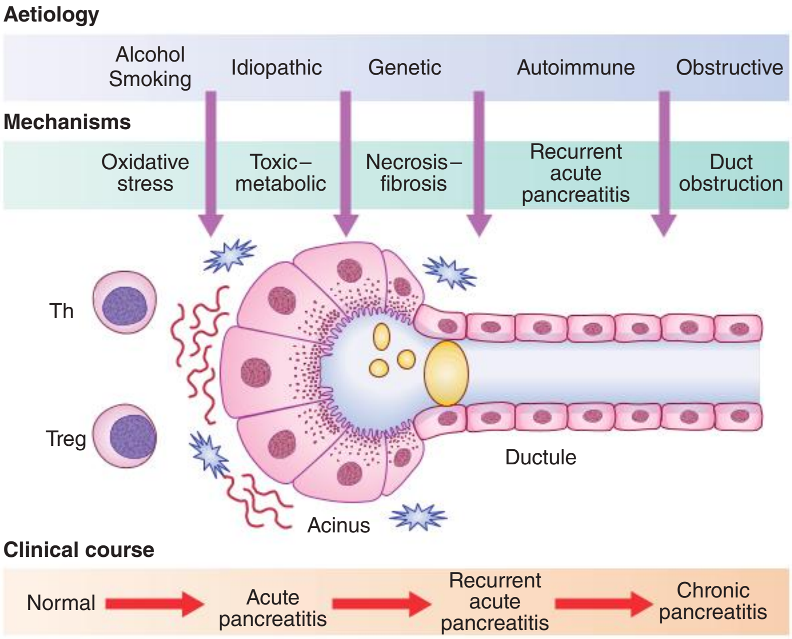

Fig. 22.69 Pathophysiology of chronic pancreatitis. Alcohol and other risk factors may trigger acute pancreatitis through multiple mechanisms. The first (or 'sentinel') episode of acute pancreatitis initiates an inflammatory response involving T-helper (Th) cells. Ongoing exposure to alcohol drives further inflammation, but this is modified by regulatory T cells (Treg) with subsequent fibrosis, via activation of pancreatic stellate cells. A cycle of inflammation and fibrosis ensues, with development of chronic pancreatitis. Alcohol is the most relevant risk factor, as it is involved at multiple steps.

i 22.83 Investigations in chronic pancreatitis

Tests to establish the diagnosis

- Ultrasound
- Computed tomography (may show atrophy, calcification or ductal dilatation)
- Abdominal X-ray (may show calcification)
- Magnetic resonance cholangiopancreatography
- Endoscopic ultrasound

Tests to define pancreatic function

- Collection of pure pancreatic juice after secretin injection (gold standard but invasive and seldom used)
- Faecal pancreatic elastase (see Box 22.12)

Tests to demonstrate anatomy prior to surgery

- Magnetic resonance cholangiopancreatography

Investigations

Investigations (Box 22.83) and imaging (Fig. 22.70) should be carried out to:

- make a diagnosis of chronic pancreatitis
- define pancreatic function
- demonstrate anatomical abnormalities prior to surgical intervention.

Management

Alcohol misuse

Alcohol avoidance is crucial in halting progression of the disease and reducing pain.

Pain relief

A range of analgesic drugs, particularly NSAIDs, are valuable but the severe and unremitting nature of the pain often leads to opiate use with the risk of addiction. Analgesics, such as pregabalin and tricyclic antidepressants at a low dose, may be effective. Oral pancreatic enzyme supplements suppress pancreatic secretion and their regular use reduces analgesic consumption in some patients. Patients who are abstinent from alcohol and who have severe chronic pain that is resistant to conservative measures should be considered for surgical or endoscopic pancreatic therapy (Box 22.84). Coeliac plexus neurolysis sometimes produces long-lasting pain relief, although relapse occurs in the majority of cases. In some patients, MRCP does not show a surgically or endoscopically correctable abnormality and, in these individuals, the only surgical approach is total pancreatectomy. Unfortunately, even after this operation, some continue to experience pain. Moreover, the procedure causes diabetes, which may be difficult to control, with a high risk of hypoglycaemia (since both insulin and glucagon are absent) and significant morbidity and mortality.

Malabsorption

This is treated by dietary fat restriction (with supplementary medium-chain triglyceride therapy in malnourished patients) and oral pancreatic enzyme supplements. A PPI is added to optimise duodenal pH for pancreatic enzyme activity.

Management of complications

Surgical or endoscopic therapy may be necessary for the management of pseudocysts, pancreatic ascites, common bile duct or duodenal stricture and the consequences of portal hypertension. Many patients with chronic pancreatitis also require treatment for other alcohol- and smoking-related diseases and for the consequences of self-neglect and malnutrition.

Autoimmune pancreatitis

Autoimmune pancreatitis (AIP) is a chronic fibroinflammatory disease of the pancreas that can mimic cancer, but which responds to glucocorticoids. There are two different subtypes, type 1 and type 2 AIP. Type 1 AIP belongs to IgG4-related disorders, which can include various organs such as bile ducts, salivary glands, kidneys, lungs and thyroid glands. Type 2 AIP affects the pancreas only, but is strongly associated with inflammatory bowel disease, particularly ulcerative colitis. AIP can present with obstructive jaundice, weight loss and abdominal pain. Blood tests may reveal increased serum IgG4 in type 1 AIP, but there are no reliable serological markers for type 2 AIP. Imaging in type 1 AIP may show a diffusely enlarged pancreas, narrowing of the pancreatic duct and stricturing of the lower bile duct. Focal mass-like pancreatic lesions may be seen in type 2 AIP. The symptom response to glucocorticoids is usually good in AIP, but recurrence can occur after initial response, particularly in type 1 AIP, and some patients may require immunosuppressives such as azathioprine or rituximab.

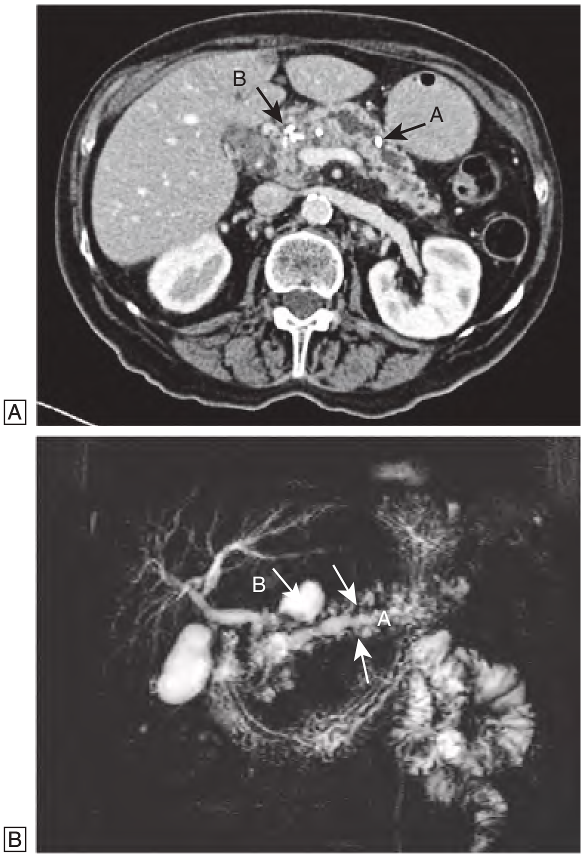

Fig. 22.70 Imaging in chronic pancreatitis. **A** Computed tomogram showing a grossly dilated and irregular duct with a calcified stone (arrow A). Note the calcification in the head of the gland (arrow B). **B** Magnetic resonance cholangiopancreatogram of the same patient showing marked ductal dilatation with abnormal dilated side branches (arrows A). A small cyst is also present (arrow B).

i 22.84 Interventions in chronic pancreatitis

Endoscopic therapy

- Dilatation or stenting of pancreatic duct strictures
- Removal of calculi (mechanical or shock-wave lithotripsy)
- Drainage of pseudocysts

Surgical methods

- Partial pancreatic resection, preserving the duodenum
- Pancreatico-jejunostomy

Descargado para Dr R
Para uso persona

Congenital abnormalities affecting the pancreas

Pancreas divisum

This is due to failure of the primitive dorsal and ventral ducts to fuse during embryonic development of the pancreas. As a consequence, most of the pancreatic drainage occurs through the smaller accessory ampulla rather than through the major ampulla. The condition occurs in 7%–10% of the normal population and is usually asymptomatic, but some patients develop acute pancreatitis, chronic pancreatitis or atypical abdominal pain.

Annular pancreas

In this congenital anomaly, the pancreas encircles the second/third part of the duodenum, leading to gastric outlet obstruction. Annular pancreas is associated with malrotation of the intestine, atresias and cardiac anomalies.

Cystic fibrosis

This disease is considered in more detail in Chapter 17. The major gastrointestinal manifestations are pancreatic insufficiency and meconium ileus. Peptic ulcer and hepatobiliary disease may also occur. In cystic fibrosis, pancreatic secretions are protein- and mucus-rich. The resultant viscous juice forms plugs that obstruct the pancreatic ductules, leading to progressive destruction of acinar cells. Steatorrhoea is universal and the large-volume bulky stools predispose to rectal prolapse. Malnutrition is compounded by the metabolic demands of respiratory failure and by diabetes, which develops in 40% of patients by adolescence.

Nutritional counselling and supervision are important to ensure intake of high-energy foods, providing 120%–150% of the recommended intake for normal subjects. Fats are an important calorie source and, despite the presence of steatorrhoea, fat intake should not be restricted. Supplementary fat-soluble vitamins are also necessary. High-dose oral pancreatic enzymes are required, in doses sufficient to control steatorrhoea and stool frequency. A PPI aids fat digestion by producing an optimal duodenal pH.

Meconium ileus

Mucus-rich plugs within intestinal contents can obstruct the small or large intestine of a newborn child. Meconium ileus is treated by the mucolytic agent *N*-acetylcysteine, given orally, by Gastrografin enema or by gut lavage using polyethylene glycol. In resistant cases of meconium ileus, surgical resection may be necessary.

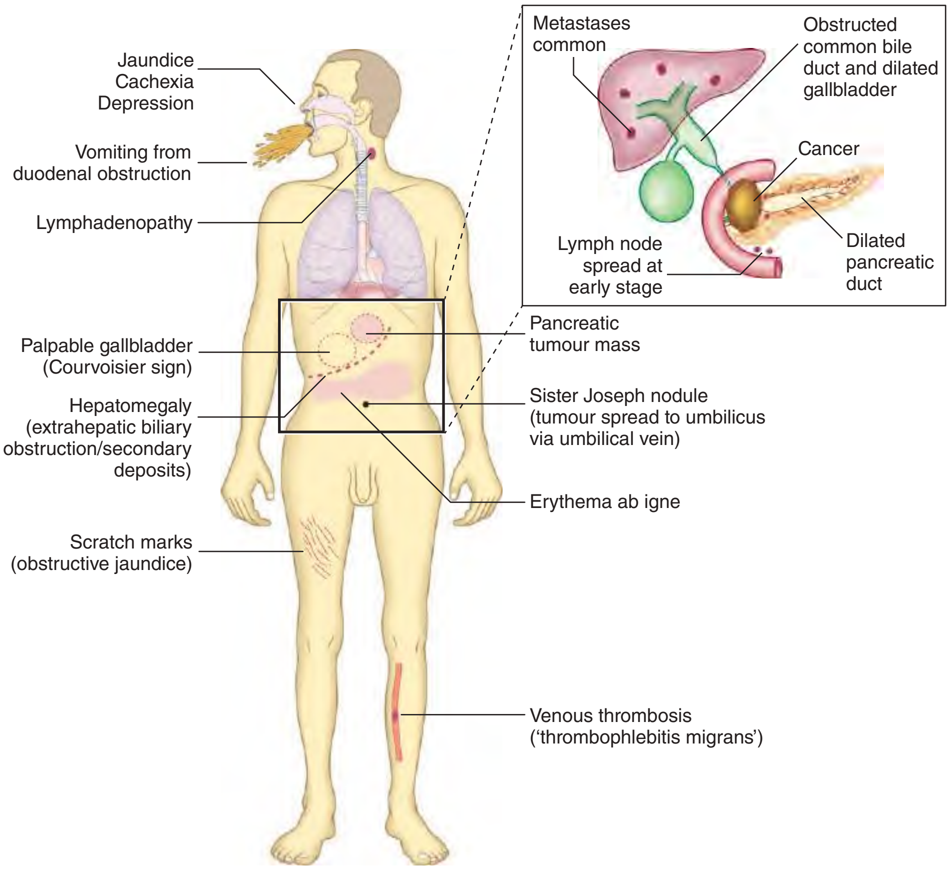
Tumours of the pancreas

Adenocarcinoma of the pancreas

Some 90% of pancreatic neoplasms are adenocarcinomas that arise from the pancreatic ducts. These tumours involve local structures and metastasise to regional lymph nodes at an early stage. Most patients have advanced disease at the time of presentation. Neuroendocrine tumours also arise in the pancreas, but tend to grow more slowly and have a better prognosis; these are discussed in Chapter 20. The incidence of pancreatic adenocarcinoma is higher in high-income countries, affecting 10–15 per 100 000 in Western populations, rising to 100 per 100 000 in those over the age of 70. Men are affected more often than women. The disease is associated with increasing age, smoking, diabetes and chronic pancreatitis. Between 5% and 10% of patients have a genetic predisposition: hereditary pancreatitis, HNPCC and familial atypical mole multiple melanoma syndrome (FAMMM). The overall survival is only 3%–5%, with a median survival of 6–10 months for those with locally advanced disease and 3–5 months if metastases are present.

Clinical features

Many patients are asymptomatic until an advanced stage, when they present with central abdominal pain, weight loss and obstructive jaundice (Fig. 22.71). The pain results from invasion of the coeliac plexus



Jaundice
Cachexia
Depression
Vomiting from duodenal obstruction
Lymphadenopathy
Palpable gallbladder (Courvoisier sign)
Hepatomegaly (extrahepatic biliary obstruction/secondary deposits)
Scratch marks (obstructive jaundice)
Metastases common
Obstructed common bile duct and dilated gallbladder
Cancer
Lymph node spread at early stage
Dilated pancreatic duct
Pancreatic tumour mass
Sister Joseph nodule (tumour spread to umbilicus via umbilical vein)
Erythema ab igne
Venous thrombosis ('thrombophlebitis migrans')

Fig. 22.71 Features of pancreatic cancer.

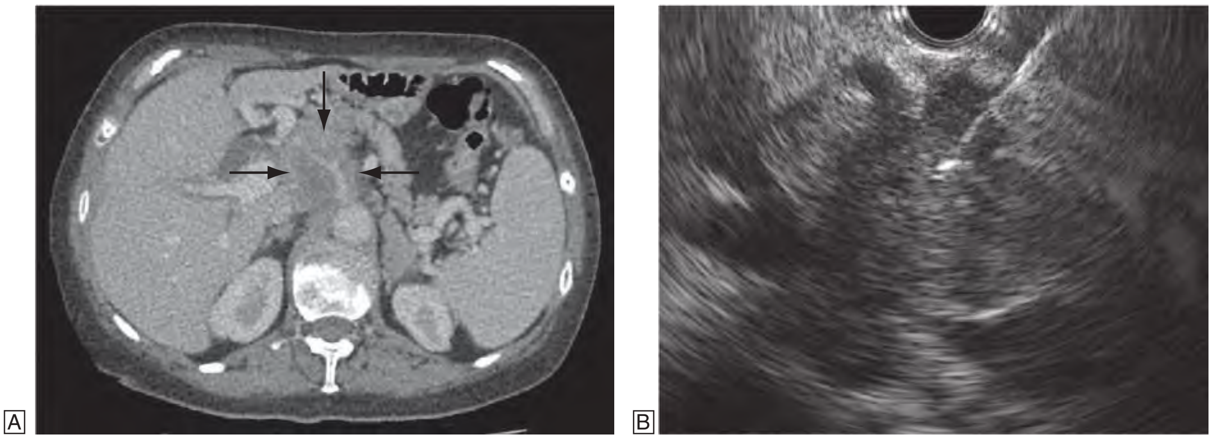


Fig. 22.72 Carcinoma of the pancreas. **A** A computed tomogram showing a large, necrotic mass encasing the coeliac axis (arrows). **B** Endoscopic ultrasound was subsequently performed to enhance staging and to obtain a fine needle aspiration biopsy, which confirmed pancreatic ductal adenocarcinoma.

and is characteristically incessant and gnawing. It often radiates from the upper abdomen through to the back and may be eased a little by bending forwards. Almost all patients lose weight and many are cachectic. Around 60%–70% of tumours arise from the head of the pancreas, and involvement of the common bile duct results in the development of obstructive jaundice, often with severe pruritus. Some patients present with diarrhoea, vomiting from duodenal obstruction, diabetes mellitus, recurrent venous thrombosis, acute pancreatitis or depression. Physical examination reveals clear evidence of weight loss. An abdominal mass due to the tumour, a palpable gallbladder or hepatic metastases is commonly found. A palpable gallbladder in a jaundiced patient is usually the consequence of distal biliary obstruction by a pancreatic cancer (Courvoisier sign).

Investigations

The diagnosis is usually made by ultrasound and contrast-enhanced CT (Fig. 22.72). Diagnosis in non-jaundiced patients is often delayed because presenting symptoms are relatively non-specific. Fit patients with small, localised tumours should undergo staging to define operability. EUS or laparoscopy with laparoscopic ultrasound will define tumour size, involvement of blood vessels and metastatic spread. In patients unsuitable for surgery because of advanced disease, frailty or comorbidity, EUS- or CT-guided cytology or biopsy can be used to confirm the diagnosis (see Fig. 22.72). MRCP and ERCP are sensitive methods of diagnosing pancreatic cancer and are valuable when the diagnosis is in doubt, although differentiation between cancer and localised chronic pancreatitis can be difficult. The main role of ERCP is to insert a stent into the common bile duct to relieve obstructive jaundice in inoperable patients. Serum cancer antigen 19-9 (CA 19-9) can be used to monitor response to treatment and as a marker of recurrent disease. It has a poor predictive value for diagnosis.

Curative management

Only 10%–15% of patients present with localised (usually stage I and II) disease where surgical resection is the only method of effecting cure. However, long-term outcomes remain poor, with the majority of patients relapsing within 3 years. Perioperative chemotherapy with 5-fluorouracil, leucovorin, irinotecan and oxaliplatin improves survival and should be offered to patients who are fit enough for it. In those individuals who did not have pre-operative chemotherapy, post-operative adjuvant chemotherapy with 5-fluorouracil, leucovorin, irinotecan and oxaliplatin should be offered. If there are contraindications to this regimen, capecitabine and gemcitabine are alternatives. Up to 30% 5-year survival can now be seen in patients with early, localised disease treated with combined oncological and surgical approaches and completing 6 months of perioperative or adjuvant chemotherapy. For patients with localised disease who are not suitable for surgery and are clinically stable, radiotherapy or chemoradiotherapy can be considered.

Most patients who have/have had pancreatic cancer will benefit from pancreatic enzyme replacement therapy, proton pump inhibitors and prokinetics. Glycaemic control should also be optimised.

Palliative management

Over 80% of exocrine pancreatic cancers present at an advanced, incurable stage and prognosis is usually limited to months. In these circumstances treatment is palliative. Chemotherapy with 5-fluorouracil, leucovorin, irinotecan and oxaliplatin has improved median survival to 11 months for fit patients, but for less fit patients less intensive chemotherapy (gemcitabine +/– nab-paclitaxel) or a best supportive care approach will be more appropriate. Palliative radiotherapy can be used for pain or bleeding.

Pain relief can be achieved using analgesics, but in some patients coeliac plexus neurolysis may be required. Jaundice can be relieved by choledochojejunostomy in fit patients, whereas percutaneous or endoscopic stenting is preferable in older patients and those with very advanced disease. Ampullary or periampullary adenocarcinomas are rare neoplasms that arise from the ampulla of Vater or adjacent duodenum. They are often polypoid and may ulcerate; they frequently infiltrate the duodenum, but behave less aggressively than pancreatic adenocarcinoma. Around 25% of patients undergoing resection of ampullary or periampullary tumours survive for 5 years, in contrast to patients with pancreatic ductal cancer.

Incidental pancreatic mass

Cystic neoplasms of the pancreas are increasingly being seen with widespread use of CT. These are a heterogeneous group; serous cystadenomas rarely, if ever, become malignant and do not require surgery. Mucinous cysts occur more often in women, are usually in the pancreatic tail and display a spectrum of behaviour from benign to frankly malignant. Aspiration of the cyst contents for cytology and measurement of CEA and amylase concentrations in fluid obtained at EUS can help determine whether a lesion is mucinous or not. In fit patients, all mucinous lesions should be resected. A variant, called intraductal papillary mucinous neoplasia (IPMN), is often discovered coincidentally on CT, frequently in older men. This may affect the main pancreatic duct with marked dilatation and plugs of mucus or may involve a side branch. The histology varies from villous adenomatous change to dysplasia or carcinoma. Since IPMN is a pre-malignant, but indolent, condition, the decision to resect or to monitor depends on age and fitness of the patient and location, size and evolution of lesions.

Diseases of the peritoneal cavity

Peritonitis

Surgical peritonitis occurs as the result of a ruptured viscus (for details see this book's companion text, *Principles and Practice of Surgery*). Peritonitis may also complicate ascites in chronic liver disease (spontaneous bacterial peritonitis) or may occur in children in the absence of ascites, due to infection with *Streptococcus pneumoniae* or β-haemolytic streptococci (p. 355).

Chlamydial peritonitis is a complication of pelvic inflammatory disease (p. 411). The patient presents with right upper quadrant pain, pyrexia and a hepatic rub (the Fitz-Hugh–Curtis syndrome). Tuberculosis may cause peritonitis and ascites (p. 556).

Tumours

The most common is secondary adenocarcinoma from the ovary or gastrointestinal tract. Mesothelioma is a rare tumour complicating asbestos exposure. It presents as a diffuse abdominal mass, due to omental infiltration, and with ascites. The prognosis is extremely poor. Pseudomyxoma peritonei is a rare tumour of the appendix that spreads into the peritoneal cavity and is often found incidentally. Diagnosis can be confirmed by abdominal CT or MRI, with cytoreductive surgery and hyperthermic intraperitoneal chemotherapy being used for curative treatment.

Other disorders

Endometriosis

Ectopic endometrial tissue can become embedded on the serosal aspect of the intestine, most frequently in the sigmoid and rectum. The overlying mucosa is usually intact. Cyclical engorgement and inflammation result in pain, bleeding, diarrhoea, constipation and adhesions or obstruction. Low backache is frequent. The onset is usually between 20 and 45 years and the condition is more common in nulliparous women. Bimanual examination may reveal tender nodules in the pouch of Douglas. Endoscopic studies reveal the diagnosis only if carried out during menstruation, when a bluish mass with intact overlying mucosa is apparent. In some patients, laparoscopy is required. Treatment options include laparoscopic diathermy and hormonal therapy with progestogens (e.g. norethisterone), gonadotrophin-releasing hormone analogues or danazol.

Pneumatosis cystoides intestinalis

In this rare condition, multiple gas-filled submucosal cysts line the colonic and small bowel walls. The cause is unknown but the condition may be seen in patients with chronic cardiac or pulmonary disease, pyloric obstruction, systemic sclerosis or dermatomyositis. Most patients are asymptomatic, although there may be abdominal cramps, diarrhoea, tenesmus, rectal bleeding and mucus discharge. The cysts are recognised on sigmoidoscopy, plain abdominal X-rays, CT or MRI. Therapies reported to be effective include prolonged high-flow oxygen, elemental diets and antibiotics.

HIV/AIDS and the gastrointestinal tract

Patients with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) may develop several symptoms referable to the gastrointestinal tract, as discussed in detail on page 327. HIV testing should be considered in all patients with atypical or unexplained gastrointestinal symptoms and in those resident in areas of high prevalence.

Multiple Choice Questions

22.1. A 27-year-old woman with coeliac disease presents with ongoing symptoms of chronic diarrhoea despite being on a gluten-free diet. Bloods tests for tTG are taken, which are elevated. Which would be the next appropriate test?
- A. Capsule endoscopy
- B. Colonoscopy
- C. Endoscopy with duodenal biopsies
- D. CT abdomen
- E. Lactose hydrogen breath test

Answer: C.

The most likely cause of symptoms in this patient is ongoing disease activity from coeliac disease. The gold standard of assessment of adherence in coeliac disease is an endoscopy with duodenal biopsies. Other causes of diarrhoea are also possible, and investigations such as a colonoscopy may be later considered, provided that there is no ongoing villous atrophy on biopsy.

22.2. A 72-year-old man presents with a 24-hour history of haematemesis. He receives resuscitation prior to a planned endoscopy. Which of the medications below should he continue to take if possible?
- A. Rivaroxaban
- B. Warfarin
- C. Clopidogrel
- D. Aspirin
- E. Prasugrel

Answer: D.

Low-dose aspirin (75 mg) can be continued during an upper gastrointestinal bleed. Caution should be taken with discontinuation, in view of an increased association of cardiovascular and cerebrovascular events noted within one week of discontinuation. Whilst bleeding risk may be increased during an upper gastrointestinal bleed with aspirin, all-cause mortality is reduced with continuation. Direct oral anticoagulants, P2Y12-receptor antagonists and warfarin should be discontinued in most cases, although balance and risks may need to be evaluated, such as the continuation of dual antiplatelets (aspirin and clopidogrel) being considered for patients with drug-eluting coronary artery stents.

22.3. A 28-year-old pregnant woman with known pan-ulcerative colitis presents to clinic. Her most recent colonoscopy prior to pregnancy showed severe active colonic disease both macroscopically and histologically. She is 30 weeks pregnant and currently is taking infliximab for management of her ulcerative colitis, opening her bowels 4 times per day. What is the most appropriate ongoing management?
- A. Commence methotrexate in addition to infliximab
- B. Switch to vedolizumab
- C. Discontinue infliximab and restart post-partum
- D. Discontinue infliximab with restart in future if she has symptoms
- E. Continue with infliximab during remainder of pregnancy

Answer: E.

The best course of action in this circumstance would be to continue with infliximab during her third trimester. Women with moderate to active disease can experience disease activity during pregnancy, which can be associated with low birth weight and pre-term birth. Despite significant exposure of the fetus to anti-TNF drugs during the third trimester, no negative impact on neonatal outcomes or pregnancy has been shown. In individuals with inactive disease, it may be reasonable to discontinue TNF therapy during the third trimester. Patients must be counselled on the risks and benefits during pregnancy. There is no indication for changing class of drug at this point, with methotrexate being shown to be teratogenic.

22.4. A 28-year-old man with a background of asthma presents with a history of intermittent dysphagia to solids and liquids, in addition to chest pain. An endoscopy is performed which shows longitudinal furrows and exudate in the oesophagus. Oesophageal biopsies demonstrate 25 eosinophils/HPF. What is the most appropriate initial pharmacological management?
- A. Amitriptyline
- B. 8-week empirical trial of PPI
- C. Swallowed fluticasone
- D. Oral budesonide
- E. Inhaled salbutamol

Answer: B.

The most likely diagnosis in this man is eosinophilic oesophagitis. An empirical 8-week trial of PPIs should be used in the first instance, with around one-third of patients responding, known as PPI-responsive oesophageal eosinophilia. In individuals who fail to respond to this, 8–12 weeks of topical therapy with glucocorticoids can be used, such as fluticasone or budesonide. In addition, dietary modifications are an effective management strategy, including elemental and elimination diets.

22.5. A 55-year-old female with a history of chronic constipation presents having failed to respond to fibre supplements, lactulose and bisacodyl. In view of this, anorectal manometry is performed, suggesting dyssynergic defaecation. What is the next appropriate management step?
- A. Low FODMAP diet
- B. Reassurance
- C. Biofeedback
- D. Linaclotide
- E. Prucalopride

Answer: C.

Biofeedback therapy has been shown to be an effective management option in individuals with dyssynergic defaecation, with up to 70% of individuals responding to this therapy. Agents such as linaclotide and prucalopride may be considered in individuals with functional or slow transit constipation. It is worth noting that patients with dyssynergic defaecation may have secondary slow transit constipation, which may respond to pharmacological management. However, biofeedback would be the first-line management for dyssynergic defaecation.

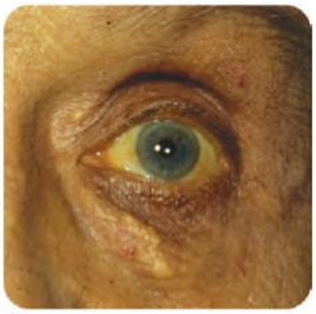
Clinical examination of the abdomen for liver and biliary disease

2 Face

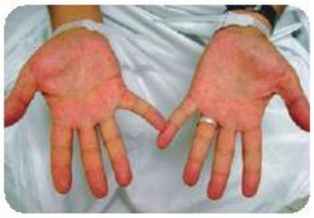
Jaundice
Spider naevi
Parotid swelling



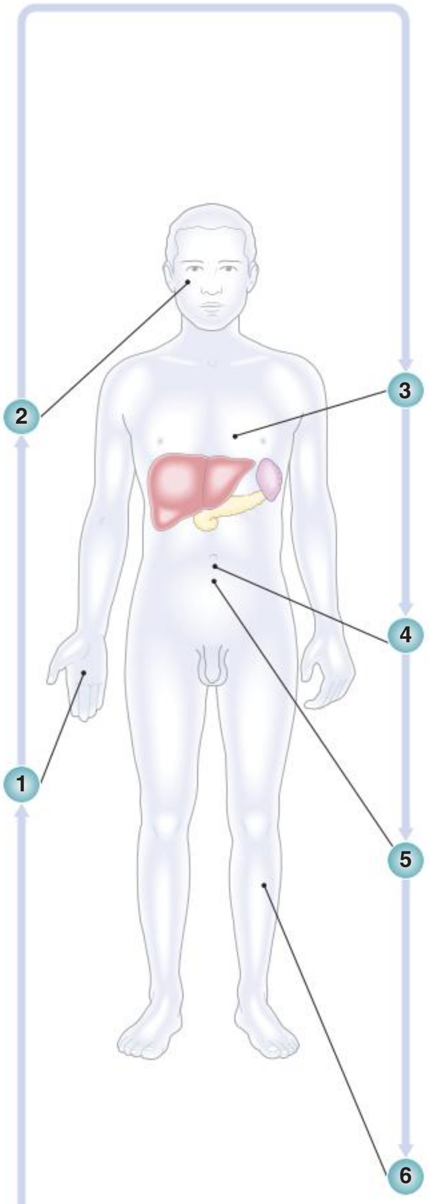
Xanthelasma and jaundiced sclera in a patient with chronic cholestasis

1 Hands

Clubbing
Dupuytren contracture
Leuconychia
Bruising
Flapping tremor (hepatic encephalopathy)



Palmar erythema

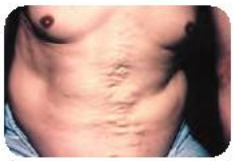


Observation

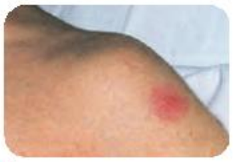
- Smell of alcohol or fetor hepaticus
- Encephalopathy
- Weight loss
- Scratch marks from itching

3 Chest

Loss of body hair



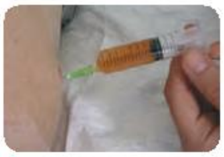
Gynaecomastia



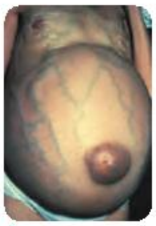
Spider naevi

4 Abdomen: inspection

Scars
Distension
Veins
Testicular atrophy



Aspiration of ascitic fluid



Dilated abdominal wall veins (caput medusae)

5 Abdomen: palpation/ percussion/auscultation

Hepatomegaly
Splenomegaly
Ascites
Palpable gallbladder

History and significance of abdominal signs

i Interpretation of physical signs in cirrhosis

Signs of cirrhosis

- Spider naevi
- Palmar erythema
- Leuconychia
- Bruising (low platelets)
- Loss of body hair (increased oestrogens)
- Gynaecomastia (increased oestrogens)

Signs of portal hypertension

- Splenomegaly
- Dilated abdominal wall veins

Signs of decompensation

- Jaundice
- Ascites/peripheral oedema
- Flapping tremor (encephalopathy)
- Evidence of gastrointestinal bleeding: anaemia/haematemesis/haematochezia and melaena

Signs related to specific aetiologies

- Dupuytren contracture (alcohol)
- Parotid swelling (alcohol)
- Intoxication/withdrawal (alcohol)
- Xanthelasma (PBC, MASLD)
- Scratch marks (cholestatic liver disease)
- Clubbing (hepatopulmonary syndrome)

(MASLD = metabolic dysfunction–associated steatotic liver disease; PBC = primary biliary cholangitis)

i Silent presentation of liver disease

It is important to note that patients with liver disease can present silently following detection of abnormality on screening investigation. This occurs frequently in practice in three settings:

Biochemical abnormality

- Liver enzyme abnormality detected during health screening or drug monitoring

Radiological abnormality

- Observation of an unexpected structural abnormality such as an altered liver texture or contour, or a mass lesion on ultrasound, computed tomography or other imaging undertaken for reasons unrelated to the liver

Serological abnormality

- Detection of a liver-related autoantibody

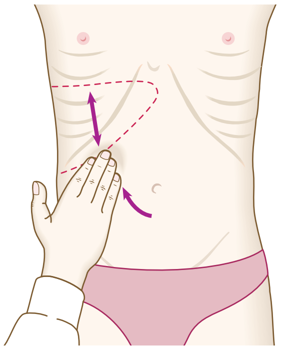
i Ascites

Causes	Associated clinical findings
Low serum-ascites albumin gradient (SAAG): < 11 g/L	
Carcinoma	Weight loss Abdominal mass 'Craggy' hepatomegaly
Tuberculosis	Weight loss ± fever Evidence of lung disease
High serum-ascites albumin gradient (SAAG): ≥ 11 g/L	
Cirrhosis	Stigmata of cirrhosis (see above)
Renal failure (including nephrotic syndrome)	Severe generalised oedema
Congestive heart failure	Elevated jugular venous pressure Peripheral oedema

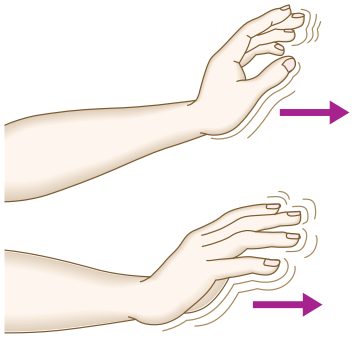
5 Assessment of liver size

Clinical assessment of hepatomegaly is important in diagnosing liver disease.

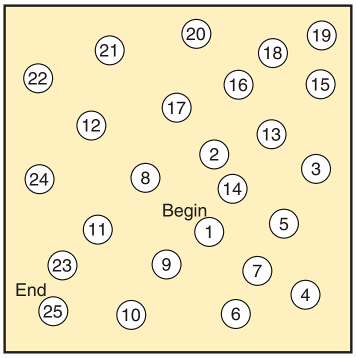
- Start in the right iliac fossa.
- Press hand gently up towards ribcage as patient breathes in.
- Progress up the abdomen 2 cm with each breath.
- Detect if smooth or irregular, tender or non-tender; ascertain the shape.
- Confirm the lower border of the liver by percussion.
- Identify the upper border by percussion.



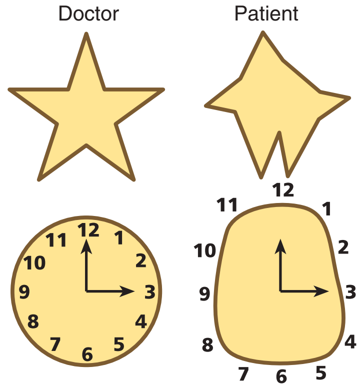
1 Assessment of encephalopathy



Flapping tremor. Jerky forward movements every 5–10 secs, when arms are outstretched and hands are dorsiflexed, suggest hepatic encephalopathy. The movements are coarser than those seen in tremor.



Number connection test. These 25 numbered circles can normally be joined together within 30 secs. Serial observations may provide useful information, as long as the position of the numbers is varied to avoid the patient learning their pattern.



Constructional apraxia. Drawing stars and clocks may reveal marked abnormality.

Functional anatomy and physiology

Applied anatomy

Normal liver structure and blood supply

The liver weighs 1.2–1.5 kg and has multiple functions, including roles in metabolism, control of infection, and elimination of toxins and by-products of metabolism. It is classically divided into left and right lobes by the falciform ligament, but a more useful functional division is into the right and left hemilivers, based on blood supply (Fig. 23.1). These are further divided into eight segments, according to subdivisions of the hepatic and portal veins. Each segment has its own branch of the hepatic artery and biliary tree. The segmental anatomy of the liver has an important influence on imaging and treatment of liver tumours, given the increasing use of surgical resection. A liver segment is made up of multiple smaller units known as lobules, composed of a central vein, radiating sinusoids separated from each other by single liver cell (hepatocyte) plates, and peripheral portal tracts containing terminal branches of the hepatic artery, portal vein and bile duct. The functional unit of the liver is the hepatic acinus (Fig. 23.2).

Fig. 23.1 Liver blood supply.

Blood flows into the acinus via a single branch of the portal vein and hepatic artery situated centrally in the portal tract. Blood flows outwards along the hepatic sinusoids into one of several tributaries of the hepatic vein at the periphery of the acinus. Bile is excreted by hepatocytes into channels called cholangioles, which lie between them, and flows in the opposite direction from the periphery of the acinus back to the interlobular bile duct in the portal tract. The hepatocytes in each acinus lie in three zones, depending on their position relative to the portal tract. Those in zone 1 are closest to the terminal branches of the portal vein and hepatic artery, and are richly supplied with oxygenated blood, and with blood containing the highest concentration of nutrients and toxins. Conversely, hepatocytes in zone 3 are furthest from the portal tracts and closest to the hepatic veins and are therefore relatively hypoxic and exposed to lower concentrations of nutrients and toxins compared to zone 1. The different perfusion and toxin exposure patterns, and thus vulnerability, of hepatocytes in the different zones contribute to the often patchy nature of liver injury.

Liver cells

Hepatocytes comprise 80% of liver cells. The remaining 20% are the endothelial cells lining the sinusoids, cholangiocytes lining the intrahepatic bile ducts, cells of the immune system including macrophages (Kupffer cells) and key populations of non-parenchymal cells, including hepatic stellate cells (Ito cells) and other myofibroblast precursors.

Endothelial cells line the sinusoids (Fig. 23.3), a network of capillary vessels that differ from other capillary beds in the body, in that there is no basement membrane. The endothelial cells have gaps between them (fenestrae) of about 0.1 μm in diameter, allowing free flow of fluid and particulate matter to the hepatocytes. Individual hepatocytes are separated

from the leaky sinusoids by the space of Disse, which contains stellate cells that store vitamin A and play an important part in regulating liver blood flow. They may also be immunologically active and play a role in the liver's contribution to defence against pathogens. The key role of stellate cells in terms of pathology is in the development of hepatic fibrosis, the precursor of cirrhosis. They undergo activation in response to cytokines produced following liver injury, differentiating into myofibroblasts, which are the major producers of the collagen-rich matrix that forms fibrous tissue (Fig. 23.4).

Blood supply

The liver is unique as an organ, as it has dual perfusion. The majority of its blood supply (50%–90%) is via the portal vein, which drains blood from the gut via the superior mesenteric vein and from the spleen. In this vascular arrangement, blood is moved from one set of capillaries to another at low pressure (normal portal pressure gradient is less than 5 mmHg) via a larger vessel without passing through the heart. The portal vein is the principal route for nutrient trafficking to the liver. A minority of inflow is oxygenated blood from the hepatic artery. The dual perfusion system, and the variable contribution from portal vein and hepatic artery, can have important effects on the clinical expression of liver ischaemia (which typically exhibits a less dramatic pattern than ischaemia in other organs, a fact that can sometimes lead to it being missed clinically), and can raise practical challenges in liver surgery.

Biliary system and gallbladder

Hepatocytes provide the driving force for bile flow by creating osmotic gradients of bile acids, which form micelles in bile (bile acid–dependent bile flow), and of sodium (bile acid–independent bile flow). Hepatocytes secrete bile into the biliary canaliculi that then progressively merge into a system of interlobular, septal and major ducts. The right and left hepatic ducts join as they emerge from the liver to form the common hepatic duct, which becomes the common bile duct after joining the cystic duct (see Fig. 23.2). The common bile duct is approximately 5 cm long and 4–6 mm wide. The distal portion of the duct passes through the head of the pancreas and usually joins the pancreatic duct before entering the duodenum through the ampullary sphincter (sphincter of Oddi). It should be noted, though, that the anatomy of the lower common bile duct can vary widely. Common bile duct pressure is maintained by rhythmic

Fig. 23.4 Pathogenic mechanisms in hepatic fibrosis. Stellate cell activation occurs under the influence of cytokines released by other cell types in the liver, including hepatocytes, Kupffer cells (tissue macrophages), platelets and lymphocytes. Once stellate cells become activated, they can perpetuate their own activation by synthesis of transforming growth factor beta (TGF-β_1), platelet-derived growth factor (PDGF) and reactive oxygen species (ROS) through autocrine loops. Activated stellate cells produce TGF-β_1, stimulating the production of collagen matrix, as well as inhibitors of collagen breakdown. Matrix degrading enzymes including matrix metalloproteinases 2 and 9 (MMP 2 and 9) are inactivated by tissue inhibitors of metalloproteinases (TIMP 1 and 2). In fibrogenesis, the balance between these enzymes and their inhibitors promotes matrix accumulation. Activated stellate cells also produce endothelin-1 (ET1), which may contribute to portal hypertension. Inflammation also contributes to fibrosis, with the cytokine profile produced by Th2 lymphocytes, such as interleukin-6 and 13 (IL-6 and IL-13). Toll-like receptors (TLR) induce innate immune responses by recognising both pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs). TLR activation by PAMPs and DAMPs promotes transcription of pro-inflammatory cytokines including interleukin-6, interleukin-12 (IL-12) and tumour necrosis factor alpha (TNF-α). Liver injury can be ameliorated through the action of a number of signalling pathways including: peroxisome proliferator-activated receptors (PPARs), glucagon-like peptide 1 (GLP-1) receptors and farnesoid X receptors (FXR) that are present in hepatocytes. (EGF = epidermal growth factor; IGF-1 = insulin-like growth factor 1; ROS = reactive oxygen species)

contraction and relaxation of the sphincter of Oddi; this pressure exceeds gallbladder pressure in the fasting state, so that bile normally flows into the gallbladder, where it is concentrated 10-fold by resorption of water and electrolytes.

The gallbladder is a pear-shaped sac typically lying under the right hemiliver, with its fundus located anteriorly behind the tip of the 9th costal cartilage. Anatomical variation is common. The function of the gallbladder is to concentrate, and provide a reservoir for, bile. Gallbladder tone is maintained by vagal activity, and cholecystokinin released from the duodenal mucosa during feeding causes gallbladder contraction and reduces sphincter pressure, so that bile flows into the duodenum. The body and neck of the gallbladder pass posteromedially towards the porta hepatis, and the cystic duct then joins it to the common hepatic duct. The cystic duct mucosa has prominent crescentic folds (valves of Heister), giving it a beaded appearance on cholangiography.

Hepatic function

Carbohydrate, amino acid and lipid metabolism

The liver plays a central role in carbohydrate, lipid and amino acid metabolism, and is also involved in metabolising drugs and environmental toxins (Fig. 23.5). An important and increasingly recognised role for the liver is in the integration of metabolic pathways, regulating the response of the body to feeding and starvation. Abnormality in metabolic pathways and their regulation can play an important role both in liver disease such as metabolic dysfunction–associated steatotic liver disease (MASLD) and in diseases that are not conventionally regarded as diseases of the liver (such as type 2 diabetes and inborn errors of metabolism). Hepatocytes have specific pathways to handle each of the nutrients absorbed from the gut and carried to the liver via the portal vein:

- Amino acids from dietary proteins are used for synthesis of plasma proteins, including albumin. The liver produces 8–14 g of albumin per day, and this plays a critical role in maintaining oncotic pressure in the vascular space and in the transport of small molecules like bilirubin, hormones and drugs throughout the body. Amino acids that are not required for the production of new proteins are broken down, with the amino group being converted ultimately to urea.
- Following a meal, more than half of the glucose absorbed is taken up by the liver and stored as glycogen or converted to glycerol and fatty acids, thus preventing hyperglycaemia. During fasting, glucose is synthesised (gluconeogenesis) or released from glycogen (glycogenolysis) in the liver, thereby preventing hypoglycaemia.
- The liver plays a central role in lipid metabolism, producing very low-density lipoproteins and further metabolising low- and high-density lipoproteins (see Fig. 19.12).

Fig. 23.5 Important liver functions.

Clotting factors

The liver produces key proteins that are involved in the coagulation cascade. Many of these coagulation factors (II, VII, IX and X) are post-translationally modified by vitamin K–dependent enzymes, and their synthesis is impaired in vitamin K deficiency. Reduced clotting factor synthesis is an important and easily accessible biomarker of liver function in the setting of liver injury. The short half-life of clotting factors makes the prothrombin time (PT; or the International Normalised Ratio, INR) a rapidly responsive measure of hepatocyte function. However, the deranged PT or INR seen in liver disease does not directly equate to increased bleeding risk, as these tests do not capture the concurrent reduced synthesis of anticoagulant factors, including protein C and protein S. In stable patients with liver disease, the coagulation is rebalanced by these offsetting factors that restore a neutral or marginally pro-thrombotic state (balanced coagulopathy). Correction of PT using blood products before minor invasive procedures should be guided by clinical risk rather than the absolute value of the PT.

Bilirubin metabolism and bile

The liver plays a central role in the metabolism of bilirubin and is responsible for the production of bile (Fig. 23.6). Between 425 and 510 mmol (250–300 mg) of unconjugated bilirubin is produced from the catabolism of haem daily. Bilirubin in the blood is normally almost all unconjugated and, because it is not water-soluble, is bound to albumin and does not pass into the urine. Unconjugated bilirubin is taken up by hepatocytes at the sinusoidal membrane, where it is conjugated in the endoplasmic reticulum by UDP-glucuronyl transferase, producing bilirubin mono- and diglucuronide. Impaired conjugation by this enzyme is a cause of inherited hyperbilirubinaemias (see Box 23.12). These bilirubin conjugates are water-soluble and are exported into the bile canaliculi by specific carriers

Fig. 23.6 Pathway of bilirubin excretion.

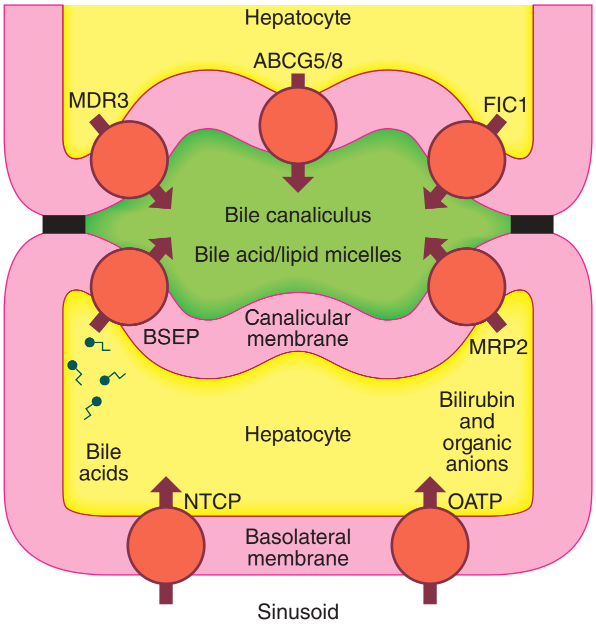

Fig. 23.7 Biliary transporter proteins. On the hepatocyte basolateral membrane, sodium taurocholate co-transporting polypeptide (NTCP) mediates uptake of conjugated bile acids from portal blood. At the canalicular membrane, bile salts are secreted via the bile salt export pump (BSEP) into bile. Multidrug resistance protein 3 (MDR3) transports (flips) phospholipid onto the outer side of the canalicular membrane. The ATP-binding cassette subgroup G 5 and 8 transporters (ABCG5/8) transport sterols including cholesterol into bile. These lipids form mixed micelles with bile salts and protect the membranes lining the biliary tree against the detergent action of bile salts. The familial intrahepatic cholestasis 1 (FIC1) transporter, encoded by the *ATP8B1* gene, transports phosphatidylserine to the outer side of the canalicular membrane and is essential for normal bile flow. Pathogenic variants in *ATP8B1* can result in either progressive familial intrahepatic cholestasis (PFIC) in children or benign recurrent intrahepatic cholestasis (BRIC). Similarly, pathogenic variants in the *ABCB11* gene encoding BSEP can result in either PFIC in children or BRIC in adolescents/adults. Genetic polymorphisms in the genes encoding BSEP, MDR3 and more rarely FIC1 are linked to intrahepatic cholestasis of pregnancy. Organic anion transporter protein (OATP) transports bilirubin and organic anions from portal blood into hepatocytes. Multidrug resistance protein 2 (MRP2) transports bilirubin, a range of organic anions and conjugates into bile. Pathogenic variants in a range of bile duct transporter genes have been linked to drug-induced liver injury (DILI).

on the hepatocyte membranes. The conjugated bilirubin is excreted in the bile and passes into the duodenal lumen.

Once in the intestine, conjugated bilirubin is metabolised by colonic bacteria to form stercobilinogen, which may be further oxidised to stercobilin. Both stercobilinogen and stercobilin are then excreted in the stool, contributing to its brown colour. Biliary obstruction results in reduced stercobilinogen in the stool, and the stools become pale. A small amount of stercobilinogen (4 mg/day) is absorbed from the bowel, passes through the liver and is excreted in the urine, where it is known as urobilinogen or, following further oxidisation, urobilin. The liver secretes 1–2 L of bile daily. Bile contains bile acids (formed from cholesterol), phospholipids, bilirubin and cholesterol. Several biliary transporter proteins have been identified (Fig. 23.7). Pathogenic variants in genes encoding these proteins have been identified in inherited intrahepatic biliary diseases presenting in childhood, and in adult-onset disease such as intrahepatic cholestasis of pregnancy and gallstone formation.

Storage of vitamins and minerals

Vitamins A, D and B_{12} are stored by the liver in large amounts, while others, such as vitamin K and folate, are stored in smaller amounts and disappear rapidly if dietary intake is reduced. The liver is also responsible for hydroxylating cholecalciferol at the 25 position in the sterol ring to form to 25(OH) cholecalciferol. Vitamin K is a fat-soluble vitamin and so the inability to absorb fat-soluble vitamins, as occurs in biliary obstruction, results in a coagulopathy. The liver also stores minerals such as iron, in ferritin and haemosiderin, and copper, which is excreted in bile.

Immune regulation

Approximately 9% of the normal liver is composed of immune cells (see Fig. 23.3). Cells of the innate immune system include Kupffer cells derived from blood monocytes, liver macrophages and natural killer (NK) cells, as well as ‘classical’ B and T cells of the adaptive immune response. Additional populations of atypical lymphocytes, with phenotypic features of both T cells and NK cells, are thought to play an important role in host defence through linking of innate and adaptive immunity. The enrichment of such cells in the liver reflects the unique importance of the liver in preventing microorganisms from the gut from entering the systemic circulation.

Kupffer cells constitute the largest single mass of tissue-resident macrophages in the body and account for 80% of the phagocytic capacity of this system. They remove aged and damaged red blood cells, bacteria, viruses, antigen–antibody complexes and endotoxin. They also produce a wide variety of inflammatory mediators that can act locally or may be released into the systemic circulation.

The immunological environment of the liver is unique in that antigens presented within it tend to induce immunological tolerance. This is of importance in liver transplantation, where classical major histocompatibility (MHC) barriers may be crossed, and also in chronic viral infections, when immune responses may be attenuated. The mechanisms that underlie this phenomenon have not been fully defined.

Investigation of liver and hepatobiliary disease

Investigations play an important role in the management of liver disease in three settings:

- identifying the presence of liver disease in those with risk factors
- establishing the aetiology in those with incidentally found liver disease
- understanding disease severity (in particular, identification of fibrosis which leads to cirrhosis with its complications).

When planning investigations, it is important to be clear as to which of these goals is being addressed.

Suspicion of the presence of liver disease is normally based on blood biochemistry abnormality (liver function tests, or LFTs).

Aetiology is typically established through a combination of history, specific blood tests and, where appropriate, imaging and liver biopsy.

Staging of disease involves the assessment of fibrosis and identification of cirrhosis and its complications. Although histology remains the gold standard for staging liver fibrosis, it has been largely replaced by non-invasive approaches, including novel imaging modalities, elastography, serum markers of fibrosis and predictive scoring systems.

The aims of investigation in patients with suspected liver disease are shown in Box 23.1.

23.1 Aims of investigations in patients with suspected liver disease

- Detect hepatic abnormality
- Measure the severity of liver damage
- Detect the pattern of liver function test abnormality: hepatitis, cholestatic or mixed
- Identify the specific cause
- Investigate possible complications

Liver blood biochemistry

Liver blood biochemistry can be divided into liver enzymes and measures of liver function. Liver enzymes provide evidence of active liver injury and the pattern can help to distinguish the type of injury: hepatocellular injury (ALT and AST) or cholestasis (ALP and GGT), as shown in Box 23.2. In contrast, liver function is best assessed by the serum bilirubin, albumin and prothrombin time because of the role played by the liver in clearance of bilirubin and in synthesis of albumin and clotting factors. These measures reflect the severity of liver disease and are related to clinical outcomes, reflected by their use in several prognostic scores: the Child–Pugh and MELD (Model for End-stage Liver Disease) scores in cirrhosis (see Box 23.31, Box 23.32), the Glasgow score in alcoholic hepatitis (see Box 23.50) and the King's College Hospital criteria for liver transplantation in acute liver failure (see Box 23.18).

Bilirubin

Serum bilirubin can be raised because of either reduced hepatocyte clearance (conjugation and excretion into bile) or impaired biliary drainage. A raised bilirubin often occurs earlier in the natural history of biliary diseases such as primary sclerosing cholangitis than in parenchymal liver disease such as cirrhosis. Prolonged cholestasis may also follow some acute liver injuries, so caution is therefore needed in interpreting the level of liver injury purely on the basis of bilirubin elevation. Bilirubin may also be elevated in the absence of liver injury as a result of haemolysis (resulting in increased bilirubin production) or inherited disorders of bilirubin metabolism (see Box 23.12).

Albumin

Serum albumin levels are often low in patients with cirrhosis. This is due to both reduced synthesis and a change in the volume of distribution of albumin. Since the plasma half-life of albumin is about 2 weeks, albumin levels may be normal in acute liver failure but are almost always reduced in chronic liver failure. Albumin is not a specific marker of liver disease and is reduced in a range of conditions, including sepsis, malnutrition, nephrotic syndrome and protein-losing enteropathy.

Alanine aminotransferase and aspartate aminotransferase

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are intracellular enzymes that are released during damage to hepatocytes. Although AST may also be released from heart or skeletal muscle, expression of ALT outside the liver is relatively low and this enzyme is therefore considered more specific for hepatocellular damage. Large increases of aminotransferase activity favour hepatocellular damage, and this pattern of enzyme abnormality is known as 'hepatitic'.

The AST level is usually lower than the ALT, resulting in an AST/ALT ratio of less than 0.8. This ratio reverses in two situations: in alcohol-related liver disease (particularly in alcoholic hepatitis, where the ratio can be > 2), or as an indicator of advanced fibrosis in non-alcohol-related liver disease such as hepatitis C or MASLD.

23.2 Patterns of abnormal liver enzymes

Pattern	AST and ALT	GGT	ALP
Cholestasis	↑	↑↑	↑↑↑
Hepatitis	↑↑↑	↑	↑
Steatosis	N/↑	↑↑	N
Enzyme-inducing drugs	N	↑↑	N

N = normal; ↑ mild elevation (< twice normal); ↑↑ moderate elevation (2–5 times normal); ↑↑↑ marked elevation (> 5 times normal).
(ALP = alkaline phosphatase; ALT = alanine aminotransferase; AST = aspartate aminotransferase; GGT = gamma-glutamyl transferase)

Alkaline phosphatase and γ-glutamyl transferase

Alkaline phosphatase (ALP) is the collective name given to several different enzymes that hydrolyse phosphate esters at alkaline pH. These enzymes are widely distributed in the body but the main sites of production are the liver, bone, kidney and placenta. ALPs are post-translationally modified, resulting in the production of several different isoenzymes, which differ in abundance in different tissues. ALP enzymes in the liver are located in cell membranes of the hepatic sinusoids and the biliary canaliculi. Accordingly, levels rise with biliary injury and with sinusoidal obstruction, as occurs in infiltrative liver disease.

Gamma-glutamyl transferase (GGT) is a microsomal enzyme found in many cells and tissues of the body. The highest concentrations are located in the liver, where it is produced by hepatocytes and biliary epithelium.

The pattern of a modest increase in aminotransferase activity and large increases in ALP and GGT activity suggests impaired bile excretion and is commonly described as 'cholestatic' (see Box 23.2). Isolated elevation of the serum GGT is relatively common and may occur during ingestion of microsomal enzyme-inducing drugs, including alcohol (Box 23.3), but also in MASLD. Elevated ALP with normal GGT is suggestive of non-hepatic origin, such as bone disease or pregnancy. Similarly, 5′-nucleotidase, an intrinsic membrane glycoprotein found in a range of cells including hepatocytes, is raised in hepatobiliary disease but not in other causes of raised ALP.

Other biochemical tests

Other widely available biochemical tests may become altered in patients with liver disease:

- Hyponatraemia occurs in severe liver disease despite a high total body sodium content due to increased production of arginine vasopressin (Fig. 19.7) and may be exacerbated by diuretic use. A low sodium level predicts a poor prognosis in cirrhosis.
- Serum urea may be reduced in hepatic failure or due to loss of muscle mass, whereas levels of urea may be increased following gastrointestinal haemorrhage.
- Ferritin is elevated in patients with haemochromatosis, systemic inflammatory disease and a range of conditions causing significant parenchymal inflammation, including alcohol excess and MASLD. In the absence of systemic or hepatic inflammation, serum ferritin reflects total body iron stores.
- Transferrin is a protein that transports iron in the blood. It is reduced in acute inflammation (negative acute phase reactant) and in chronic liver disease. Transferrin saturation refers to the proportion of transferrin that is bound to iron and is increased in patients with haemochromatosis. Conversely total iron binding capacity (TIBC) refers to the amount of iron that can be bound to iron binding proteins in the blood and is reduced in haemochromatosis.

23.3 Drugs that increase levels of γ-glutamyl transferase

- Ethanol
- Phenytoin
- Carbamazepine
- Valproate
- Barbiturates
- Oral contraceptive pill
- Griseofulvin
- Isotretinoin

Haematological tests

Blood count

The peripheral blood count is often abnormal and can give a clue to the underlying diagnosis:

- *A normochromic normocytic anaemia* may reflect anaemia of chronic disease or recent gastrointestinal haemorrhage, whereas chronic blood loss is characterised by a hypochromic microcytic anaemia secondary to iron deficiency. A high erythrocyte mean cell volume (macrocytosis) is associated with alcohol misuse or haemolysis, but target cells in any jaundiced patient also result in a macrocytosis.
- *Leucopenia* may complicate portal hypertension and hypersplenism, whereas leucocytosis may occur with cholangitis, alcoholic hepatitis and hepatic abscesses. Atypical lymphocytes are seen in infectious mononucleosis, which may be complicated by an acute hepatitis.
- *Thrombocytopenia* is common in cirrhosis and is due to reduced platelet production and increased breakdown because of hypersplenism. Thrombopoietin, required for platelet production, is produced in the liver and levels fall with worsening liver function. Accordingly, platelet levels are usually more depressed than both white cells and haemoglobin in the presence of hypersplenism in patients with cirrhosis. Thrombocytosis is unusual in patients with liver disease but may occur in those with active gastrointestinal haemorrhage and, rarely, in hepatocellular carcinoma.

Coagulation tests

These are often abnormal in patients with liver disease, although they correlate poorly with bleeding risk. An increased PT is an indicator of impaired liver function. The normal half-lives of the vitamin K–dependent coagulation factors in the blood are short (5–72 hours). Because of this, changes in the PT occur relatively quickly following liver damage, and these changes provide valuable prognostic information in patients with both acute and chronic liver failure. Vitamin K does not reverse an abnormal PT if it is due to liver disease but will correct the PT if the cause is vitamin K deficiency, as may occur with cholestasis due to malabsorption of fat-soluble vitamins, or poor diet.

Immunological tests

A variety of tests are available to evaluate the aetiology of hepatic disease (Boxes 23.4, 23.5). The presence of liver-related autoantibodies can be suggestive of autoimmune liver disease (although false-positive results can occur in other inflammatory diseases such as MASLD). Elevation in overall serum immunoglobulin levels (either IgG or IgM) can also indicate autoimmunity. In contrast, elevated serum IgA may be seen in alcohol-related liver disease and MASLD.

Imaging

Several imaging techniques can be used to determine the site and nature of structural lesions in the liver and biliary tree. In general, however, imaging techniques are unable to identify hepatic inflammation and have poor sensitivity for liver fibrosis unless advanced cirrhosis with portal hypertension is present.

Ultrasound

Ultrasound is non-invasive and most commonly used as a first-line test to identify gallstones, biliary obstruction (Fig. 23.8) or thrombosis in the hepatic vasculature. Ultrasound may show changes of cirrhosis (nodular liver contour, coarse echotexture, right lobe atrophy and left lobe hypertrophy) or portal hypertension (splenomegaly, ascites) but has a relatively low sensitivity for diagnosing compensated cirrhosis. Focal lesions, such as tumours, may not be detected if they are less than 2 cm in diameter and have similar echogenicity to normal liver tissue. Bubble-based

23.4 Chronic liver disease screen

- Hepatitis B surface antigen
- Hepatitis C antibody
- Liver autoantibodies (antinuclear antibody, smooth muscle antibody, antimitochondrial antibody, anti-liver–kidney microsomal antibody)
- Immunoglobulins
- Ferritin +/– transferrin saturation
- α1-antitrypsin
- Caeruloplasmin

23.5 How to identify the cause of abnormal liver function tests

Diagnosis	Clinical clue	Initial test	Additional tests
Alcohol-related liver disease	History	LFTs AST > ALT; high MCV	Random blood alcohol
Metabolic dysfunction–associated steatotic liver disease (MASLD)	Metabolic syndrome (central obesity, diabetes, hypertension)	LFTs Ultrasound showing fatty liver	
Chronic hepatitis B	Born in high-prevalence area; injection drug use; blood transfusion	HBsAg	HBeAg, HBeAb HBV-DNA
Chronic hepatitis C	Injection drug use; blood transfusion	HCV antibody	HCV-RNA or antigen
Primary biliary cholangitis	Itch; raised ALP	AMA Raised IgM	
Primary sclerosing cholangitis	Inflammatory bowel disease	MRCP	
Autoimmune hepatitis	Other autoimmune diseases	ASMA, ANA, LKM, raised IgG	Liver biopsy
Haemochromatosis	Diabetes/joint pain	Transferrin saturation, ferritin	HFE gene test
Wilson disease	Neurological signs; haemolysis	Caeruloplasmin	24-hour urinary copper
Alpha-1-antitrypsin deficiency	Lung disease	α1-antitrypsin level	α1-antitrypsin genotype
Drug-induced liver disease	Drug/herbal remedy history	LFTs	Liver biopsy

(ALP = alkaline phosphatase; ALT = alanine aminotransferase; AMA = antimitochondrial antibody; ANA = antinuclear antibody; ASMA = anti-smooth muscle antibody; AST = aspartate aminotransferase; HBeAb = antibody to hepatitis B e antigen; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HBV = hepatitis B virus; HCV = hepatitis C virus; HFE = haemochromatosis (high iron/Fe); IgM = immunoglobulin M; IgG = immunoglobulin G; LKM = liver–kidney microsomal antibody; MCV = mean cell volume; MRCP = magnetic resonance cholangiopancreatography)

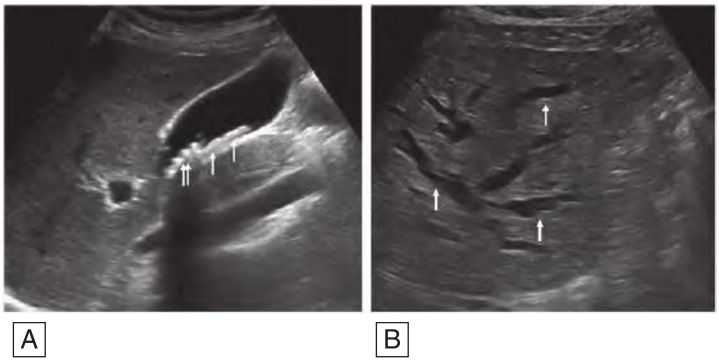

Fig. 23.8 Ultrasound imaging of gallstones and biliary obstruction. **A** Multiple small gallstones (arrows), with several demonstrating acoustic shadowing (double arrow). **B** Dilated intrahepatic bile ducts (arrows) in patient with jaundice due to bile duct obstruction.

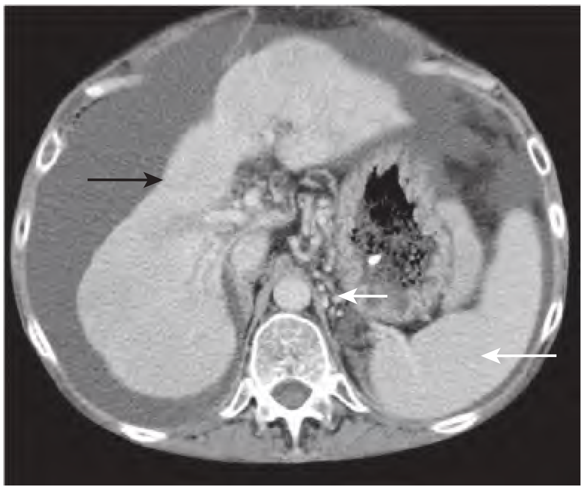

Fig. 23.9 Computed tomography in a patient with cirrhosis. The liver is small and has an irregular outline (black arrow), the spleen is enlarged (long white arrow), fluid (ascites) is seen around the liver, and collateral vessels are present around the proximal stomach (short white arrow).

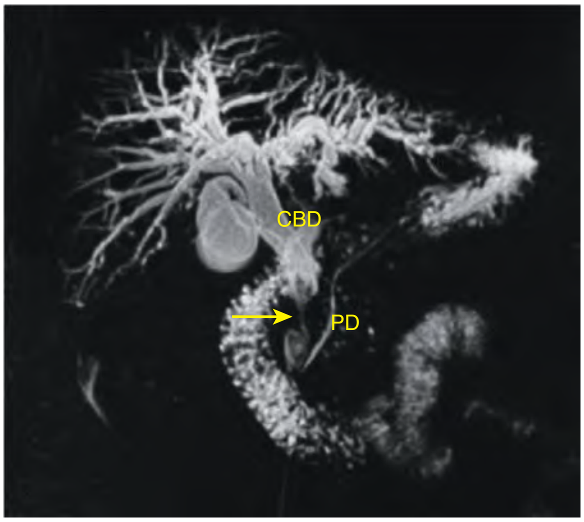

Fig. 23.10 Cholangiocarcinoma. Magnetic resonance cholangiopancreatography showing a biliary stricture due to cholangiocarcinoma in the distal common bile duct (arrow). The proximal common bile duct (CBD) is dilated but the pancreatic duct (PD) is normal.

contrast media can enhance discriminant capability. Doppler ultrasound allows blood flow in the hepatic artery, portal vein and hepatic veins to be investigated.

Computed tomography and magnetic resonance imaging

Computed tomography (CT) detects smaller focal lesions in the liver, especially when combined with contrast injection (Fig. 23.9). Multiphase imaging (arterial, portal–venous and delayed phase) after contrast injection can further define the characteristics of focal lesions and vascular abnormalities. Magnetic resonance imaging (MRI) can also be used to localise and confirm the aetiology of focal liver lesions, particularly primary and secondary tumours.

Hepatic angiography is seldom used nowadays as a diagnostic tool, since CT and MRI are both able to provide images of hepatic vasculature, but it still has a therapeutic role in the embolisation of vascular tumours, such as hepatocellular carcinoma. Hepatic venography is now rarely performed.

Cholangiography

Cholangiography can be undertaken by magnetic resonance cholangiopancreatography (MRCP; Fig. 23.10), endoscopy (endoscopic retrograde cholangiopancreatography, ERCP) or the percutaneous approach (percutaneous transhepatic cholangiography, PTC). The latter does not allow the ampulla of Vater or pancreatic duct to be visualised. Endoscopic ultrasound can also provide high-quality biliary imaging safely (see below). MRCP is as good as ERCP at providing images of the biliary tree but is safer, and there is now little, if any, role for diagnostic ERCP. Both endoscopic and percutaneous approaches allow therapeutic interventions, such as the insertion of biliary stents across bile duct strictures. The percutaneous approach is used only if it is not possible to access the bile duct endoscopically. ERCP can be combined with cholangioscopy for direct visualisation +/− targeted biopsy of bile duct lesions. Intraoperative cholangiograms are helpful for exclusion of ductal stones at the time of cholecystectomy.

Endoscopic ultrasound

Endoscopic ultrasound (EUS) provides high-resolution images of the pancreas, biliary tree and liver (see Fig. 23.46) and is complementary to MRCP in the diagnostic evaluation of the extrahepatic biliary tree, ampulla of Vater and pancreas. With the ultrasonic probe in the duodenum, tissue sampling can be performed and, increasingly, therapeutic drainage of biliary obstruction can be performed. EUS has the advantage over ERCP of not exposing patients to the risk of pancreatitis, among other complications of bile duct cannulation.

Non-invasive markers of hepatic fibrosis

Fibrosis is a key predictor of prognosis in chronic liver disease and can help to guide monitoring and treatment decisions. This is now largely assessed by non-invasive markers of liver fibrosis. A number of indirect fibrosis markers have been described, including bilirubin, AST/ALT ratio and platelet count. Simple scoring systems such as the Fibrosis-4 (FIB-4) score combine routinely available blood tests and clinical risk factors and are often used as screening tests for fibrosis risk. These tests generally have a high negative predictive value, with a normal value making advanced fibrosis very unlikely, but a relatively low positive predictive value. Whilst these have been validated across a range of aetiologies, the cut-off values used (for FIB-4) may differ according to aetiology, and serum-based tests are less reliable in alcohol-related liver disease.

Fibrosis can also be assessed using more specific serum tests. FibroTest combines five serum markers including α2-macroglobulin, haptoglobin and apolipoprotein A1. The Enhanced Liver Fibrosis (ELF) serological assay provides direct assessment of fibrogenesis and fibrolysis using a combination of hyaluronic acid, procollagen peptide III (PIIINP) and tissue inhibitor of metalloproteinase 1 (TIMP1).

An alternative to serological markers is transient elastography (FibroScan), in which ultrasound-based shock waves are sent through the liver to measure stiffness as a surrogate for hepatic fibrosis. Shear-wave elastography combined with conventional ultrasound provides similar measurements. This is quick, non-invasive and provides immediate results. Depending on the threshold used, this can exclude significant fibrosis or diagnose cirrhosis. However, results can be influenced by the presence of severe inflammation and become less reliable with increasing obesity. Magnetic resonance elastography appears more reliable and is not influenced by obesity but is costly and not widely available.

Histological examination

A liver biopsy can confirm the severity of liver damage and provide aetiological information. It should be performed percutaneously using a 16 G aspiration or spring-loaded cutting needle, usually through an intercostal space under local anaesthesia, or radiologically using a transjugular approach. Liver biopsy can now also be performed endoscopically in selected cases with EUS guidance. It can be particularly useful for targeted lesional biopsy and fine needle aspiration (FNA) for cytology.

Percutaneous liver biopsy is a relatively safe procedure if the conditions detailed in Box 23.6 are met but carries a mortality of about 0.01%. The main complications are pain at the biopsy site or referred pain at the right shoulder tip, bleeding or infection. Liver biopsies can be carried out in patients with defective haemostasis if:

- the defect is corrected with fresh frozen plasma and/or platelet transfusion,
- the biopsy is obtained by the transjugular route, *or*
- the procedure is conducted percutaneously under ultrasound control and the needle track is then plugged with procoagulant material.

In patients with potentially resectable malignancy, biopsy should be avoided where possible due to the potential risk of tumour dissemination (biopsy track seeding). Operative or laparoscopic liver biopsy may sometimes be valuable.

Liver biopsy is used where there is uncertainty as to the cause of liver disease, or to quantify the degree of inflammation ('grade') or fibrosis ('stage'). Semi-quantitative scoring systems may be used to describe the degree of inflammation or fibrosis. Although often regarded as the 'gold standard' investigation for liver disease, liver biopsies are limited by sampling error, with studies showing significant variation in both grade and stage between simultaneous paired biopsies. The use of special histological stains can help in determining aetiology. The clinical features and prognosis of these changes are dependent on the underlying aetiology and are discussed in the relevant sections below.

23.6 Conditions required for safe percutaneous liver biopsy

- Cooperative patient
- It is recommended that if INR is >1.4, non-lesional biopsies should be done via a transvenous route
- Percutaneous lesional biopsies can be performed if the INR is <1.4
- Fresh frozen plasma should only be used prior to biopsy to correct an INR of ≥ 2
- If the platelet count is $<50\times10^9$/L, a transvenous approach is recommended
- The effectiveness and/or the risks of platelet transfusion for a platelet count <50 have not been established but can be considered
- Thrombopoietin receptor agonists (TPO-RAs) can be considered as an alternative to platelet transfusion for elective biopsy
- Exclusion of bile duct obstruction, localised skin infection, advanced chronic obstructive pulmonary disease, marked ascites and severe anaemia
- Liver biopsy should be avoided in unstable patients with uncontrolled bleeding, bacterial infection and significant renal impairment
- Anticoagulants should be stopped prior to liver biopsy and there are local/international guidelines on when to stop or continue aspirin/antiplatelet drugs

(INR = International Normalised Ratio)

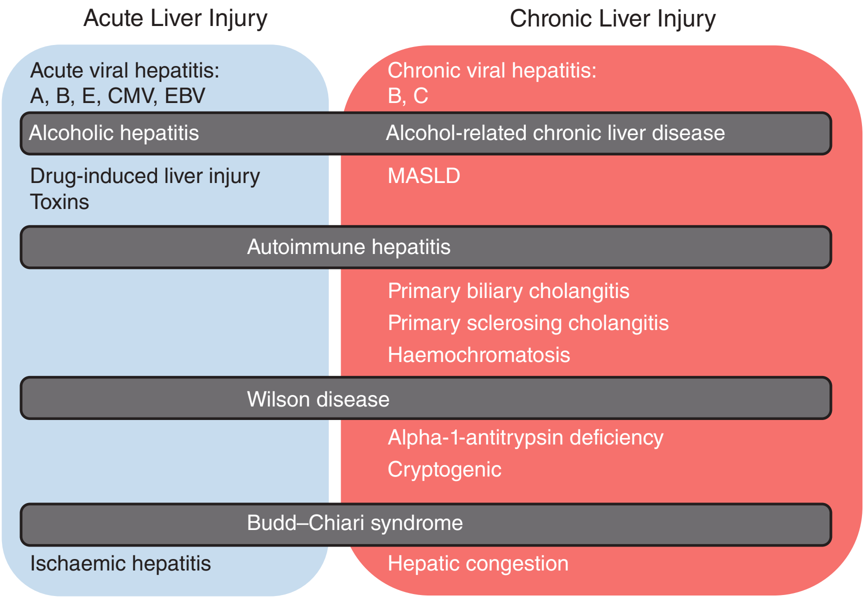
Presenting problems in liver disease

Liver injury may be either acute or chronic. The main causes are listed in Figure 23.11 and discussed in more detail later in the chapter. In the UK, liver disease is the an important cause of mortality that is steadily increasing (Fig. 23.12). Mortality rates have risen substantially over the last 30 years, with a near-fivefold increase in liver-related mortality in people younger than 65 years. The rate of increase is substantially higher in the UK than in other countries in Western Europe.

- *Acute liver injury* may present with non-specific symptoms of fatigue and abnormal LFTs, or with jaundice and acute liver failure.
- *Chronic liver injury* is defined as hepatic injury, inflammation and/or fibrosis occurring in the liver for more than 6 months. In the early stages, patients can be asymptomatic, with fluctuating abnormal LFTs. With more severe liver damage, however, the presentation can be with jaundice, portal hypertension or other signs of cirrhosis and hepatic decompensation (Box 23.7). Patients with clinically silent chronic liver disease frequently present when abnormalities in liver function are observed on routine blood testing, or when clinical events, such as an intercurrent infection or surgical intervention, cause the liver to decompensate. Many liver disorders are more common in older age and can pursue a more aggressive course (Box 23.8).

Abnormal liver function tests

Liver function tests are frequently requested in patients who have no symptoms or signs of liver disease, as part of routine health checks, insurance medicals or drug monitoring. The prevalence of abnormal LFTs has been reported to be as high as 10%–20% in some studies. In the majority of cases, these will not reflect significant underlying liver disease. However, many patients with chronic liver disease are asymptomatic or have vague, non-specific symptoms. The most common cause of abnormalities is steatotic liver disease due to obesity, metabolic dysfunction or alcohol. Since effective medical treatments are now available for many types of chronic liver disease, further evaluation is usually warranted to make sure the patient does not have a treatable condition. Biochemical abnormalities in chronic liver disease often fluctuate over time; even mild abnormalities can therefore indicate significant underlying disease and so warrant follow-up and investigation.



Acute Liver Injury
Chronic Liver Injury
Acute viral hepatitis: A, B, E, CMV, EBV
Chronic viral hepatitis: B, C
Alcoholic hepatitis
Alcohol-related chronic liver disease
Drug-induced liver injury
Toxins
MASLD
Autoimmune hepatitis
Primary biliary cholangitis
Primary sclerosing cholangitis
Haemochromatosis
Wilson disease
Alpha-1-antitrypsin deficiency
Cryptogenic
Budd–Chiari syndrome
Ischaemic hepatitis
Hepatic congestion

Fig. 23.11 **Causes of acute and chronic liver injury.** Alcohol is typically a cause of chronic liver disease, but patients with alcohol-related liver disease may present with jaundice due to alcoholic hepatitis either acutely or on a background of chronic liver fibrosis or cirrhosis. (CMV = cytomegalovirus; EBV = Epstein–Barr virus; MASLD = metabolic dysfunction–associated steatotic liver disease; PBC = primary biliary cholangitis; PSC = primary sclerosing cholangitis)

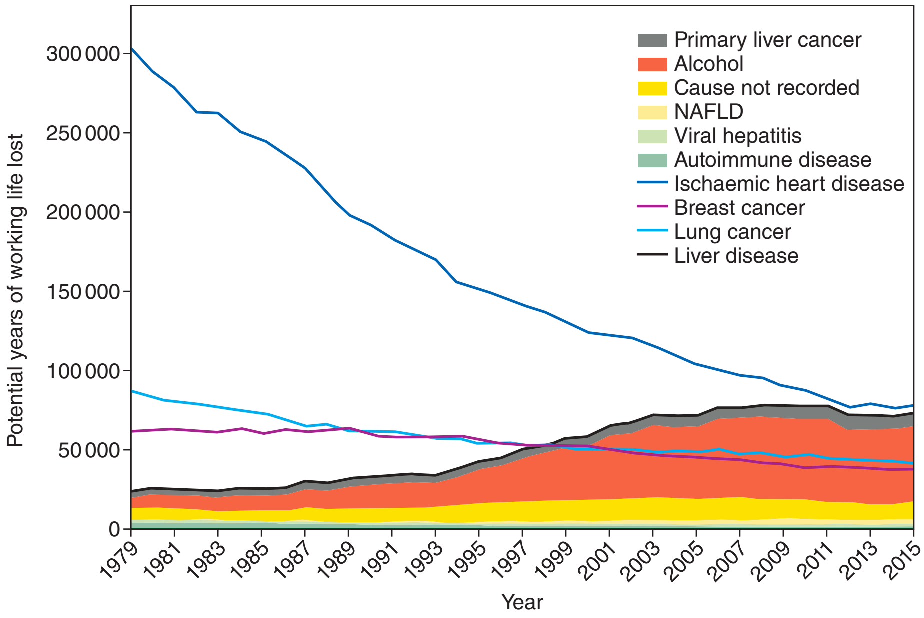


Fig. 23.12 **Potential years of working life lost due to liver disease.** The dates shown compare potential years of working life lost before 65 years of age in various types of liver disease with lung cancer, breast cancer and ischaemic heart disease. The figures are derived from the UK Office for National Statistics mortality data for 1979–2015. (NAFLD = non-alcoholic fatty liver disease) *From Williams R, Alexander G, Armstrong I, et al. Disease burden and costs from excess alcohol consumption, obesity, and viral hepatitis: fourth report of the Lancet Standing Commission on Liver Disease in the UK. Reprinted with permission from Elsevier (The Lancet 2018;391:1097–1107).*

When abnormal LFTs are detected, a thorough history should be compiled to determine the patient's alcohol consumption, drug use (prescribed, over the counter or recreational), risk factors for viral hepatitis (blood transfusion, injection drug use, tattoos), the presence of autoimmune diseases, family history, neurological symptoms and the presence of features of the metabolic syndrome, including diabetes and/or obesity (see Box 23.5). Stigmata of chronic liver disease should be looked for, but further investigations are indicated even in the absence of these signs.

Both the pattern of enzyme abnormality (hepatitic or cholestatic) and the degree of elevation are helpful in determining the cause of underlying liver disease (Boxes 23.9, 23.10). The investigations that make up a standard liver screen and additional or confirmatory tests are shown in Boxes 23.4 and 23.5. An algorithm for investigating abnormal LFTs is provided in Figure 23.13.

Jaundice

Jaundice is due to a raised bilirubin level and is usually detectable clinically when the plasma bilirubin exceeds 40 µmol/L (~2.5 mg/dL). It is possible to measure the conjugated (direct) bilirubin level and hence also calculate the unconjugated bilirubin level. Unconjugated hyperbilirubinaemia is present when serum unconjugated (indirect) bilirubin is > 20 µmol/L (~1.2 mg/dL) AND when the conjugated fraction is < 20% of total bilirubin.

23.7 Presentation of liver disease

	Acute liver injury (days–weeks)	Chronic liver injury (months–years)
Early features	Abnormal liver enzymes (high transaminases)	Abnormal liver enzymes
Intermediate	Prolonged PT Raised bilirubin	Signs of cirrhosis or portal hypertension
Late features	Encephalopathy	Jaundice Ascites/oedema Variceal bleeding Hepatic encephalopathy

(PT = prothrombin time)

23.8 Liver disease in old age

- **Alcohol-related liver disease**: 10% of cases present over the age of 70 years, when disease is more likely to be severe and has a worse prognosis.
- **Hepatitis A**: causes more severe illness and runs a more protracted course.
- **Primary biliary cholangitis**: one-third of cases are over 65 years.
- **Liver abscess**: more than 50% of all cases in the UK are over 60 years.
- **Hepatocellular carcinoma**: approximately 50% of cases in the UK present over the age of 65 years.
- **Surgery**: older people are less likely to survive liver surgery (including transplantation) because comorbidity is more prevalent.

23.9 Common causes of elevated serum transaminases

Minor elevation* (< 100 U/L)

- Chronic hepatitis C
- Chronic hepatitis B
- Alcohol-related liver disease
- Metabolic dysfunction–associated steatotic liver disease
- Alcoholic hepatitis
- Haemochromatosis

Moderate elevation (100–300 U/L)

As above plus:

- Autoimmune hepatitis
- Wilson disease

Major elevation (> 300 U/L)

- Paracetamol poisoning
- Acute viral hepatitis
- Autoimmune hepatitis
- Ischaemic hepatitis
- *Amanita phalloides* poisoning
- Flare of chronic hepatitis B
- Idiosyncratic drug-induced liver injury

*Note that the cut-offs between minor, moderate and major elevations in transaminases are indicative only and do not definitively discriminate between different aetiologies.

The causes of jaundice overlap with the causes of abnormal LFTs discussed above. In a patient with jaundice, it is useful to consider whether the cause might be pre-hepatic, hepatic or post-hepatic, and there are often important clues in the history (Box 23.11).

Pre-hepatic jaundice

This is caused either by haemolysis or by congenital hyperbilirubinaemia and is characterised by an isolated raised bilirubin level. This is typically an unconjugated hyperbilirubinaemia and is associated with increased urinary urobilinogen.

In haemolysis, destruction of red blood cells or their marrow precursors causes increased bilirubin production. Jaundice due to haemolysis is usually mild because a healthy liver can excrete a bilirubin load six times greater than normal before unconjugated bilirubin accumulates in the plasma. This does not apply to newborns, who have less capacity to metabolise bilirubin.

23.10 Causes of cholestatic jaundice

Hepatic

- Primary biliary cholangitis
- Primary sclerosing cholangitis
- Alcohol
- Drugs
- Hepatic infiltrations (lymphoma, granuloma, amyloid, metastases)
- Sepsis
- Right heart failure
- Cystic fibrosis
- Pregnancy
- Inherited cholestatic liver disease

Post-hepatic

- Carcinoma:
  Pancreatic head
  Bile duct (cholangiocarcinoma)
  Ampullary
  Liver metastases
- Choledocholithiasis
- Primary sclerosing cholangitis
- Parasitic infection
- Traumatic biliary strictures
- Chronic pancreatitis
- IgG4 cholangitis

Inherited disorders of bilirubin conjugation (Box 23.12) produce the same pattern (isolated raised unconjugated bilirubin with normal liver enzymes). The most common of these is Gilbert syndrome, and the other inherited disorders are very rare. Although the defect is within the hepatocyte, it is listed as a 'pre-hepatic' cause due to the biochemical similarity to haemolysis and otherwise normal liver function.

Hepatic jaundice

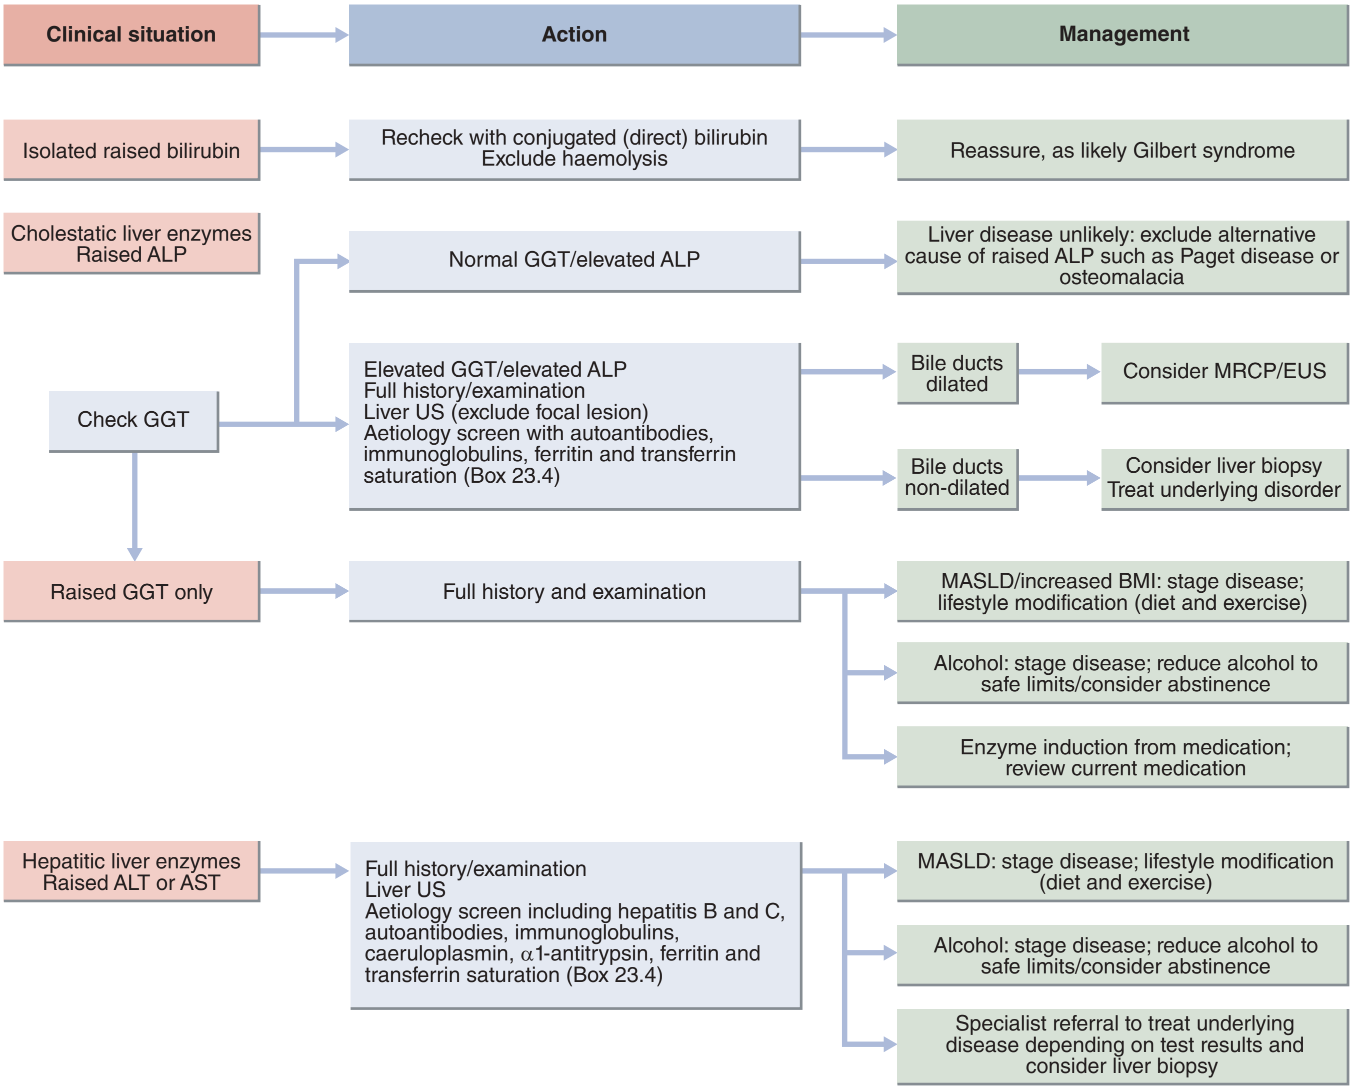
This is characterised by jaundice due to hepatic dysfunction (usually indicated by abnormal liver enzymes) but normal biliary imaging. This can be due to acute hepatocellular injury (see Box 23.9), intrahepatic cholestasis (see Box 23.10) or decompensation of cirrhosis. 'Hepatic' jaundice can be a manifestation of extrahepatic disease such as sepsis or right heart failure. In all of these, jaundice results from an inability of the liver to transport bilirubin into the bile, occurring at any point between uptake of unconjugated bilirubin into the cells and transport of conjugated bilirubin into the canaliculi. In addition, swelling of cells and oedema resulting from parenchymal damage may cause obstruction of the biliary canaliculi. Consequently, the concentrations of both unconjugated and conjugated bilirubin in the blood increase. Jaundice due to acute parenchymal liver disease is associated with increases in transaminases (AST/ALT). Acute jaundice in the presence of an ALT of > 1000 U/L is highly suggestive of an infectious cause such as hepatitis A, B and E, drugs such as paracetamol or hepatic ischaemia. Imaging is essential, not only to exclude a post-hepatic cause but to identify features suggestive of cirrhosis or portal hypertension, and to define the patency of the hepatic vasculature. Liver biopsy has an important role in defining the aetiology of unexplained hepatocellular jaundice and the extent of liver injury.

Post-hepatic jaundice

Post-hepatic jaundice may be caused by obstruction of the larger bile ducts, usually between the hilum and the ampulla of Vater, resulting in biliary dilatation on imaging.

The causes of post-hepatic jaundice are listed in Box 23.10. Post-hepatic jaundice is most commonly due to diseases affecting the extrahepatic bile ducts, which are often amenable to surgical or endoscopic correction.

Clinical features (Box 23.13) comprise those due to cholestasis itself, those due to secondary infection (cholangitis) and those of the underlying condition (Box 23.14). Post-hepatic jaundice is characteristically associated with pale stools, dark urine and itch, although these features also occur with intrahepatic cholestasis. If the gallbladder is palpable, the jaundice is unlikely to be caused by biliary obstruction due to gallstones, probably because a chronically inflamed, stone-containing gallbladder



Clinical situation
Action
Management
Isolated raised bilirubin
Recheck with conjugated (direct) bilirubin
Exclude haemolysis
Reassure, as likely Gilbert syndrome
Cholestatic liver enzymes
Raised ALP
Normal GGT/elevated ALP
Liver disease unlikely: exclude alternative cause of raised ALP such as Paget disease or osteomalacia
Check GGT
Elevated GGT/elevated ALP
Full history/examination
Liver US (exclude focal lesion)
Aetiology screen with autoantibodies, immunoglobulins, ferritin and transferrin saturation (Box 23.4)
Bile ducts dilated
Consider MRCP/EUS
Bile ducts non-dilated
Consider liver biopsy
Treat underlying disorder
Raised GGT only
Full history and examination
MASLD/increased BMI: stage disease; lifestyle modification (diet and exercise)
Alcohol: stage disease; reduce alcohol to safe limits/consider abstinence
Enzyme induction from medication; review current medication
Hepatitic liver enzymes
Raised ALT or AST
Full history/examination
Liver US
Aetiology screen including hepatitis B and C, autoantibodies, immunoglobulins, caeruloplasmin, α1-antitrypsin, ferritin and transferrin saturation (Box 23.4)
MASLD: stage disease; lifestyle modification (diet and exercise)
Alcohol: stage disease; reduce alcohol to safe limits/consider abstinence
Specialist referral to treat underlying disease depending on test results and consider liver biopsy

Fig. 23.13 **Suggested management of abnormal liver function tests in asymptomatic patients.** (ALP = alkaline phosphatase; ASP = aspartate aminotransferase; BMI = body mass index; EUS = endoscopic ultrasound; GGT = γ-glutamyl transferase; MASLD = metabolic dysfunction–associated steatotic liver disease; MRCP = magnetic resonance cholangiopancreatography; US = ultrasound)

i 23.11 Key history points in patients with jaundice

Symptoms*

- Itch
- Abdominal pain (suggests gallstones)
- Weight loss (chronic liver disease and malignancy)
- Dark urine and pale stools
- Fever ± rigors
- Dry eyes/dry mouth

Recent drug history

Other

- Alcohol history
- Exposure to intravenous drugs or blood transfusions
- Travel history and country of birth
- Metabolic syndrome (increased body mass index ± type 2 diabetes/hypertension)
- Autoimmune disease history
- Inflammatory bowel disease
- Family history of liver disease, autoimmune disease or the metabolic syndrome

*Symptoms may be absent and abnormal liver function tests detected incidentally.

cannot readily dilate. This is Courvoisier's law, and suggests that jaundice is due to a malignant biliary obstruction such as pancreatic cancer. Cholangitis is characterised by the 'Charcot triad' of jaundice, right upper quadrant pain and fever.

Cholestatic jaundice is characterised by a relatively greater elevation of ALP and GGT than ALT, although a high ALT is often seen with ductal gallstones presumably due to a cholangitic element. Ultrasound is usually the first-line imaging to determine whether there is dilatation of the biliary tree (Fig. 23.14). MRCP provides a more detailed assessment of the biliary tree, especially where ductal stones are suspected, whereas CT is preferred for assessing malignant lesions. EUS provides an additional modality for investigation of lower common bile duct obstruction.

Management of post-hepatic jaundice depends on the underlying cause and is discussed in the relevant sections below.

Acute liver failure

Acute liver failure is a rare but life-threatening condition characterised by a rapid progressive deterioration in liver function. A variety of insults can lead to marked elevation of transaminases, or acute liver injury. This

23.12 Congenital non-haemolytic hyperbilirubinaemia

Syndrome	Inheritance	Abnormality	Clinical features	Treatment
Unconjugated hyperbilirubinaemia				
Gilbert	Typically autosomal recessive, although autosomal dominant forms are also described	↓Glucuronyl transferase ↓Bilirubin uptake	Mild jaundice, especially with fasting	None necessary
Crigler–Najjar:				
Type I	Autosomal recessive	Absent glucuronyl transferase	Rapid death in neonate (kernicterus)	
Type II	Autosomal recessive	↓↓Glucuronyl transferase	Presents in neonate	Phenobarbital, phototherapy or liver transplant
Conjugated hyperbilirubinaemia				
Dubin–Johnson	Autosomal recessive	↓Canalicular excretion of organic anions, including bilirubin	Mild jaundice	None necessary
Rotor	Autosomal recessive	↓Bilirubin uptake ↓Intrahepatic binding	Mild jaundice	None necessary

23.13 Clinical features and complications of cholestatic jaundice

Cholestasis

Early features

- Jaundice
- Dark urine
- Pale stools
- Pruritus

Late features

- Malabsorption (vitamins A, D, E and K): weight loss, steatorrhoea, osteomalacia, bleeding tendency
- Xanthelasma and xanthomas

Cholangitis

- Fever
- Rigors
- Pain (if gallstones present)

23.14 Clinical features suggesting an underlying cause of cholestatic jaundice

Clinical feature	Underlying causes
Jaundice	
Static or increasing	Carcinoma Primary biliary cholangitis Primary sclerosing cholangitis
Fluctuating	Choledocholithiasis Stricture Pancreatitis Choledochal cyst Primary sclerosing cholangitis
Abdominal pain	Choledocholithiasis Pancreatitis Choledochal cyst
Cholangitis	Choledocholithiasis Stricture Choledochal cyst
Irregular hepatomegaly	Hepatic carcinoma
Palpable gallbladder	Carcinoma below cystic duct (usually pancreas)

Note that each of these diseases can give rise to almost any of the clinical features shown, but the most likely underlying cause for each of the clinical features listed is shown.

is considered severe if it results in jaundice and coagulopathy. A small number of such patients will go on to develop encephalopathy, which is the cardinal feature of acute liver failure. The absence of evidence of pre-existing liver disease distinguishes it from encephalopathy due to decompensated cirrhosis or acute-on-chronic liver failure. It is critical, therefore, to understand whether liver failure is a truly acute event or an acute deterioration on a background of pre-existing injury (which may itself not have been diagnosed). Although liver biopsy may ultimately be necessary, it is the presence or absence of the clinical features suggesting chronicity that guides the clinician.

Acute liver failure may be subclassified into hyperacute, acute and subacute, according to the interval between onset of jaundice and encephalopathy (Box 23.15). This can help to identify likely cause and predict prognosis. Patients with subacute liver failure are more likely to be drug-induced or of indeterminate cause and have a worse outcome with medical care alone than those with a hyperacute course.

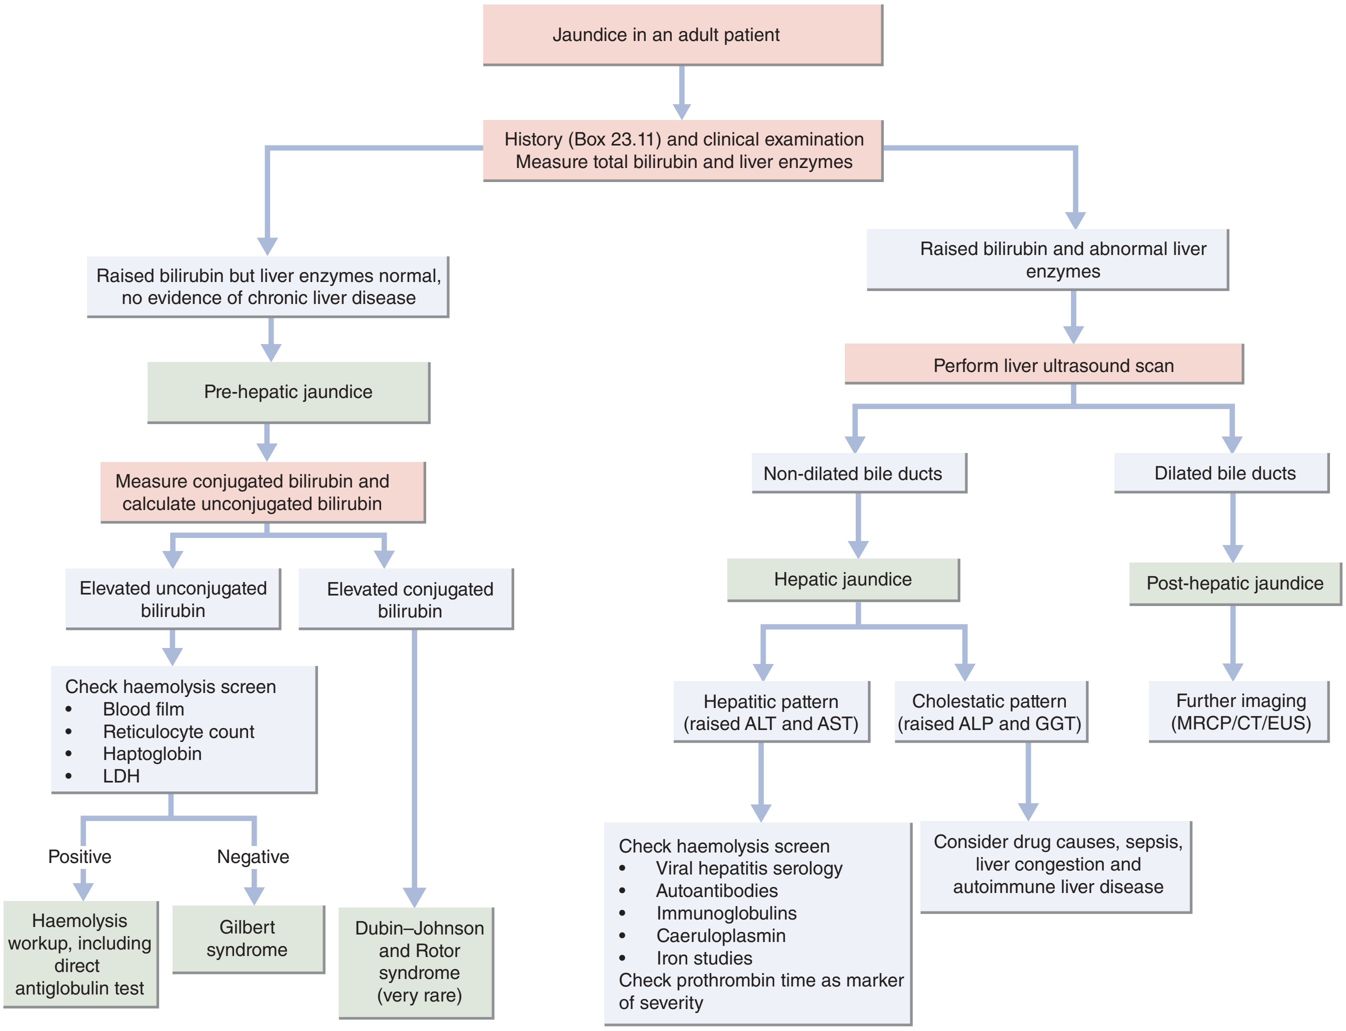
Pathophysiology

Any cause of hepatocyte damage can produce acute liver failure, provided it is sufficiently severe (Fig. 23.15). Acute viral hepatitis is the most common cause worldwide, whereas paracetamol toxicity is the most frequent cause in the UK. Acute liver failure occurs occasionally with other drugs (prescription, recreational or herbal), or from *Amanita phalloides* (mushroom) poisoning, in autoimmune hepatitis, in acute fatty liver of pregnancy, in Wilson disease, following shock and, rarely, in extensive malignant disease of the liver. In 10% of cases, the cause of acute liver failure remains unknown and these patients are often labelled as having 'non-A–E viral hepatitis' or 'cryptogenic' acute liver failure.

Clinical assessment

Cerebral disturbance (hepatic encephalopathy and/or cerebral oedema) is the cardinal manifestation of acute liver failure. The initial clinical features are often subtle and include reduced alertness and poor concentration, progressing through behavioural abnormalities, such as restlessness and aggressive outbursts, to drowsiness and coma (Box 23.16). Cerebral oedema may occur, leading to increased intracranial pressure, causing unequal or abnormally reacting pupils, fixed pupils, hypertensive episodes, bradycardia, hyperventilation, profuse sweating, local or general myoclonus, focal fits or decerebrate posturing. Papilloedema occurs rarely and is a late sign.

More general symptoms include weakness, nausea and vomiting. The patient may be jaundiced but jaundice may not be present at the outset, such as in paracetamol overdose, and there are a number of exceptions,



Jaundice in an adult patient
History (Box 23.11) and clinical examination
Measure total bilirubin and liver enzymes
Raised bilirubin but liver enzymes normal, no evidence of chronic liver disease
Pre-hepatic jaundice
Measure conjugated bilirubin and calculate unconjugated bilirubin
Elevated unconjugated bilirubin
Elevated conjugated bilirubin
Check haemolysis screen
• Blood film
• Reticulocyte count
• Haptoglobin
• LDH
Positive
Negative
Haemolysis workup, including direct antiglobulin test
Gilbert syndrome
Dubin–Johnson and Rotor syndrome (very rare)
Raised bilirubin and abnormal liver enzymes
Perform liver ultrasound scan
Non-dilated bile ducts
Dilated bile ducts
Hepatic jaundice
Post-hepatic jaundice
Hepatitic pattern (raised ALT and AST)
Cholestatic pattern (raised ALP and GGT)
Further imaging (MRCP/CT/EUS)
Check haemolysis screen
• Viral hepatitis serology
• Autoantibodies
• Immunoglobulins
• Caeruloplasmin
• Iron studies
Check prothrombin time as marker of severity
Consider drug causes, sepsis, liver congestion and autoimmune liver disease

Fig. 23.14 **Investigation of jaundice.** (CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasound; LDH = lactate dehydrogenase; LFTs = liver function tests; MRCP = magnetic resonance cholangiopancreatography)

i 23.15 Classification of acute liver failure

Type	Time: jaundice to encephalopathy	Cerebral oedema	Common causes
Hyperacute	< 7 days	Common	Paracetamol, viral
Acute	8–28 days	Common	Cryptogenic, drugs, viral
Subacute	29 days to 12 weeks	Uncommon	Cryptogenic, drugs, autoimmune hepatitis

including Reye syndrome, in which jaundice is rare. Occasionally, death may occur in hyperacute liver failure before jaundice develops. Fetor hepaticus can be present. The liver is usually of normal size but later becomes smaller. Hepatomegaly is unusual and, in the presence of a sudden onset of ascites, suggests venous outflow obstruction as the cause (Budd–Chiari syndrome, p. 928). Splenomegaly is uncommon and never prominent. Ascites and oedema are late developments and may be a consequence of fluid therapy.

Investigations

The patient should be investigated to determine the cause of the liver failure and the prognosis (Boxes 23.17, 23.18). Hepatitis B core IgM antibody is the best screening test for acute hepatitis B infection, as liver damage is due to the immunological response to the virus, which has often been eliminated, and the test for hepatitis B surface antigen (HBsAg) may be negative by the time liver failure develops. The PT rapidly becomes prolonged as coagulation factor synthesis fails; this is the laboratory test of greatest prognostic value and should be carried out at least twice daily. Vitamin K should be given to ensure that the PT is not prolonged as a result of underlying vitamin K deficiency, but fresh frozen plasma should be avoided except in major bleeding as it will interfere with the use of PT for monitoring. Factor V levels can be used instead of the PT to assess the degree of liver impairment. Plasma bilirubin also predicts outcome in non-paracetamol causes of acute liver failure. Plasma aminotransferase activity is particularly high after paracetamol overdose, reaching 100–500 times normal, but falls as liver damage progresses and is not helpful in determining prognosis. Plasma albumin remains normal unless the course is prolonged. Percutaneous liver biopsy is contraindicated because of the severe coagulopathy, but biopsy can be undertaken using the transjugular route if appropriate.

Management

Patients with acute liver failure should be monitored closely and treated in a high-dependency or intensive care unit as soon as progressive prolongation of the PT occurs or hepatic encephalopathy is identified (Box 23.19) so that treatment of complications (Box 23.20) can be initiated promptly. Specialist intensive care has dramatically improved survival in patients with acute liver failure. Conservative treatment aims to support other organ systems in the hope that hepatic regeneration will occur. Important supportive measures include treatments to minimise

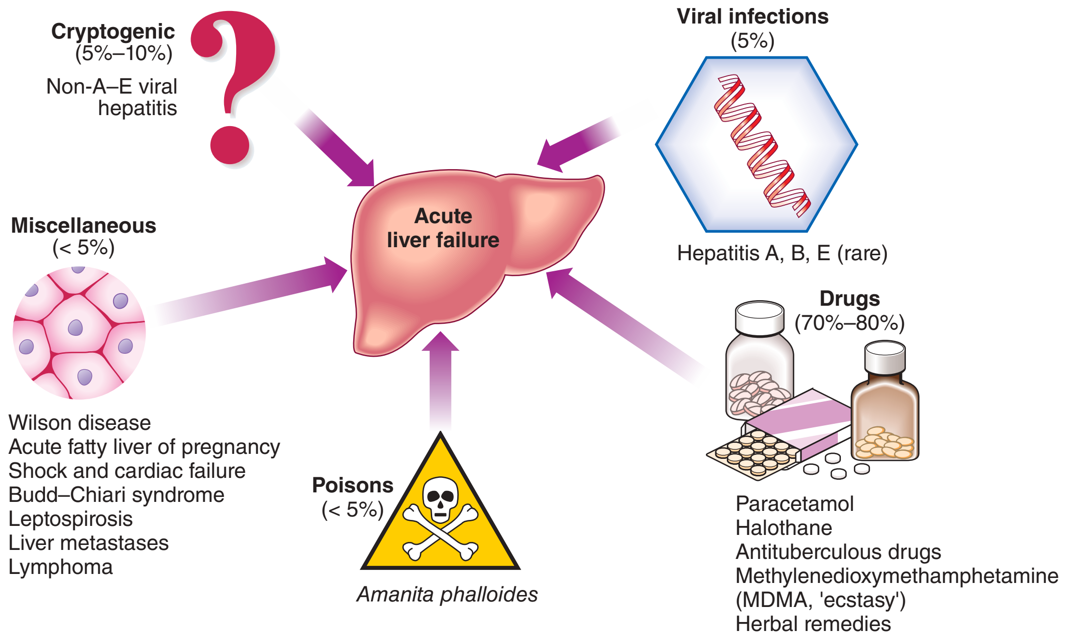


Fig. 23.15 Causes of acute liver failure in the UK. The relative frequency of the different causes varies according to geographical area.

23.16 How to assess clinical grade of hepatic encephalopathy

Clinical grade	Clinical signs
Grade 1	Poor concentration, slurred speech, slow mentation, disordered sleep rhythm
Grade 2	Drowsy but easily rousable, occasional aggressive behaviour, lethargic, flapping tremor
Grade 3	Marked delirium, drowsy, sleepy but responds to pain and voice, gross disorientation, flapping tremor
Grade 4	Unresponsive to voice, may or may not respond to painful stimuli, unconscious

23.17 Investigations to determine the cause of acute liver failure

- Toxicology screen of blood and urine
- HBsAg, IgM anti-HBc
- HAV IgM
- Anti-HEV IgM (+/– HEV PCR), HCV IgG, cytomegalovirus IgM, Epstein–Barr virus IgM
- HSV PCR
- Caeruloplasmin, serum copper, urinary copper, slit-lamp eye examination
- Autoantibodies: ANA, ASMA, LKM, SLA
- Immunoglobulins
- Ultrasound of liver and Doppler of hepatic veins

(ANA = antinuclear antibody; anti-HBc = antibody to hepatitis B core antigen; ASMA = anti-smooth muscle antibody; HAV = hepatitis A virus; HBsAg = hepatitis B surface antigen; HCV = hepatitis C virus; HEV = hepatitis E virus; HSV = herpes simplex; IgM = immunoglobulin M; LKM = liver–kidney microsomal antibody; PCR = polymerase chain reaction; SLA = soluble liver antigen)

23.18 Adverse prognostic criteria in acute liver failure

Liver failure due to paracetamol overdose

- pH < 7.25 at or beyond 24 hours following the overdose and after fluid resuscitation
  Or
- Prothrombin time > 100 secs *plus* encephalopathy grade 3 or 4 *plus* serum creatinine > 300 μmol/L (≅ 3.38 mg/dL) or anuria
  Or
- Arterial lactate > 5 mmol/L at presentation and > 4 mmol/L 24 hours later after fluid resuscitation

Liver failure due to other causes

- Prothrombin time > 100 secs (or INR > 6.5) with any grade of encephalopathy
  Or
- Any three of the following five features in the absence if encephalopathy
  - Jaundice to encephalopathy time > 7 days
  - Age < 10 or > 40 years
  - Bilirubin > 300 μmol/L (≅ 17.6 mg/dL)
  - Prothrombin time > 50 secs (or INR > 3.5)
  - Unfavourable aetiology, such as seronegative hepatitis or idiosyncratic drug reaction

If the patient meets the adverse prognostic criteria for either cause, the mortality rate is ≥ 90% and this represents an indication for possible liver transplantation. In the absence of encephalopathy, INR > 2 after vitamin K repletion is mandatory. (INR = International Normalised Ratio)

increases in intracranial pressure such as hypertonic saline or mannitol. *N*-acetylcysteine therapy should be given early to all patients in whom paracetamol toxicity is suspected, although the benefits are less clear in non-paracetamol-induced acute liver failure. Therapeutic plasma exchange (PLEX) significantly improves haemodynamic parameters in patients with acute liver failure and in some studies is associated with increased survival. Liver transplantation is an important treatment option for acute liver failure, and criteria have been developed to identify patients unlikely to survive without a transplant (see Box 23.18). Suitability for transplantation should be considered early to allow transfer to a transplant centre before meeting these criteria in appropriate cases. Survival following liver transplantation for acute liver failure is improving and 1-year survival rates of 80%–90% can be expected. A number of artificial liver support systems have been developed and evaluated for use as a bridge to either transplantation or recovery. None, however, has entered routine clinical use.

Hepatomegaly

Hepatomegaly may occur as the result of a general enlargement of the liver or because of primary or secondary liver tumour (Box 23.21). The most common liver tumours in Europe and the United States are liver metastases, whereas primary liver cancer complicating chronic viral

23.19 Monitoring in acute liver failure

Cardiorespiratory

- Pulse
- Blood pressure
- Central venous pressure
- Respiratory rate

Neurological

- Signs of intracranial hypertension including pupillary responses. Invasive intracranial pressure monitor is now less commonly used
- Conscious level

Fluid balance

- Hourly output (urine, vomiting, diarrhoea)
- Input: oral, intravenous

Blood analyses

- Arterial blood gases
- Peripheral blood count (including platelets)
- Sodium, potassium, HCO^{3-}, calcium, magnesium
- Creatinine, urea
- Glucose (2-hourly in acute phase)
- Prothrombin time

Infection surveillance

- Cultures: blood, urine, throat, sputum, cannula sites
- Chest X-ray
- Temperature

23.20 Complications of acute liver failure

- Encephalopathy and cerebral oedema
- Hypoglycaemia
- Metabolic acidosis
- Infection (bacterial, fungal)
- Renal failure
- Multi-organ failure (hypotension and respiratory failure)

23.21 Causes of hepatomegaly

- Liver metastases
- Cirrhosis (early): metabolic dysfunction–associated steatotic liver disease, alcohol, haemochromatosis
- Right heart failure
- Multiple or large hepatic cysts
- Hepatic vein outflow obstruction
- Infiltration: amyloid

hepatitis is more common in Asia. Unlike carcinoma metastases, those from neuroendocrine tumours typically cause massive hepatomegaly but without significant weight loss. Cirrhosis can be associated with either hepatomegaly or reduced liver size in advanced disease.

Ascites

Ascites is present when there is accumulation of free fluid in the peritoneal cavity. Small amounts of ascites are asymptomatic, but with larger accumulations of fluid (> 1 L) there is abdominal distension, fullness in the flanks, shifting dullness on percussion and, when the ascites is marked, a fluid thrill/fluid wave. Other features include eversion of the umbilicus, herniae, abdominal striae, divarication of the recti and scrotal oedema. Dilated superficial abdominal veins may be seen if the ascites is due to portal hypertension.

23.22 Causes of ascites

Low SAAG	High SAAG
Common causes	
Malignant disease: Hepatic Peritoneal	Cirrhosis Cardiac failure
Other causes	
Acute pancreatitis Lymphatic obstruction Infection: Tuberculosis Nephrotic syndrome Protein-losing enteropathy Severe malnutrition	Hepatic venous occlusion: Budd–Chiari syndrome[1] Sinusoidal obstruction syndrome
Rare causes	
Hypothyroidism Meigs syndrome[2]	Constrictive pericarditis

[1] Early Budd–Chiari syndrome presents with ascites with high protein content (> 25 g/L) and elevated SAAG. In chronic Budd–Chiari syndrome the protein concentration may fall but SAAG remains elevated.

[2] Meigs syndrome is the association of a right pleural effusion with or without ascites and a benign ovarian tumour. The ascites resolves on removal of the tumour. Although usually reported as being associated with a low SAAG, it can also be seen with a high SAAG.

(SAAG = serum-ascites albumin gradient; see text)

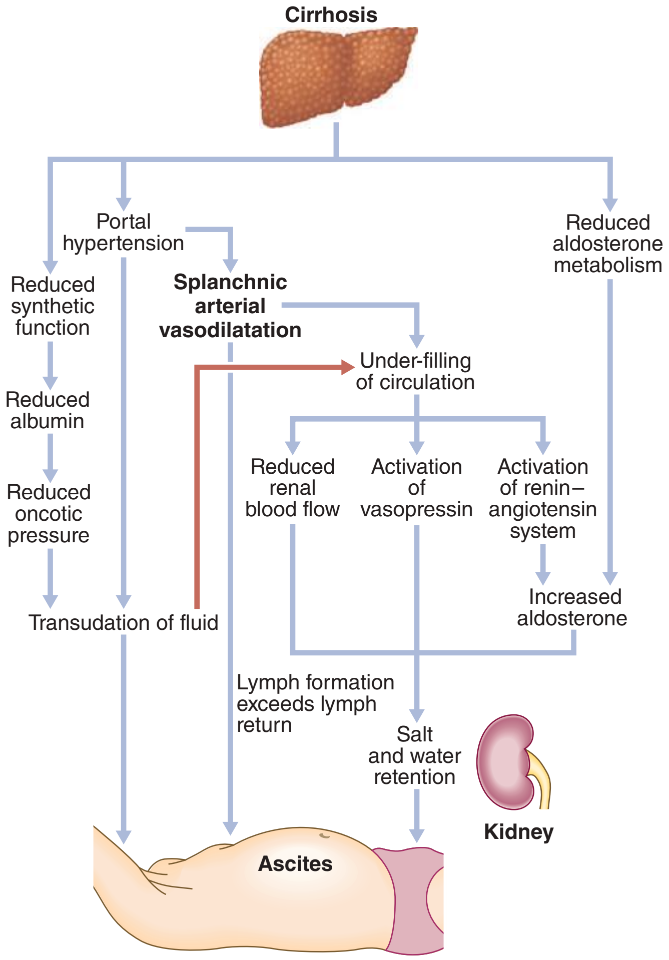
Pathophysiology

The causes of ascites are shown in Box 23.22. The most common causes of ascites are cirrhosis, intra-abdominal malignancy and heart failure. Many primary disorders of the peritoneum and visceral organs can also cause ascites, and these need to be considered even in a patient with chronic liver disease. Splanchnic arterial vasodilatation is thought to be the main factor leading to ascites in cirrhosis. This is mediated by vasodilators (mainly nitric oxide) that are released when portal hypertension causes shunting of blood into the systemic circulation. Systemic arterial pressure falls due to pronounced splanchnic vasodilatation as cirrhosis advances. This leads to activation of the renin–angiotensin system with secondary aldosteronism, increased sympathetic nervous activity, increased atrial natriuretic hormone secretion and altered activity of the kallikrein–kinin system (Fig. 23.16). These systems tend to normalise arterial pressure initially but produce salt and water retention. In this setting, the combination of splanchnic arterial vasodilatation and portal hypertension alters intestinal capillary permeability, promoting accumulation of fluid within the peritoneum.

Investigations

Ultrasonography is the best means of detecting ascites, particularly in the obese and those with small volumes of fluid. Paracentesis (if necessary under ultrasonic guidance) can be used to obtain ascitic fluid for analysis. The appearance of ascitic fluid may point to the underlying cause (Box 23.23). Pleural effusions are found in about 10% of patients, usually on the right side (hepatic hydrothorax); most are small and identified only on chest X-ray, but occasionally a massive hydrothorax occurs. Pleural effusions, particularly those on the left side, should not be assumed to be due to the ascites.

Measurement of the serum-ascites albumin gradient (SAAG) is often the most useful tool to distinguish the underlying cause of ascites. Cirrhotic patients typically develop ascites with a low protein concentration (protein concentration < 25 g/L (2.5 g/dL)) and relatively few cells. However, in up to 30% of patients, the total protein concentration is > 30 g/L (3.0 g/dL). A SAAG gradient of > 11 g/L (1.1 g/dL) is 96% predictive that ascites is due to portal hypertension. Venous outflow obstruction due to cardiac failure or hepatic venous outflow obstruction can also cause a SAAG of > 11 g/L (1.1 g/dL) but, unlike in cirrhosis, the total protein content



Cirrhosis
Portal hypertension
Reduced aldosterone metabolism
Reduced synthetic function
Splanchnic arterial vasodilatation
Under-filling of circulation
Reduced albumin
Reduced renal blood flow
Activation of vasopressin
Activation of renin–angiotensin system
Reduced oncotic pressure
Increased aldosterone
Transudation of fluid
Lymph formation exceeds lymph return
Salt and water retention
Kidney
Ascites

Fig. 23.16 Pathogenesis of ascites.

23.23 Ascitic fluid: appearance and analysis

Cause/appearance

- Cirrhosis: clear, straw-coloured
- Malignant disease: bloody
- Infection: cloudy
- Biliary communication: heavy bile staining
- Lymphatic obstruction: milky-white (chylous)

Useful investigations

- Ascitic albumin (plus serum albumin) and ascitic protein
- Neutrophil count
- Cytology
- Microscopy and culture
- Amylase
- Triglycerides

23.24 Some drugs containing relatively large amounts of sodium or causing sodium retention

High sodium content

- Alginates
- Antacids
- Antibiotics
- Phenytoin
- Effervescent preparations (e.g. aspirin, calcium, paracetamol)
- Sodium valproate

Sodium retention

- Carbenoxolone
- Glucocorticoids
- Metoclopramide
- Non-steroidal anti-inflammatory drugs
- Oestrogens

is usually >25 g/L (2.5 g/dL). Conversely, conditions including nephrotic syndrome, protein-losing enteropathy and severe malnutrition result in ascites with low protein concentration and a SAAG of <11 g/L (1.1 g/dL) due to diminished serum oncotic pressure.

A SAAG of <11 g/L (1.1 g/dL) typically occurs with high ascites protein concentration of <25 g/L (2.5 g/dL) raising the possibility of infection (especially tuberculosis), malignancy, pancreatic ascites or, rarely, hypothyroidism. Ascitic amylase activity of >1000 U/L identifies pancreatic ascites, whereas low ascites glucose concentrations suggest malignant disease or tuberculosis. Cytological examination may reveal malignant cells but has a low sensitivity unless large volumes are sent. Polymorphonuclear leucocyte counts of >250 × 10^6/L strongly suggest infection (spontaneous bacterial peritonitis; see below). Laparoscopy can be valuable in detecting peritoneal disease.

The presence of triglyceride at a level >1.1 g/L (110 mg/dL) is diagnostic of chylous ascites and suggests anatomical or functional abnormality of lymphatic drainage from the abdomen. Chylous ascites has a characteristic milky-white appearance.

Management

Successful treatment relieves discomfort but does not prolong life; if over-vigorous, it can produce serious disorders of fluid/electrolyte balance, hepatorenal syndrome with acute kidney injury and precipitate hepatic encephalopathy (see below). Treatment of portal hypertensive ascites is based on restricting sodium intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Non-portal hypertensive ascites due to malignancy is treated with paracentesis, but fluid replacement is generally not required. During management of ascites, the patient should be weighed regularly. Diuretics should be titrated to remove no more than 1 L of fluid (or 1 kg body weight) daily to avoid excessive fluid depletion.

Sodium restriction

Restriction of dietary sodium intake is essential to achieve negative sodium balance, and a few patients can be managed satisfactorily by this alone. Restriction of sodium intake to 100 mmol/24 hrs (a no added salt diet) is usually adequate. Drugs containing relatively large amounts of sodium, and those promoting sodium retention, such as non-steroidal anti-inflammatory drugs (NSAIDs), must be avoided (Box 23.24) Restriction of water intake to 1.0–1.5 L/24 hrs is rarely needed unless the plasma sodium falls below 125 mmol/L.

Diuretics

Most patients require diuretics in addition to sodium restriction. Spironolactone (100–400 mg/day) is the first-line drug because it is a powerful aldosterone antagonist; it can, however, cause painful gynaecomastia and hyperkalaemia, in which case eplerenone (50–100 mg) or amiloride (5–10 mg/day) can be substituted. This is often combined with a loop diuretic, such as furosemide (40–160 mg/day). Patients must be monitored for electrolyte imbalance and renal dysfunction. Diuresis may be improved if patients are rested in bed, perhaps because renal blood flow increases in the horizontal position. Patients who do not respond to maximal doses of spironolactone and furosemide (diuretic-resistant), or who are unable to tolerate these doses due to hyponatraemia or renal impairment (diuretic-intolerant), are considered to have refractory ascites and should be treated by other measures.

Paracentesis

First-line treatment of refractory ascites is large-volume paracentesis. Paracentesis to dryness is safe, provided the circulation is supported with an intravenous colloid such as human albumin (6–8 g per litre of ascites removed, usually as 100 mL of 20% or 25% human albumin solution (HAS) for every 2–3 L of ascites drained). Paracentesis can be used as an initial therapy or when other treatments fail. Drains should be removed after 6–12 hours to reduce risk of infection. Long-term tunnelled peritoneal drains are now available.

Transjugular intrahepatic portosystemic stent shunt

A transjugular intrahepatic portosystemic stent shunt (TIPSS; p. 902) can relieve resistant ascites but does not prolong life; it may be an option where the only alternative is frequent, large-volume paracentesis. TIPSS can be used in patients awaiting liver transplantation or in those with reasonable liver function but can aggravate encephalopathy in those with poor function.

Complications

Renal failure

Renal dysfunction is commonly seen in patients with liver cirrhosis, related to pre-renal, intrinsic and post-renal causes. It is most frequently related to dehydration, diuretic therapy and/or sepsis. However, patients with cirrhosis and ascites may develop a distinct type of renal dysfunction termed hepatorenal syndrome.

Hepatorenal syndrome

Hepatorenal syndrome (HRS) is renal dysfunction that occurs in patients with portal hypertension and reduced renal perfusion, resulting from both haemodynamic alterations in the arterial circulation (splanchnic vasodilatation/renal vasoconstriction) and overactivity of endogenous vasoactive systems. HRS has traditionally been classified into two subtypes, but the terminology has recently changed to reflect changes in the understanding and definition of both acute kidney injury (AKI) and chronic kidney disease (CKD).

Hepatorenal syndrome with acute kidney injury (HRS-AKI), formerly known as type I HRS, involves a rapid reduction in renal function (AKI) that is usually precipitated by an acute event, including bacterial infection, gastrointestinal haemorrhage, alcoholic hepatitis or acute liver failure, which disturbs the abnormal renal haemodynamics. Type I HRS has a poor prognosis.

Traditionally HRS was diagnosed with a serum creatinine cut-off of >1.5 g/dL (>133 μmol/L), but this has been modified to use a change in renal function from baseline and removing the cut-off threshold. This was necessary to avoid delay in diagnosis and initiation of treatment for HRS. The diagnostic criteria from HRS-AKI are shown in Box 23.25.

HRS with non-acute kidney injury (HRS-NAKI), formerly type II HRS, is a stable or slowly progressive form of renal dysfunction developing over weeks to months, in the absence of an obvious precipitant. It typically develops in patients with diuretic-resistant ascites.

Management of HRS-AKI involves identifying and treating precipitating factors. Diuretics and β-adrenoceptor antagonists (β-blockers) should be discontinued. Nephrotoxic drugs including vasodilators and non-steroidal anti-inflammatories should be stopped. Infections should be sought and treated. Volume replacement should be used to treat fluid loss/deficits. Intravenous albumin infusions in combination with terlipressin (1–2 mg every 4–6 hours) have been shown to improve short-term survival. In countries where terlipressin is not available, a combination of midodrine, octreotide and albumin may be used. Noradrenaline (norepinephrine) and albumin can be used in the intensive care setting. TIPSS may be effective for treatment of HRS in highly selected patients. Haemodialysis may be considered in patients who fail to respond to treatment as either a bridge to transplant (in suitable patients) or as a bridge to recovery in patients with a reversible liver injury (typically acute liver failure).

i 23.25 Diagnostic criteria for hepatorenal syndrome with acute kidney injury

- Diagnosis of cirrhosis, acute liver failure, acute-on-chronic liver failure
- Increase in serum creatinine ≥ 26.5 μmol/L (≥ 0.3 mg/dL) within 48 hours or $\geq 50\%$ from baseline according to IAC-AKI criteria *and/or*
- Urinary output ≤ 0.5 mL/kg per hr for ≥ 6 hrs
- No response after 2 consecutive days of diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 g/kg body weight to a maximum of 100 g
- Absence of shock
- No current or recent treatment with nephrotoxic drugs
- Absence of parenchymal kidney disease, as defined as
  1. Absence of pre-existing significant proteinuria (>500 mg/day)
  2. Absence of pre-existing microhaematuria (>50 RBC per high power field)
  3. Normal findings on renal ultrasound

(AKI = acute kidney injury; IAC = International Ascites Club; RBC = red blood cells)

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) is the most common bacterial infection in patients with cirrhosis, and results from translocation of bacteria from the intestine into ascites. It may present with abdominal pain or fever in a patient with obvious features of cirrhosis and ascites. However, abdominal signs are mild or absent in about one-third of patients, and it may present with hepatic encephalopathy or a non-specific deterioration. SBP is associated with a high rate of acute kidney injury and mortality, and prompt recognition is critical. It should always therefore be considered in the assessment of any unwell patient with cirrhosis and ascites. Diagnostic paracentesis may show cloudy fluid, and an ascites neutrophil count of $>250 \times 10^6$/L almost invariably indicates infection. Most organisms isolated are of enteric origin and *Escherichia coli* is the most frequently found. Ascitic culture in blood culture bottles gives the highest yield of organisms. SBP needs to be differentiated from other intra-abdominal emergencies, and the finding of multiple organisms on culture should arouse suspicion of a perforated viscus.

Treatment should be started immediately with broad-spectrum antibiotics, such as cefotaxime or piperacillin/tazobactam. Patients with jaundice or renal impairment also benefit from intravenous albumin (1.5 g/kg on day 1 and 1.0 g/kg on day 3). Recurrence of SBP is common but is reduced by prophylactic antibiotics such as norfloxacin (400 mg/day) or co-trimoxazole (960 mg/day). Primary antibiotic prophylaxis also reduces the incidence of SBP in patients with low ascitic protein <15 g/L.

Prognosis

Only 10%–20% of patients survive for 5 years from the first appearance of ascites due to cirrhosis. The outlook is not universally poor, however, and is best in those with well-maintained liver function and a good response to therapy. The prognosis is also better when a treatable cause for the underlying cirrhosis is present or when a precipitating cause for ascites, such as excess salt intake, is found. The mortality at 1 year is 50% following the first episode of bacterial peritonitis.

Hepatic encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by liver disease that occurs in 30%–40% of patients with cirrhosis. It causes a spectrum of symptoms ranging from mild fluctuating cognitive impairment to coma. The degree of encephalopathy can be graded from 1 to 4, and this is useful in assessing progression or response to therapy (see Box 23.16). The earliest features are very mild and easily overlooked, but as the condition becomes more severe, inability to concentrate, delirium, disorientation, drowsiness, slurring of speech and eventually coma develop. Seizures are rare. Examination usually shows a flapping tremor (asterixis), inability to perform simple mental arithmetic tasks or to draw objects such as a star (constructional apraxia, p. 879) and, as the condition progresses, hyper-reflexia and bilateral extensor plantar responses. Hepatic encephalopathy rarely causes focal neurological signs; if these are present, other causes must be sought. Fetor hepaticus, a sweet musty odour to the breath, is usually present but is more a sign of liver failure and portosystemic shunting than of hepatic encephalopathy. Rarely, chronic hepatic encephalopathy (hepatocerebral degeneration) gives rise to variable combinations of cerebellar dysfunction, Parkinsonian syndromes, spastic paraplegia and dementia.

Many conditions can cause similar presentations to hepatic encephalopathy (Box 23.26). Simple delirium needs to be differentiated from infection, alcohol withdrawal and Wernicke encephalopathy, and coma from subdural haematoma, which can occur after a fall, especially in alcohol misuse. When an episode develops acutely, a precipitating factor may be found (Box 23.27).

Pathophysiology

Hepatic encephalopathy is thought to be due to a disturbance of brain function provoked by circulating gut-derived neurotoxins that are normally metabolised by the liver and excluded from the systemic circulation. Affected patients usually have evidence of both liver failure and portosystemic shunting of blood, but the balance between these varies between individuals. Some degree of liver failure is a key factor, as portosystemic shunting of blood alone hardly ever causes encephalopathy. The 'neurotoxins' causing encephalopathy are unknown but are thought to be mainly nitrogenous substances produced in the gut, at least in part by bacterial action. Ammonia has traditionally been considered an important factor, but the correlation between serum ammonia levels and encephalopathy is poor. Recent interest has focused on γ-aminobutyric acid (GABA) as a mediator, along with octopamine, amino acids, mercaptans and fatty acids that can act as neurotransmitters. The brain in cirrhosis may also be sensitised to other factors, such as drugs that can precipitate hepatic encephalopathy (see Box 23.27). Disruption of the function of the blood–brain barrier is a feature of acute hepatic failure and may lead to cerebral oedema.

Investigations

The diagnosis can usually be made clinically; when doubt exists, an electroencephalogram shows diffuse slowing of the normal alpha waves with eventual development of delta waves. The arterial ammonia is usually increased in patients with hepatic encephalopathy. Increased concentrations can, however, occur in the absence of clinical encephalopathy, rendering this investigation of little diagnostic value.

i 23.26 Differential diagnosis of hepatic encephalopathy

- Hypoactive delirium
- Intracranial bleed (subdural/extradural haematoma)
- Drug or alcohol intoxication
- Delirium tremens/alcohol withdrawal
- Wernicke encephalopathy
- Primary psychiatric disorders
- Hypoglycaemia
- Neurological Wilson disease
- Post-ictal state

i 23.27 Factors precipitating hepatic encephalopathy

- Drugs (especially sedatives, antidepressants)
- Dehydration (including diuretics, paracentesis)
- Portosystemic shunting
- Infection
- Acute kidney injury
- Hypokalaemia
- Hyponatraemia
- Constipation
- Increased protein load (including gastrointestinal bleeding)

Management

The principles are to treat or remove precipitating causes and to suppress the production of neurotoxins by bacteria in the bowel. Lactulose is recommended following a first episode of hepatic encephalopathy. The dose should be titrated to obtain 2 to 3 bowel movements per day. It produces an osmotic laxative effect, reduces the pH of the colonic content, thereby limiting colonic ammonia absorption, and promotes the incorporation of nitrogen into bacteria. Phosphate enemas may be required in patients where the oral route is compromised or in patients with refractory constipation. Rifaximin (550 mg twice daily) is a well-tolerated, non-absorbed antibiotic that acts by reducing the bacterial content of the bowel and is effective in reducing episodes of recurrent hepatic encephalopathy. There is some evidence to support the amino acid combination L-ornithine L-arginine (LOLA) in lowering ammonia levels and improving encephalopathy. In cases of reduced conscious level, endotracheal intubation may be required for airway protection. Dietary protein restriction is no longer recommended because it can lead to a worsening nutritional state in already malnourished patients. Chronic or refractory encephalopathy is one of the main indications for liver transplantation.

Variceal bleeding

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices (Fig. 23.17) is common in chronic liver disease. Investigation and management are discussed on page 815 and the specific management of variceal bleeding on page 901.

Cirrhosis

Cirrhosis is characterised by diffuse hepatic fibrosis and nodule formation. It can occur at any age, has significant morbidity and is an important cause of premature death. It is the most common cause of portal hypertension. Worldwide, the most common causes are chronic viral hepatitis, prolonged excessive alcohol consumption and MASLD, but any condition leading to persistent or recurrent hepatocyte injury may lead to cirrhosis. The causes of cirrhosis are listed in Box 23.28.

Cirrhosis may also occur in prolonged biliary injury, as is found in primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC) and post-surgical biliary strictures. Persistent impairment of venous return from the liver, such as is found in sinusoidal obstruction syndrome (SOS; previously termed veno-occlusive disease), Budd–Chiari syndrome and cardiac hepatopathy, can also result in cirrhosis.

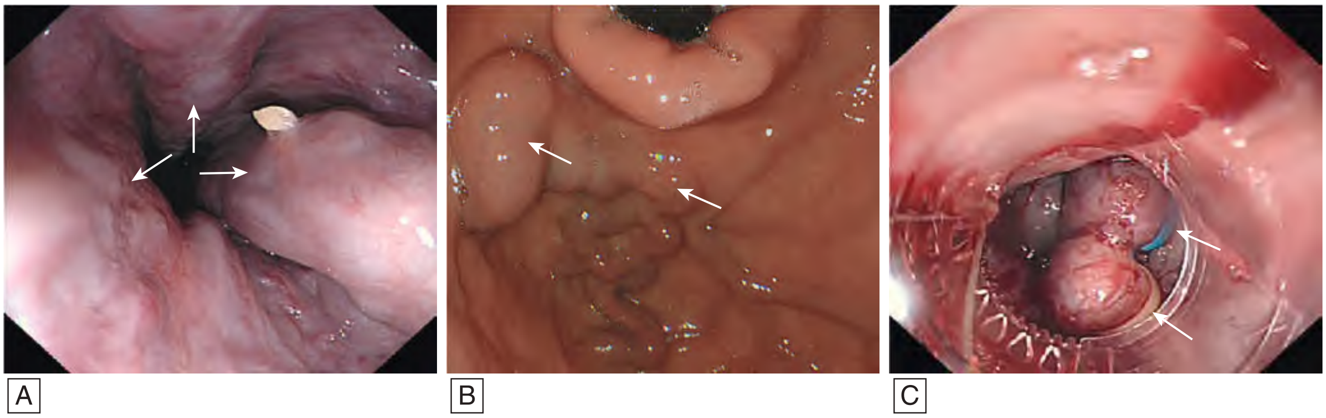


Fig. 23.17 Endoscopic view of oesophageal varices. **A** Oesophageal varices (arrows) at the lower end of the oesophagus with a prominent white fibrin plug at the site of recent haemorrhage. **B** Gastric varices (arrows). **C** Appearance of oesophageal varices following application of strangulating bands (band ligation, arrows).

i 23.28 Causes of cirrhosis

- Alcohol
- Chronic viral hepatitis (B or C)
- Metabolic dysfunction–associated steatotic liver disease
- Immune:
    - Primary biliary cholangitis
    - Primary sclerosing cholangitis
    - Autoimmune hepatitis
- Genetic:
    - Haemochromatosis
    - Wilson disease
    - Alpha-1-antitrypsin deficiency
- Biliary:
    - Secondary biliary cirrhosis
    - Cystic fibrosis
- Cryptogenic (unknown)
- Chronic venous outflow obstruction
- Cardiac hepatopathy with chronic hepatic congestion

Pathophysiology

Following liver injury, stellate cells in the space of Disse (see Fig. 23.3) are activated by cytokines produced by Kupffer cells and hepatocytes. This transforms the stellate cell into a myofibroblast-like cell, capable of producing collagen, pro-inflammatory cytokines and other mediators that promote hepatocyte damage and tissue fibrosis (see Fig. 23.4).

Cirrhosis is technically a histological diagnosis (Fig. 23.18), although most cases will be diagnosed on a combination of imaging, clinical signs and fibrosis markers. Fibrosis evolves over years, and the progression can be described semi-quantitatively (Fig. 23.19). Fibrosis and widespread hepatocyte loss lead to distortion of the normal liver architecture that disrupts the hepatic vasculature, causing portosystemic shunts. These changes usually affect the whole liver but can be patchy especially in biliary diseases such as primary biliary cholangitis (PBC).

Clinical features

The clinical presentation is highly variable. Some patients are asymptomatic and the diagnosis is made incidentally at ultrasound or at surgery. Others present with isolated hepatomegaly, splenomegaly, signs of portal hypertension or hepatic insufficiency. When symptoms are present, they are often non-specific and include weakness, fatigue, muscle cramps, weight loss, anorexia, nausea and upper abdominal discomfort (Box 23.29). Cirrhosis can occasionally present with shortness of breath due to a large right pleural effusion, or with hepatopulmonary syndrome (p. 928).

Hepatomegaly is common when the cirrhosis is due to alcohol-related liver disease or haemochromatosis. Progressive hepatocyte destruction and fibrosis gradually reduce liver size as the disease progresses in other causes of cirrhosis. The liver is often hard, irregular and non-tender. Jaundice is mild when it first appears and is due primarily to a failure to excrete bilirubin. Palmar erythema (redness over the thenar and hypothenar eminences) can be seen early in the disease but is of limited diagnostic value, as it occurs in many other conditions associated with a hyper-dynamic circulation, including pregnancy, as well as being found in some healthy people. Spider telangiectasias (or spider naevi) occur and comprise a central arteriole (that occasionally raises the skin surface), from which small vessels radiate. They blanch with pressure and refill from the centre outwards, and are usually found on the hands, face and upper chest. One or two small spider telangiectasias may be present in up to 15% of young healthy adults and may occur transiently in greater numbers in the third trimester of pregnancy, but otherwise multiple spider telangiectasias are a strong indicator of liver disease. Florid spider telangiectasia and gynaecomastia are most common in alcohol-related cirrhosis, possibly related to phyto-oestrogens in alcoholic drinks. Pigmentation is most striking in haemochromatosis and in any cirrhosis associated with prolonged cholestasis. Clubbing of the fingers and toes is not a sign of cirrhosis but is seen in combination with hypoxia in hepatopulmonary syndrome.

Endocrine changes are noticed more readily in men, who show loss of male hair distribution and testicular atrophy. Gynaecomastia is common and can be due to drugs such as spironolactone. Easy bruising becomes more frequent as cirrhosis advances.

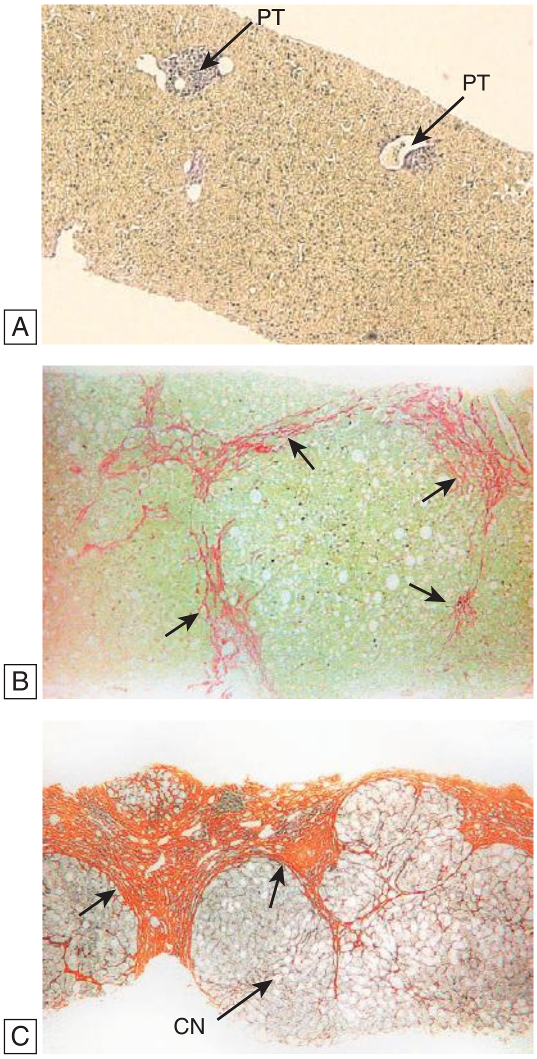

Fig. 23.18 Histological features in normal liver, hepatic fibrosis and cirrhosis. **A** Normal liver. Columns of hepatocytes 1–2 cells thick radiate from the portal tracts (PT) to the central veins. The portal tract contains a normal intralobular bile duct branch of the hepatic artery and portal venous radical. **B** Bridging fibrosis (stained pink, arrows) spreading out around the hepatic vein and single liver cells (pericellular) and linking adjacent portal tracts and hepatic veins. **C** A cirrhotic liver. The liver architecture is disrupted. The normal arrangement of portal tracts and hepatic veins is now lost and nodules of proliferating hepatocytes are broken up by strands of pink-/orange-staining fibrous tissue (arrows) forming cirrhotic nodules (CN).

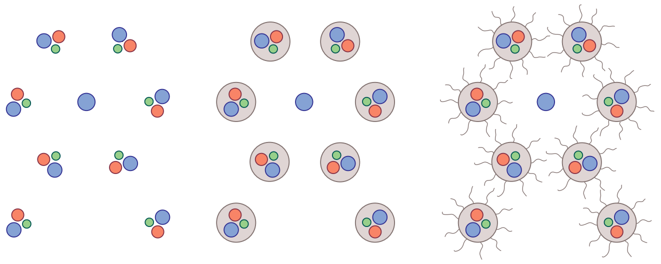
Splenomegaly and collateral vessel formation are features of portal hypertension, which occurs in more advanced disease (see below).

Jaundice, ascites, encephalopathy and variceal bleeding signify advanced disease, and are associated with a worse prognosis. The term ‘hepatic decompensation’ or ‘decompensated liver disease’ is often used when any of these features are present.

Other clinical and laboratory features may be present (Box 23.30); these include peripheral oedema, renal failure, and hypoalbuminaemia and coagulation abnormalities due to defective protein synthesis. Anaemia is common and often multifactorial, due to a combination of chronic inflammation, bone marrow suppression, haemolysis or chronic blood loss.

Management

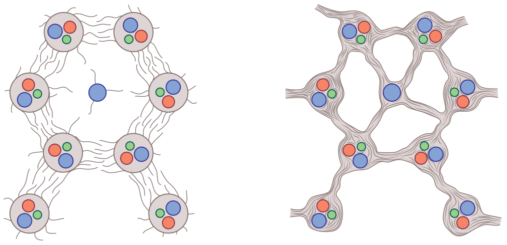
This includes treatment of the underlying cause, maintenance of nutrition and treatment of complications, including ascites, hepatic encephalopathy, portal hypertension and varices.



F0: No fibrosis

F1: Fibrous portal expansion

F2: Fibrous portal expansion with few bridges or septa



F3: Severe fibrosis with numerous bridges or septa

F4: Cirrhosis

Fig. 23.19 **Progressive liver fibrosis assessed semi-quantitatively using Metavir scoring system.**

23.29 Clinical features of hepatic cirrhosis

- Hepatomegaly (or shrunken liver)
- Jaundice
- Ascites
- Circulatory changes: spider telangiectasia, palmar erythema
- Endocrine changes: loss of libido, hair loss
  - Men: gynaecomastia, testicular atrophy, impotence
  - Women: breast atrophy, irregular menses, amenorrhoea
- Haemorrhagic tendency: bruises, purpura, epistaxis
- Portal hypertension: splenomegaly, collateral vessels, variceal bleeding
- Hepatic encephalopathy
- Other features: pigmentation (haemochromatosis), Dupuytren contracture (alcohol excess)

23.30 Features of chronic liver failure

- Worsening synthetic liver function:
  - Prolonged prothrombin time
  - Low albumin
- Jaundice
- Variceal bleeding
- Hepatic encephalopathy
- Ascites:
  - Spontaneous bacterial peritonitis
  - Hepatorenal failure

Nutrition in cirrhosis

Malnutrition is a frequent complication, affecting up to 50% of patients with decompensated cirrhosis. Loss of muscle mass (sarcopenia) is associated with a higher rate of complications including infections, encephalopathy and ascites. Although BMI is the most widely used measure of nutritional status, sarcopenia can coexist with obesity especially in patients with MASLD. Handgrip strength is a simple and inexpensive way to assess muscle function and predicts morbidity and mortality in cirrhosis. This can also be combined with further functional assessment using chair stands and balance in the Liver Frailty Index. Daily calorie intake should be no lower than 35 kcal/kg body weight with a daily protein intake of 1.2–1.5 g/kg. A late evening snack will help to minimise overnight fasting, which could otherwise trigger a catabolic state in cirrhosis. If patients are unable to achieve adequate oral intake, enteral feeding should be considered.

Screening for complications

Once the diagnosis of cirrhosis is made, the risk of oesophageal varices should be assessed by either endoscopy or non-invasive testing (transient elastography and platelet count). As cirrhosis is associated with an increased risk of hepatocellular carcinoma, patients should be placed under regular surveillance with 6-monthly ultrasound, sometimes combined with alpha-fetoprotein (AFP) measurement. Cirrhosis is associated with an increased risk of osteoporosis and associated fractures, and bone mineral density assessment is recommended in those with a 10-year risk of fracture greater than 10%.

Chronic liver failure due to cirrhosis can also be treated by liver transplantation. This currently accounts for about three-quarters of all liver transplants.

Prognosis

Most chronic liver diseases run a gradually progressive course, although many patients present with advanced disease and/or serious complications that carry a high mortality. Cirrhosis can be categorised into two prognostic groups: compensated and decompensated. Decompensated cirrhosis is defined by the presence of complications, including ascites, variceal bleeding, jaundice and encephalopathy, which are the main determinants of survival. Compensated patients have a relatively good prognosis with median survival > 12 years. However, in decompensated cirrhosis median survival is around 2 years, albeit with significant patient-to-patient variability. It should be borne in mind that longer-term prognosis is significantly more favourable when the underlying cause can be corrected, a factor which is not reflected in current scoring systems.

The Child–Pugh score is based on five factors (bilirubin, prolongation of prothrombin time, albumin, ascites and encephalopathy), as shown in Box 23.31. It is easily calculated and can stratify patients into three groups (A–C) with markedly different prognoses. Studies suggest 1-year survival of 80%–100% in groups A–B, and 11%–60% in group C. Renal dysfunction and hyponatraemia also influence prognosis. MELD (Model for End-stage Liver Disease) is a complex algorithm including serum creatinine, serum bilirubin and INR (Box 23.32). It removes the subjective grading of ascites and encephalopathy, but the overall predictive value is broadly similar to the Child-Pugh score. The MELD-Na score also incorporates serum sodium into this calculation and provides slightly better prognostic accuracy in predicting mortality in patients awaiting liver transplantation. The UKELD (United Kingdom Model of End-stage Liver Disease) score is based on the same variables as MELD-Na and is used in the United Kingdom to determine the need for liver transplantation. A score ≥ 49 indicates a 9% 1-year risk of death and is the minimum score required for listing for liver transplantation for liver failure. Although these scores give a guide to prognosis, the course of cirrhosis is unpredictable, being heavily influenced by the incidence of sporadic decompensating events such as sepsis, variceal bleeding, alcoholic hepatitis, surgery and other intercurrent illnesses.

23.31 Child–Pugh classification of prognosis in cirrhosis

Score	1	2	3
Bilirubin (µmol/L (*mg/dL*))	< 34 (*2*)	34–50 (*2–3*)	> 50 (*3*)
Albumin (g/L (*g/dL*))	> 35 (*3.5*)	28–35 (*2.8–3.5*)	< 28 (*2.8*)
Prothrombin time (secs prolonged)	< 4	4–6	> 6
Ascites	None	Mild	Marked
Encephalopathy	None	Mild	Marked

Add the individual scores:
< 7 = Child A, 7–9 = Child B, > 9 = Child C

Child–Pugh score can be easily calculated using free online calculators: www.gihep.com/calc_childs.php.

23.32 One-year survival rate depending on MELD score

MELD score	3 month mortality (%)
≤9	1.9
10–19	6.0
20–29	19.6
30–39	52.6
≥40	71.3

MELD scores can be easily calculated using free online calculators: www.mdcalc.com/calc/10437/model-end-stage-liver-disease-meld.
(MELD = Model for End-stage Liver Disease)

Surgery in cirrhosis

Patients with compensated cirrhosis can undergo most forms of surgery without significantly increased risk, but it can trigger decompensation. Surgical complications are more common in patients with decompensated cirrhosis, and the presence of portal hypertension with intra-abdominal varices can make abdominal surgery more hazardous. The risk depends on both the type of surgery and the patient's liver function and can be assessed using online risk calculators such as the VOCAL-Penn score calculator: www.vocalpennscore.com. The possibility of undiagnosed liver disease should be borne in mind in all patients in at-risk groups undergoing significant surgery.

Acute-on-chronic liver failure

Acute-on-chronic liver failure (ACLF) is a term used to describe acute decompensation of chronic liver disease with features of liver failure (jaundice and coagulopathy) and other extrahepatic organ failures. It is associated with a high short-term mortality. Common triggering events include alcoholic hepatitis, systemic infection or viral hepatitis. However, up to 40% of patients have no identifiable precipitant. Persistent inflammation and immune dysfunction results in a systemic inflammatory response syndrome leading to extrahepatic organ failure. The number of extrahepatic organs involved determines prognosis. The 28-day mortality with single organ failure (typically renal failure or hepatic encephalopathy) is 23%, increasing to 32% in patients with two organ failures and >75% in patients with three or more organ failures. Management involves identification and treatment of the precipitating event and organ support as required. Transplantation can be considered in selected patients.

Portal hypertension

Portal hypertension frequently complicates cirrhosis but has other causes. The normal hepatic venous pressure gradient (HVPG – difference between the wedged hepatic venous pressure (WHVP) and free hepatic venous pressure (FHVP); see below) is 5–6 mmHg. Clinically significant portal hypertension is present when the gradient exceeds 10 mmHg, and risk of variceal bleeding increases beyond a gradient of 12 mmHg. The causes are classified in accordance with the main sites of obstruction to blood flow in the portal venous system (Fig. 23.20). Extrahepatic portal vein obstruction is the usual source of portal hypertension in childhood and adolescence, while cirrhosis causes at least 90% of cases of portal hypertension in adults in developed countries. Schistosomiasis is the most common cause of portal hypertension worldwide but is infrequent outside endemic areas, such as Egypt.

23.33 Complications of portal hypertension

- Variceal bleeding: oesophageal, gastric, other (rare)
- Congestive gastropathy
- Hypersplenism
- Ascites
- Iron deficiency anaemia
- Renal failure
- Hepatic encephalopathy (due to portosystemic shunting)

Clinical features

The clinical features result principally from portal venous congestion and collateral vessel formation (Box 23.33). Splenomegaly is a cardinal finding, and a diagnosis of portal hypertension is unusual when splenomegaly cannot be detected clinically or by ultrasonography. The spleen is rarely enlarged more than 5 cm below the left costal margin in adults but more marked splenomegaly can occur in childhood and adolescence. Collateral vessels may be visible on the anterior abdominal wall and occasionally several radiate from the umbilicus to form a 'caput medusae' (p. 878). The most important collateral vessel formation occurs in the oesophagus and stomach, as this can be a source of severe bleeding. Rectal varices also cause bleeding and are often mistaken for haemorrhoids (which are no more common in portal hypertension than in the general population). Fetor hepaticus results from portosystemic shunting of blood, which allows mercaptans to pass directly to the lungs.

Ascites occurs as a result of renal sodium retention and portal hypertension that may be due, for example, to post-hepatic causes (hepatic outflow obstruction, p. 894) or cirrhosis.

The most important consequence of portal hypertension is variceal bleeding, which commonly arises from oesophageal varices located within 3–5 cm of the gastro-oesophageal junction, or from gastric varices. The size of the varices, endoscopic variceal features such as red spots and stripes, high portal pressure and liver failure are all factors that predispose to bleeding. Drugs capable of causing mucosal erosion, such as salicylates, other NSAIDs and oral bisphosphonates when taken incorrectly, can also precipitate bleeding. Variceal bleeding is often severe, and recurrent if preventative treatment is not given.

Pathophysiology

Increased portal vascular resistance leads to a gradual reduction in the flow of portal blood to the liver and simultaneously to the development of collateral vessels, allowing portal blood to bypass the liver and enter the systemic circulation directly. Portosystemic shunting occurs, particularly in the gastrointestinal tract and especially the distal oesophagus, stomach and rectum, in the anterior abdominal wall, and in the renal, lumbar, ovarian and testicular vasculature. Stomal varices can also occur at the site of an ileostomy. As collateral vessel formation progresses, more than half of the portal blood flow may be shunted directly to the systemic circulation. Increased portal flow contributes to portal hypertension but is not the dominant factor.

Investigations

The diagnosis can often be made clinically. Portal venous pressure measurements are rarely needed for clinical assessment or routine management but can be used to confirm portal hypertension and to differentiate sinusoidal and pre-sinusoidal forms. Pressure measurements can be made by using a balloon catheter inserted using the transjugular route (via the inferior vena cava into a hepatic vein and then hepatic venule) to measure the WHVP. This is an indirect measurement of portal vein pressure. Thrombocytopenia is common due to hypersplenism, and platelet counts are usually in the region of 100×10^9/L; values below 50×10^9/L are uncommon. Leucopenia occurs occasionally but anaemia is seldom attributed directly to hypersplenism.

Endoscopy is the most useful investigation to determine whether high-risk gastro-oesophageal varices are present (see Fig. 23.17). However, transient elastography measurement and platelet count can help to predict risk of varices non-invasively. Ultrasonography often shows features of portal hypertension, such as splenomegaly and collateral vessels, and can sometimes indicate the cause, such as cirrhosis or portal vein thrombosis. CT and magnetic resonance angiography can identify the extent of portal vein clot and check hepatic vein patency.

Management

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices is a common manifestation of chronic liver disease. In the presence of portal hypertension, the risk of a variceal bleed occurring within 2 years varies from 7% for small varices up to 30% for large varices. The mortality following a variceal bleed has improved to around 15% overall but is still about 45% in those with Child–Pugh C.

The management of portal hypertension is largely focused on the prevention and/or control of variceal haemorrhage. It is important to remember, though, that bleeding can also result from peptic ulceration, which is more common in patients with liver disease than in the general population. The investigation and management of gastrointestinal bleeding are dealt with in more detail in Chapter 22.

Primary prevention of variceal bleeding

Non-selective β-adrenoceptor blocker (NSBB) therapy has been shown to be effective both in reducing portal pressure and primary prevention of variceal bleeding in patients with oesophageal varices. The current treatment of choice for primary prophylaxis for variceal bleeding is carvedilol (6.25–12.5 mg daily) as it is more effective than other NSBBs, better tolerated and reduces the risk of decompensation and mortality in patients with compensated cirrhosis. Alternative NSBBs include propranolol and nadolol, which are less commonly used. The Baveno VII consensus guidelines (see 'Further information') recommend that patients with compensated liver cirrhosis that are predicted to have clinically significant portal hypertension (based on liver stiffness and platelet count) should be commenced on carvedilol without the need for endoscopy. Patients that are not candidates for carvedilol due to contraindications or intolerance should undergo an endoscopy for variceal screening. Medium to large (grade 2/3) oesophageal varices, if present, should then be treated with oesophageal band ligation (see Fig. 23.17). The Baveno VII guidelines emphasise the importance of monitoring arterial blood pressure in patients receiving NSBBs with the aim of achieving mean arterial pressure >65 mmHg and/or systolic blood pressure >90 mmHg. In patients with ascites that are more prone to systemic hypotension, NSBBs may need to be dose reduced or discontinued where there is persistent arterial hypotension.

Management of acute variceal bleeding

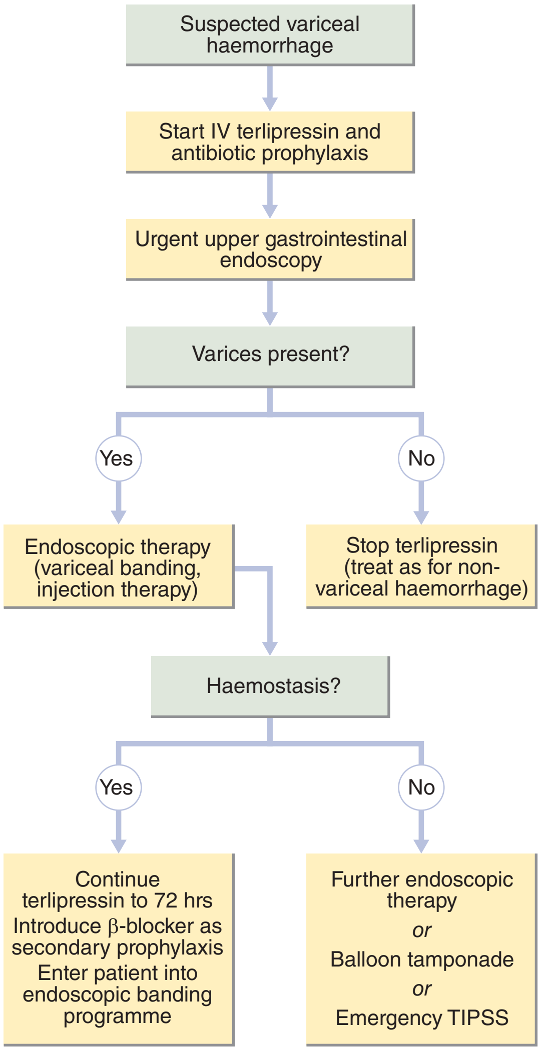
The priority in acute bleeding is to restore the circulation, not least because shock reduces liver blood flow and causes further deterioration of liver function. However, restrictive transfusion (aiming for a haemoglobin level >70 g/L) is associated with better outcomes than liberal transfusion. The source of bleeding should always be confirmed by endoscopy because about 20% of patients are bleeding from non-variceal lesions. Management of acute variceal bleeding is described in Box 23.34 and illustrated in Figure 23.21. All patients with cirrhosis and gastrointestinal bleeding should receive prophylactic broad-spectrum antibiotics, such as intravenous cephalosporin or piperacillin/tazobactam, because sepsis is common and treatment with antibiotics improves survival. The measures used to control acute variceal bleeding include vasoactive medications such as terlipressin (see below), endoscopic therapy (banding), balloon tamponade and TIPSS.

Pharmacological reduction of portal venous pressure Terlipressin is a synthetic vasopressin analogue that, in contrast to vasopressin, can be given by intermittent injection rather than continuous infusion. It reduces portal blood flow and/or intrahepatic resistance and hence brings down portal pressure. It lowers mortality in the setting of acute variceal bleeding. The dose of terlipressin is 2 mg intravenously 4 times daily until bleeding stops, and then 1 mg 4 times daily for up to 72 hours. Caution is needed in patients with severe ischaemic heart disease or peripheral vascular disease because of the drug's vasoconstrictor properties. In countries where terlipressin is not available, octreotide is a frequently used alternative.

23.34 Emergency management of variceal bleeding

Management	Reason
Intravenous fluids	To replace intravascular volume
Blood transfusion (restrictive)	To maintain haemoglobin over 7 g/dL
Vasopressor (terlipressin)*	To reduce portal pressure, acute bleeding and risk of early rebleeding
Prophylactic antibiotics (IV cephalosporin or tazobactam)	Reduces incidence of spontaneous bacterial peritonitis and improves survival in cirrhotic patients with upper GI bleeding
Emergency endoscopy	To confirm variceal rather than ulcer bleed
Variceal band ligation	To stop bleeding
Phosphate enema and/or lactulose	To prevent hepatic encephalopathy

*Caution in patients with significant coronary artery, peripheral or other vascular disease.
(GI = gastrointestinal; IV = intravenous)



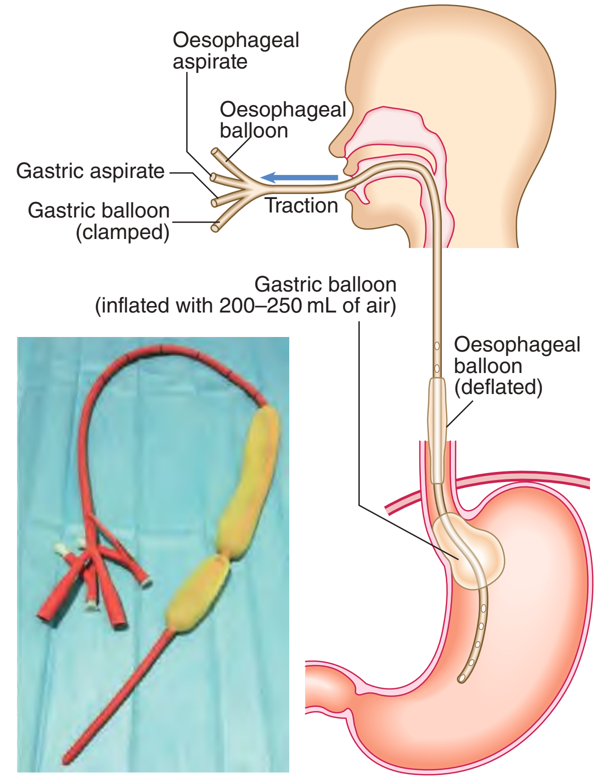
Suspected variceal haemorrhage
Start IV terlipressin and antibiotic prophylaxis
Urgent upper gastrointestinal endoscopy
Varices present?
Yes
No
Endoscopic therapy (variceal banding, injection therapy)
Stop terlipressin (treat as for non-variceal haemorrhage)
Haemostasis?
Yes
No
Continue terlipressin to 72 hrs
Introduce β-blocker as secondary prophylaxis
Enter patient into endoscopic banding programme
Further endoscopic therapy
or
Balloon tamponade
or
Emergency TIPSS

Fig. 23.21 Management of acute bleeding from oesophageal varices. (TIPSS = transjugular intrahepatic portosystemic stent shunt)

Variceal ligation Variceal ligation or banding is the most widely used initial treatment and is undertaken, if possible, at the time of diagnostic endoscopy (see Fig. 23.17C). It stops variceal bleeding in over 90% of patients and can be repeated if bleeding recurs. Band ligation involves the varices being sucked into a cap placed on the end of the endoscope, allowing them to be occluded with a tight rubber band. The occluded varix subsequently sloughs with variceal obliteration. Banding is repeated every 2–4 weeks until all varices are obliterated. Regular follow-up endoscopy is required to identify and treat any recurrence of varices. Band ligation has fewer side-effects than sclerotherapy, a technique in which varices were injected with a sclerosing agent, and has largely replaced it. Prophylactic acid suppression with proton pump inhibitors may reduce the risk of secondary bleeding from banding-induced ulceration.

In the case of gastric varices, banding is less effective and so endoscopic therapy relies on injection of agents such as thrombin or cyanoacrylate glue directly into the varix to induce thrombosis. Although highly effective, cyanoacrylate injection treatment may be complicated by 'glue embolism' to the lungs. EUS-guided coiling of gastric varices combining coiling with glue injection is an emerging technique that appears to be safe and more effective than injection therapy alone.

Active bleeding may make endoscopic therapy difficult. Protection of the patient's airway with endotracheal intubation aids the endoscopist, facilitating therapy and significantly reducing the risk of pulmonary aspiration.



Oesophageal aspirate
Oesophageal balloon
Gastric aspirate
Gastric balloon (clamped)
Traction
Gastric balloon (inflated with 200–250 mL of air)
Oesophageal balloon (deflated)

Fig. 23.22 Minnesota tube.

Balloon tamponade This technique employs a Minnesota tube, which consists of two balloons that can be positioned in the fundus of the stomach and in the lower oesophagus, respectively (Fig. 23.22). Additional lumens allow contents to be aspirated from the stomach and from the oesophagus. This technique may be used in the event of life-threatening haemorrhage if early endoscopic therapy is not available or is unsuccessful.

Endotracheal intubation prior to tube insertion reduces the risk of pulmonary aspiration. The tube should be passed through the mouth into the stomach. The gastric balloon should be inflated with 200–250 mL of air, and gentle traction applied to compress the gastro-oesophageal junction. Inadvertent inflation in the oesophagus can result in oesophageal rupture so, ideally, the gastric balloon should be inflated under direct endoscopic vision. Tamponade of the gastro-oesophageal junction with the gastric balloon will almost always control bleeding from oesophageal varices and inflation of the oesophageal balloon is rarely required. If the oesophageal balloon needs to be used because of continued bleeding, pressure should be monitored with a sphygmomanometer (to maintain < 40 mmHg) and it should be deflated for about 10 minutes every 3 hours to avoid oesophageal mucosal damage. Balloon tamponade is only a bridge to more definitive therapy. Novel endoscopic therapies such as self-expanding removable oesophageal stents and haemostatic powder spray also appear to be effective short-term alternatives in small case series.

Transjugular intrahepatic portosystemic shunt This technique, known as TIPSS, uses a stent placed between the portal vein and the hepatic vein within the liver to provide a portosystemic shunt and reduce portal pressure (Fig. 23.23). It is carried out under radiological control via the internal jugular vein; prior patency of the portal vein must be determined angiographically, coagulation deficiencies may require correction with fresh frozen plasma, and antibiotic cover is provided. Successful shunt placement stops and prevents further variceal bleeding and is an effective treatment for both oesophageal and gastric varices. The technique may be combined with radiological coiling of bleeding varices. Hepatic encephalopathy occurs in up to a third of patients following TIPSS and may require reducing the shunt diameter. Although TIPSS is associated with less rebleeding than endoscopic therapy, survival is not improved.

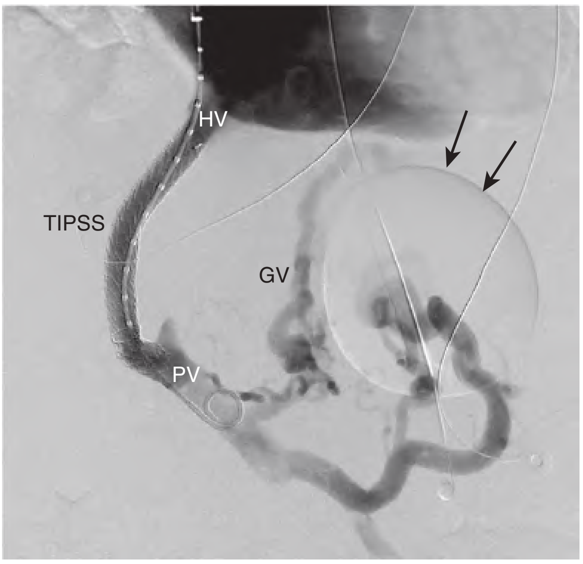


Fig. 23.23 Transjugular intrahepatic portosystemic stent shunt (TIPSS). X-ray showing placement of a TIPSS, allowing blood to flow from the portal vein (PV) into the hepatic vein (HV). Contrast can be also be seen in gastric varices (GV). Arrows show the outline of the gastric balloon of a Minnesota tube.

Portosystemic shunt surgery Surgery prevents recurrent bleeding but carries a high mortality and often leads to encephalopathy. In practice, portosystemic shunts are now reserved for when other treatments have not been successful and are offered only to patients with good liver function.

Secondary prevention of variceal bleeding

Following initial successful endoscopic therapy, patients should be entered into an oesophageal banding programme with repeated sessions of therapy at 2- to 4-week intervals until the varices are reduced or obliterated. Carvedilol should be used in combination with banding as secondary prevention. There is some evidence that early TIPSS after successful endoscopic therapy may improve survival in selected patients with advanced liver disease.

Congestive 'portal hypertensive' gastropathy

Long-standing portal hypertension causes chronic gastric congestion, which is characterised at endoscopy as multiple areas of punctate erythema ('portal hypertensive gastropathy' or 'snakeskin gastropathy') in the proximal stomach. Similar lesions may also occur more distally in the gastrointestinal tract (enteropathy and colopathy). These areas may become eroded, causing oozing from multiple sites. Acute bleeding can occur but repeated minor bleeding causing iron deficiency anaemia is more common. Anaemia may be prevented by oral iron supplements but repeated blood transfusions can become necessary. Reduction of the portal pressure using carvedilol is the best initial treatment. In selected cases, a TIPSS procedure can be considered.

Gastric antral vascular ectasia (GAVE) is an alternative cause of mucosal oozing in patients with cirrhosis. This is characterised by red spots in the distal stomach, often arranged in stripes around the pylorus ('watermelon stomach'). Therapy for GAVE is focused on endoscopic ablation using argon plasma coagulation (APC), gastric antral band ligation or radiofrequency ablation (RFA).

Infections and the liver

The liver may be subject to a number of different infections. These include hepatotropic viral infections and bacterial and protozoal infections. Each has specific clinical features and requires targeted therapies.

Viral hepatitis

This must be considered in anyone presenting with hepatitic liver blood tests (high transaminases). The causes are listed in Box 23.35.

All these viruses cause illnesses that have similar clinical and pathological features and are frequently anicteric or even asymptomatic. They differ in their tendency to cause acute and chronic infections. The features of the major hepatitis viruses are shown in Box 23.36.

Clinical features of acute infection

A non-specific prodromal illness characterised by headache, myalgia, arthralgia, nausea and anorexia usually precedes the development of jaundice by a few days to 2 weeks. Vomiting and diarrhoea may follow and abdominal discomfort is common. Dark urine and pale stools may precede jaundice. There are usually few physical signs. The liver is often tender but only minimally enlarged. Occasionally, mild splenomegaly and cervical lymphadenopathy are seen. These features are more frequent in children or those with Epstein–Barr virus (EBV) infection. Symptoms rarely last longer than 3–6 weeks. Complications may occur but are rare (Box 23.37).

Investigations

A hepatitic pattern of LFTs develops, with serum transaminases typically between 200 and 2000 U/L in an acute infection (usually lower and fluctuating in chronic infections). The ALP rarely exceeds twice the upper limit of normal. The plasma bilirubin and prothrombin time (PT) reflect the degree of liver damage. Prolongation of the PT rarely exceeds 25 seconds, except in rare cases of acute liver failure. The white cell count is usually normal with a relative lymphocytosis. Serological tests confirm the aetiology of the infection.

Management

Most individuals do not need hospital care. Drugs such as sedatives and narcotics, which are metabolised in the liver, should be avoided. Alcohol should not be taken during the acute illness. Elective surgery should be avoided in cases of acute viral hepatitis, as there is a risk of post-operative liver failure.

Liver transplantation is very rarely indicated for acute viral hepatitis complicated by liver failure.

Hepatitis A

The hepatitis A virus (HAV) belongs to the picornavirus group of enteroviruses. HAV is highly infectious and is spread by the faecal–oral route. The risk of infection is associated with poor sanitation and contamination of drinking water with virus. In occasional outbreaks, water and shellfish have been the vehicles of transmission. Infection may be asymptomatic or produce symptoms after an average incubation period of 28 days. The likelihood of symptoms relates to age. Most children under 6 years of age have no symptoms, but most adults develop jaundice. Up to 30% of adults have serological evidence of past infection but give no history of jaundice. Infected individuals excrete the virus in faeces for about 2–3 weeks before the onset of symptoms and continue to do so for a further 2 weeks or so.

i 23.35 Causes of viral hepatitis

Common	
• Hepatitis A	• Hepatitis C
• Hepatitis B ± hepatitis D	• Hepatitis E
Less common	
• Cytomegalovirus	• Epstein–Barr virus
Rare	
• Herpes simplex	• Yellow fever

Prevention					
Active	Vaccine	Vaccine	No	Prevented by hepatitis B vaccination	No
Passive	Immune serum globulin	Hyperimmune serum globulin	No		No

*All body fluids are potentially infectious, although some fluids, such as urine, are less infectious than others.

23.37 Complications of acute viral hepatitis

- Acute liver failure
- Cholestatic hepatitis (hepatitis A)
- Aplastic anaemia
- Chronic liver disease and cirrhosis (hepatitis B and C)
- Relapsing hepatitis

In contrast to hepatitis B and C, chronic infection does not occur. Almost all cases will recover fully with life-long immunity, but a very small proportion develop acute liver failure (0.1%) and may die. Infection in patients with pre-existing chronic liver disease may cause serious or life-threatening disease. In adults, a cholestatic phase with elevated ALP levels may complicate infection.

Investigations

Diagnosis of HAV infection is based on antibody testing. Only one HAV antigen has been found, and infected people make an antibody to this antigen (anti-HAV). Anti-HAV immunoglobulin (Ig)M antibody is detectable in the blood 5–10 days before the onset of symptoms and falls to low levels within about 3 months of recovery, so is diagnostic of acute HAV infection. Anti-HAV IgG antibody persists for years after infection and is a marker of previous HAV infection with resulting immunity.

Management

Infection in the community is best prevented by improving social conditions, especially overcrowding and poor sanitation. Individuals can be given substantial protection from infection by active immunisation with an inactivated HAV vaccine. Immunisation should be considered for those at particular risk, such as people travelling to endemic areas, close contacts of HAV-infected patients, older individuals, those with other major diseases (including chronic liver disease) and pregnant women.

Immediate protection can also be provided by immune serum globulin if this is given soon after exposure to the virus. The protective effect of immune serum globulin is attributed to its anti-HAV content. Intramuscular injection of immune serum globulin is recommended for close contacts of infected individuals who are less able to respond to vaccination, such as those aged 60 years or over, immunocompromised individuals or those with chronic liver disease. It may also be effective in an outbreak of hepatitis, in a school or nursery, as injection of those at risk prevents secondary spread to families. There is no role for antiviral drugs in the therapy of HAV infection.

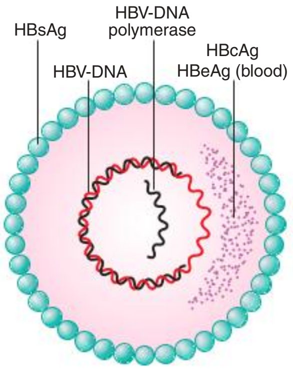

Fig. 23.24 Schematic diagram of the hepatitis B virus. Hepatitis B surface antigen (HBsAg) is a protein that makes up part of the viral envelope. Hepatitis B core antigen (HBcAg) is a protein that makes up the capsid or core part of the virus (found in the liver but not in blood). Hepatitis B e antigen (HBeAg) is part of the HBcAg that can be found in the blood and indicates infectivity. (HBV = hepatitis B virus)

Hepatitis B

The hepatitis B virus (HBV) consists of a core containing DNA and a DNA polymerase enzyme needed for virus replication, surrounded by surface protein (Fig. 23.24). The virus and some of its surface protein (known as hepatitis B surface antigen, HBsAg) circulate in the blood. The virus replicates and assembles within hepatocytes but is not directly cytotoxic; hepatocyte damage occurs during immune-mediated clearance of infected hepatocytes. The virus is able to incorporate its genetic material into the host DNA, as covalently closed circular DNA (cccDNA).

Hepatitis B is one of the most common causes of chronic liver disease and hepatocellular carcinoma worldwide. Approximately 250 million people have chronic HBV infection. There is large regional variation, with the highest rates seen in the Western Pacific and African regions.

Hepatitis B can cause acute or chronic infection. The risk of developing chronic HBV infection depends on the source and timing of exposure. Infections may occur via a number of routes (Box 23.38). In endemic areas, vertical transmission from mother to child in the perinatal period is the most common cause of infection and carries the highest risk of ongoing chronic infection (90%–95%). In contrast, exposure to HBV at an older age is much more likely to result in an acute hepatitis, with chronic infection developing in less than 5% of adult-acquired HBV.

In perinatal infection, adaptive immune responses to HBV may be absent initially, with apparent immunological tolerance. Although HBV-specific T cells are detectable in this setting, they are weak and functionally impaired. The mechanisms underlying this are incompletely understood.

Chronic hepatitis can lead to cirrhosis or hepatocellular carcinoma, usually after decades of infection (Fig. 23.25). Chronic HBV infection is a dynamic process that can be divided into five phases (Box 23.39). These are not necessarily strictly sequential and not all patients will go through all phases. Phases are considered as either ‘infection’, where circulating HBsAg is detectable but is not resulting in any current liver injury, or ‘hepatitis’ where this is accompanied by liver inflammation and fibrosis.

i 23.38 Risk factors for the acquisition of hepatitis B infection

Vertical transmission

- Hepatitis B surface antigen (HBsAg)-positive mother (especially if e antigen–positive)

Horizontal transmission

- Sexual transmission
- Intravenous drug use
- Infected unscreened blood products
- Tattoos/acupuncture needles
- Needlestick injury
- Sharing toothbrush/razor
- Close living quarters/playground play as a toddler (may contribute to high rate of horizontal transmission in Africa)

Investigations

Assessment of hepatitis B infection relies on looking at a combination of viral markers (surface antigen, e antigen and viral load) and liver markers (ALT and fibrosis markers) to determine the stage of disease.

Serology

HBV contains several antigens to which infected persons can make immune responses (Fig. 23.26). These antigens and their antibodies are important in identifying the stage of HBV infection (see Box 23.39 and Box 23.40), in addition to direct assessment of viral load by polymerase chain reaction (PCR) for HBV-DNA.

Hepatitis B surface antigen Hepatitis B surface antigen (HBsAg) is the main indicator of active infection, and a negative test for HBsAg makes HBV infection very unlikely. The exception is in acute liver failure from hepatitis B, where the liver damage is mediated by viral clearance and so HBsAg may be negative at presentation, with evidence of recent infection provided by the presence of hepatitis B core (anti-HBc) IgM (see below). In resolving acute HBV infection, antibody to HBsAg (anti-HBs) usually appears after about 3–6 months and persists for many years or perhaps permanently. Anti-HBs implies either a previous infection, in which case anti-HBc (see below) is usually also present, or previous vaccination, in which case anti-HBc is not present.

Hepatitis B core antigen Hepatitis B core antigen (HBcAg) is not found in the blood, but antibody to it (anti-HBc) appears early in the illness and rapidly reaches a high titre, which subsides gradually but then persists. Anti-HBc is initially of IgM type, with IgG antibody appearing later (see Fig. 23.26 and Box 23.40).

Hepatitis B e antigen Hepatitis B e antigen (HBeAg) is part of the core antigen that is detectable in the blood and can be used as an indicator of viral replication. Seroconversion to e antigen (loss of HBeAg and development of anti-HBe antibody) indicates a partial immune control of the virus and is associated with a significant drop in viral load. This typically

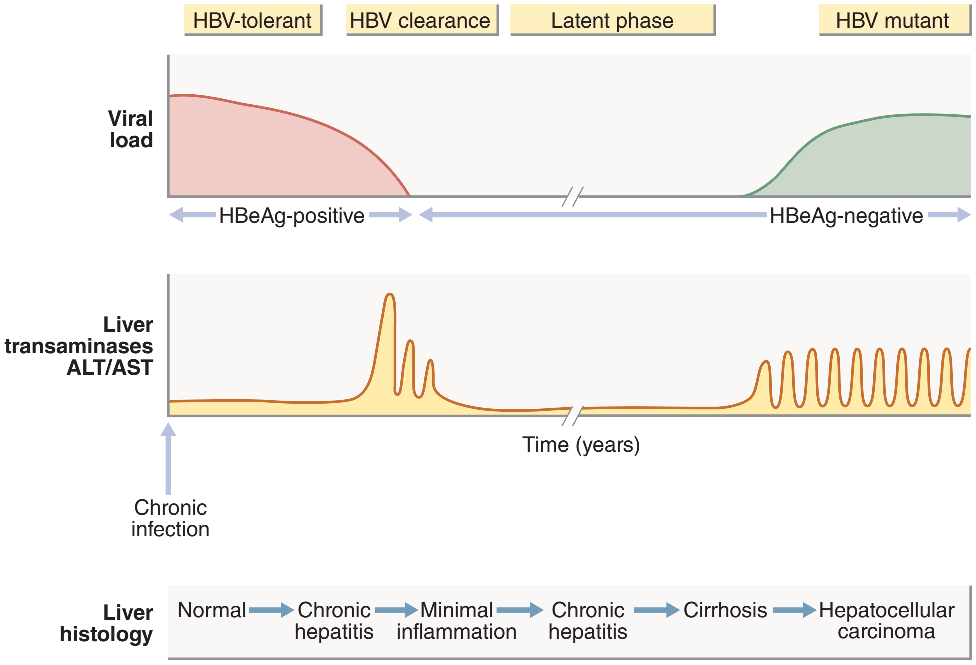

Fig. 23.25 Natural history of chronic hepatitis B virus (HBV) infection. There is an initial immunotolerant phase with high levels of virus and normal liver biochemistry. An immunological response to the virus then occurs, with elevation in serum transaminases, which causes liver damage: chronic hepatitis. If this response is sustained over many years and viral clearance does not occur promptly, chronic hepatitis may result in cirrhosis. In individuals with a successful immunological response, viral load falls, HBe antibody (HBeAb) develops and there is no further liver damage. Some individuals may subsequently develop HBV-DNA mutants that escape from immune regulation, and viral load again rises with further chronic hepatitis. Mutations in the core protein result in the virus’s inability to secrete HBe antigen despite high levels of viral replication; such individuals have HBeAg-negative chronic hepatitis. (ALT = alanine aminotransferase; AST = aspartate aminotransferase)

23.39 The five phases of chronic hepatitis B virus (HBV) infection

Phase	HBsAg	HBeAg	Viral load	ALT	Histology	Notes
HBeAg positive chronic infection	+	+	+++ (> 10^7 IU/mL)	Normal	Normal/minimal necroinflammation	Prolonged in perinatally infected individuals; may be short or absent if infected as an adult. High viral load and therefore very infectious. Previously known as ‘immune-tolerant’
HBeAg-positive chronic hepatitis	+	+	++ (10^4–10^7 IU/mL)	Raised	Moderate/severe necroinflammation	May last weeks or years. Risk of cirrhosis or HCC if prolonged. Previously known as ‘immune-reactive’
HBeAg-negative chronic infection	+	–	+/– (< 2000 IU/mL)	Normal	Normal/minimal necroinflammation	Low risk of cirrhosis or HCC in majority. Previously known as ‘inactive carrier’
HBeAg-negative chronic hepatitis	+	–	Fluctuating +/++ (> 2000 IU/mL)	Raised/ fluctuating	Moderate/severe necroinflammation	May represent late immune reactivation or presence of ‘pre-core mutant’ HBV. High risk of cirrhosis or HCC
HBsAg-negative phase	–	–	–/±	Normal	Normal	Ultrasensitive techniques may detect low-level HBV-DNA even after HBsAg loss

(HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HCC = hepatocellular carcinoma)

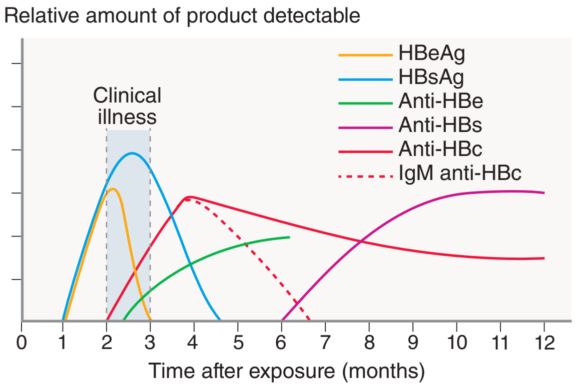

Fig. 23.26 Serological responses to hepatitis B virus infection. (anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to HBeAg; anti-HBs = antibody to HBsAg; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; IgM = immunoglobulin M)

23.40 How to interpret the serological tests of acute hepatitis B virus infection

Interpretation	HBsAg	Anti-HBc IgM	Anti-HBc IgG	Anti-HBs
Incubation period	+	–	–	–
Acute hepatitis				
Early	+	+	–	–
Established	+	+	+	–
Convalescence				
(3–6 months)	–	±	+	±
(6–9 months)	–	–	+	+
Post-infection	–	–	+	±
Immunisation without infection	–	–	–	+

+ = positive; – = negative; ± = present at low titre or absent.
(anti-HBc IgM/IgG = antibody to hepatitis B core antigen of immunoglobulin M/G type; anti-HBs = antibody to HBsAg; HBsAg = hepatitis B surface antigen)

occurs after 10–30 years in perinatally acquired infection, but within 3–6 months in adult-acquired acute infections.

Viral load and genotype

HBV-DNA can be measured by PCR in the blood. Viral loads are usually highest (in excess of 10^7 copies/mL) in HBeAg-positive infection, making this the most infectious phase. Once patients undergo HBeAg seroconversion, viral loads drop to less than 10^5 copies/mL in HBeAg-negative infection. Around 15%–20% of patients will subsequently develop further rises in viral load, due to mutations in the pre-core or core promoter region (Fig. 23.27). Such patients are classified as having HBeAg-negative chronic hepatitis.

Measurement of viral load is important in detecting flares of HBeAg-negative hepatitis and in monitoring response to antiviral therapy. Ten HBV genotypes (A–J) can also be identified using PCR. These affect the likelihood of response to pegylated interferon.

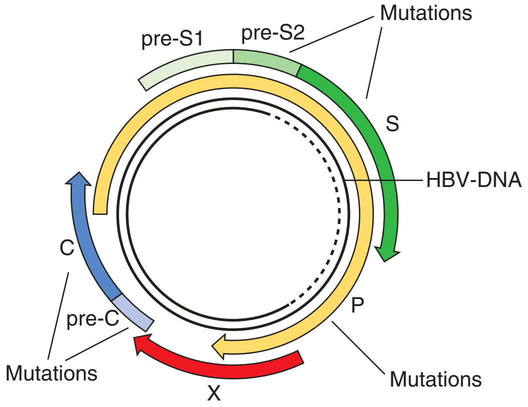

Fig. 23.27 The site of hepatitis B virus (HBV)-DNA mutations. HBV-DNA encodes four proteins: a DNA polymerase needed for viral replication (P), a surface protein (S), a core protein (C) and an X protein. The pre-C and C regions encode a core protein and an e antigen. Although mutations in the hepatitis B virus are frequent, certain mutations have important clinical consequences. Pre-C encodes a signal sequence needed for the C protein to be secreted from the liver cell into serum as e antigen. A mutation in the pre-core region leads to a failure of secretion of e antigen into serum, and so individuals have high levels of viral production but no detectable e antigen in the serum. Mutations can also occur in the surface protein and may lead to the failure of vaccination to prevent infection, since surface antibodies are produced against the native S protein. Mutations also occur in the DNA polymerase during antiviral treatment with lamivudine.

Management of acute hepatitis B

Full spontaneous recovery occurs in more than 95% of adults following acute HBV infection. Fulminant liver failure due to acute hepatitis B occurs in fewer than 1% of cases but can be life-threatening and require liver transplantation. The remaining < 5% develop chronic infection.

Treatment of acute HBV infection is supportive, with monitoring for acute liver failure. Antiviral therapy is usually only considered in those with evidence of severe liver injury with coagulopathy (INR > 1.5) or a protracted course with persistent symptoms for > 4 weeks.

Recovery from acute HBV infection occurs within 6 months and is characterised by the appearance of antibody to viral antigens. Persistence of HBeAg or HBsAg indicates chronic infection.

Management of chronic hepatitis B

Once hepatitis B infection has been present for more than 6 months, spontaneous clearance is uncommon. Most patients with chronic hepatitis B are asymptomatic and develop complications, such as cirrhosis and hepatocellular carcinoma, only after many years (see Fig. 23.25). Fibrosis accumulates during periods of liver injury (the 'hepatitis' phases) and results in cirrhosis in 15%–20% of patients with chronic HBV over 5–20 years. The rate of progression to cirrhosis is higher in HBeAg-negative hepatitis (8%–10% incidence per annum) than HBeAg-positive hepatitis (2%–5% per annum).

The ideal goal of treatment would be to achieve long-term viral clearance with loss of HBsAg, but this is rarely achieved with current therapies. There is ongoing interest in novel antivirals which may be able to achieve this, such as small interfering RNA, core assembly modulators or nucleic acid polymers. Early trials of bepirovirsen (an antisense oligonucleotide that targets HBV messenger RNA) suggest that this may lead to long-term viral clearance in around 10% of patients, but further trials are needed.

Current treatment is instead aimed at suppressing viral replication to prevent disease progression to cirrhosis or hepatocellular carcinoma. This is therefore usually targeted at those in the 'hepatitis' phases with high viral load and accompanying liver injury, either in terms of necroinflammation (raised ALT) or fibrosis (on biopsy or transient elastography). Only a minority (10%–40%) of patients with chronic hepatitis B will require treatment using this strategy. All patients with cirrhosis should be treated to prevent decompensation. Treatment may also be initiated during pregnancy in the absence of liver injury to prevent mother-to-child transmission.

Two different types of drug are currently used to treat hepatitis B: direct-acting nucleoside/nucleotide analogues and pegylated interferon-alfa.

Direct-acting nucleoside/nucleotide antiviral agents

Orally administered nucleoside/nucleotide antiviral agents are the mainstay of therapy. These act by inhibiting the reverse transcription of pregenomic RNA to HBV-DNA by HBV-DNA polymerase but do not directly affect the covalently closed circular DNA (cccDNA) template for viral replication, and so relapse is common if treatment is withdrawn. One major concern is the selection of antiviral-resistant mutations with long-term treatment. This is particularly important with some of the older agents, such as lamivudine, as mutations induced by previous antiviral exposure may also induce resistance to newer agents. Entecavir and tenofovir (see below) are potent antivirals with a high barrier to genetic resistance and so are the most appropriate first-line agents.

Lamivudine Although initially effective, long-term therapy is often complicated by the development of HBV-DNA polymerase mutants such as the 'YMDD variant', which lead to viral resistance. These occur in around half of patients after 3 years and are characterised by a rise in viral load during treatment. Outside resource-limited settings, this agent is now seldom used for the treatment of HBV but may be used to prevent reactivation in patients with past HBV infection (HBsAg-negative but HBcAb-positive) if they are undergoing treatment with rituximab or chemotherapy.

Entecavir and tenofovir Monotherapy with entecavir or tenofovir is substantially more effective than lamivudine in reducing viral load in HBeAg-positive and HBeAg-negative chronic hepatitis. Antiviral resistance mutations occur very rarely, with tenofovir in particular having a high genetic barrier to resistance. Both drugs have action against human immunodeficiency virus (HIV), and so their use as monotherapy is contraindicated in HIV-positive patients, as it may lead to HIV antiviral drug resistance. Current European guidelines advise that the other nucleoside/nucleotide antivirals should not be used as first-line monotherapy due to the induction of viral mutations, unless entecavir or tenofovir are not available or appropriate. However, HBsAg loss occurs in less than 1% of patients per year.

Pegylated interferon-alfa

Pegylated interferon-alfa (PEG-IFN) acts by augmenting the host immune response. This is most effective in patients with a pre-treatment low viral load and serum transaminases greater than twice the upper limit of normal. Treatment is for a finite period (typically around 1 year) and is associated with higher rates of HBsAg and HBeAg seroconversion than nucleoside/nucleotide agents but with greater side-effects. Interferon is contraindicated in the presence of cirrhosis, as it may cause a rise in serum transaminases and precipitate liver failure. In HBeAg-positive chronic hepatitis, PEG-IFN results in sustained HBeAg seroconversion in around 30%, and HBsAg seroconversion in 3%–5%. Response rates are higher in those with genotype A or B virus, and those with low viral load and high ALT. Sustained response rates are lower in HBeAg-negative chronic hepatitis.

Liver transplantation

Patients with advanced liver disease or hepatocellular carcinoma (HCC) may require liver transplantation. The use of nucleoside/nucleotide analogues post-transplant (with hepatitis B immunoglobulin in high-risk individuals) has made recurrent disease due to graft re-infection very uncommon, and outcomes are comparable with other indications.

Hepatocellular carcinoma risk

Chronic HBV infection is associated with an increased risk of hepatocellular carcinoma, even in the absence of cirrhosis. This risk increases with age, male sex, smoking, diabetes, family history of HCC and high viral loads. A number of scoring systems (such as REACH-B and PAGE-B) have been developed to identify high-risk non-cirrhotic patients who may benefit from HCC screening.

Prevention

Individuals are most infectious when high levels of HBV-DNA are present in the blood, typically in the HBeAg-positive infection phase. HBV-DNA can be found in saliva, urine, semen and vaginal secretions (although urine is not usually considered to be capable of transmitting infection). The virus is about ten times more infectious than hepatitis C.

A recombinant hepatitis B vaccine containing HBsAg is available (Engerix) and is capable of producing active immunisation in 95% of normal individuals. The vaccine should be offered to those at increased risk of infection who are not already immune, as evidenced by anti-HBs in the blood (Box 23.41). The vaccine is ineffective in those already infected by HBV. Following known exposure, infection can also be prevented or minimised by the intramuscular injection of specific hepatitis B immunoglobulin (HBIg) prepared from blood containing anti-HBs. This should be given within 48 hours, or at most a week, of exposure to infected blood through needlestick injury, and contamination of cuts or mucous membranes. Vaccine can be given together with HBIg (active–passive immunisation).

23.41 At-risk groups meriting hepatitis B vaccination in low-endemic areas

- Parenteral drug users
- Men who have sex with men
- Close contacts of infected individuals:
  - Newborn of infected mothers
  - Sexual contacts
- Patients on chronic haemodialysis
- Patients with chronic liver disease
- Medical, nursing and laboratory personnel

Neonates born to hepatitis B–infected mothers should be immunised at birth and given immunoglobulin. Hepatitis B serology should then be checked at 12 months of age.

Co-infection with HIV

Around 10% of the HIV-infected population has concurrent HBV, and this figure may be as high as 25% in areas where both viruses are prevalent. Up to half of injection drug users with HIV are co-infected with HBV. Co-infection increases the morbidity and mortality compared to either infection alone: there are greater levels of HBV viraemia, faster progression to chronic infection and greater risk of cirrhosis and hepatocellular carcinoma than with HBV infection alone. The immunosuppression that is seen in HIV infection can lead to loss of anti-HBs antibodies, reactivation of infection and a poorer antibody response to HBV vaccination. Pregnancy poses particular problems in co-infected patients, with increased risk of perinatal transmission of HBV to the child.

Treatment can also be problematic. Several nucleoside analogues have dual antiviral activity and some regimens have been associated with emergence of drug resistance. Co-infection is also associated with diminished response to interferons and increased resistance to lamivudine in some patients. Co-infection should be managed by specialists with expertise in this area, and combinations of antiviral agents need to be thought through carefully. Antiviral therapy should be considered for co-infected pregnant women, using drugs with dual activity, such as tenofovir with emtricitabine or lamivudine.

Globally, there is a need to identify co-infected patients earlier, especially in endemic areas, as well as a need for early effective interventions, particularly in pregnant women, to reduce perinatal transmission.

Hepatitis D

The hepatitis D virus (HDV), also known as Delta virus, is an RNA-defective virus that has no independent existence; it requires HBV's surface antigen for replication so can only infect those with hepatitis B. It has the same sources and modes of spread as hepatitis B. It can infect individuals simultaneously with HBV or can superinfect those who already have chronic HBV. Simultaneous infections give rise to acute hepatitis, which is often severe but is limited by recovery from the HBV infection. Infections in individuals with chronic HBV can cause acute hepatitis with spontaneous recovery, and occasionally there is simultaneous cessation of the chronic HBV infection. Chronic infection with HBV and HDV can also occur, and this frequently causes rapidly progressive chronic hepatitis and eventually cirrhosis.

HDV has a worldwide distribution. It is endemic in parts of the Mediterranean basin, Africa and South America, where transmission is mainly by close personal contact and occasionally by vertical transmission from mothers with HBV. In non-endemic areas, transmission is mainly a consequence of parenteral drug misuse.

Investigations

HDV contains a single antigen to which infected individuals make an antibody (anti-HDV). Delta antigen appears in the blood only transiently, and in practice diagnosis depends on detecting anti-HDV. Simultaneous infection with HBV and HDV, followed by full recovery, is associated with the appearance of low titres of anti-HDV IgM within a few days of the onset of the illness. This antibody generally disappears within 2 months but persists in a few patients. Super-infection of patients with chronic HBV infection leads to the production of high titres of anti-HDV, initially IgM and later IgG. Such patients may then develop chronic infection with both viruses, in which case anti-HDV titres plateau at high levels.

Management

Prevention of chronic hepatitis B infection prevents hepatitis D. However, in the setting of chronic co-infection, bulevirtide is an antiviral drug targeting HDV (and HBV) entry into hepatocytes which significantly reduces HDV RNA and accompanying liver injury.

Hepatitis C

Acute symptomatic infection with hepatitis C is rare. Most individuals are unaware of when they became infected and are identified only when they develop chronic liver disease. Around 70% of individuals exposed to the virus become chronically infected and late spontaneous viral clearance is rare. It is estimated that around 50 million individuals have chronic hepatitis C worldwide, with the highest prevalence in the Eastern Mediterranean region. There is no active or passive protection against hepatitis C virus (HCV).

Hepatitis C infection is usually identified in asymptomatic individuals screened because they have risk factors for infection, such as previous injecting drug use (Box 23.42), or have incidentally been found to have abnormal liver blood tests. Although most people remain asymptomatic until progression to cirrhosis occurs, fatigue can complicate chronic infection and is unrelated to the degree of liver damage.

If hepatitis C infection is left untreated, progression from chronic hepatitis to cirrhosis may occur, with 20% developing cirrhosis over 20 years. Risk factors for progression include male gender, immunosuppression (such as co-infection with HIV), prothrombotic states and heavy alcohol use. Once cirrhosis is present, 2%–5% per year will develop primary hepatocellular carcinoma, although this rate falls by around 75% following successful antiviral therapy.

Investigations

Serology and virology

HCV is an RNA virus; its genome encodes a large polypeptide precursor that is modified post-translationally to at least 10 proteins, including several antigens that give rise to antibodies in an infected person. Following an acute infection (such as a needlestick injury), HCV RNA can be detected in the blood within 2–4 weeks but it may take 6–12 weeks for antibodies to appear. Anti-HCV antibodies persist in serum even after viral clearance, whether spontaneous or post-treatment. Anti-HCV antibodies are used as the initial screening test for chronic infection, but if positive, the presence of serum HCV RNA or hepatitis C core antigen is required to confirm active infection. In cases of suspected acute infection, negative testing should be repeated after 4 weeks.

Molecular analysis

There are six common viral genotypes, the distribution of which varies worldwide. The most common genotypes are 1 (45%) and 3 (25%). Genotype has no effect on progression of liver disease but historically had a major effect on response to treatment: genotype 1 was less easy to eradicate than genotypes 2 and 3 with traditional pegylated interferon-alfa-/ribavirin-based treatments. All genotypes now have highly successful treatment options, although genotype may still be used to guide the choice of direct-acting antiviral drugs.

Liver function tests

These may be normal or show fluctuating serum transaminases, typically between 50 and 200 U/L. Jaundice can occasionally occur during acute infection and confers an increased likelihood of spontaneous viral clearance, but otherwise only appears in end-stage cirrhosis.

Fibrosis assessment

Serum transaminase levels in hepatitis C are a poor predictor of the degree of liver fibrosis. This should be assessed at diagnosis using

i 23.42 Risk factors for the acquisition of chronic hepatitis C infection

- Intravenous drug use (95% of new cases in the UK)
- Unscreened infected blood products
- Vertical transmission (3% risk)
- Needlestick injury (3% risk)
- Iatrogenic parenteral transmission (e.g. contaminated vaccination needles)
- Sharing toothbrushes/razors
- Sexual transmission (uncommon)

transient elastography, blood biomarkers or non-invasive fibrosis scoring systems such as the Fibrosis-4 (FIB-4) score or aspartate aminotransferase to platelet ratio index (APRI). Where there is diagnostic uncertainty, a liver biopsy may be required to stage the extent of liver damage.

Management

The aim of treatment is to eradicate infection, and all patients with chronic HCV infection should be treated where possible. Sustained virological response (SVR) refers to undetectable HCV RNA at least 12 weeks after treatment completion and carries a very low chance (< 1%) of subsequent relapse. Until 2013, the treatment of choice was combination therapy with pegylated interferon and ribavirin for up to 48 weeks. This treatment had many side-effects and a low SVR rate of 40%–70% depending on genotype.

Direct-acting antiviral therapies (DAAs) are interferon-free regimens with a substantially shorter treatment duration, minimal side-effects and high cure rates. There are four main classes of DAA, which are defined according to their mechanism of action and therapeutic target (Box 23.43). These compounds are targeted to specific steps in the hepatitis C viral life cycle to disrupt viral replication (Fig. 23.28). The medicines are frequently combined into single pill combinations that can be taken once daily for 8–12 weeks with SVR rates of over 95%. Whilst some DAA combinations are only licensed for specific viral genotypes, several pan-genotypic treatments are now available. Whilst the cost of these new treatments initially posed a significant financial challenge, the price of DAAs has fallen significantly in recent years and the challenges now include identification and engagement of patients with infection.

Liver transplantation should be considered when complications of cirrhosis occur. However, DAAs can be safely used even in patients with decompensated cirrhosis, and successful treatment can be associated with an improvement in liver function. It is therefore becoming less common to require liver transplantation for liver failure secondary to hepatitis C, although it may still be required for hepatocellular carcinoma. Whilst most patients will now be able to have successful antiviral treatment before transplantation, DAAs can also be used post-transplant and recurrent hepatitis C in the transplanted liver is now very rare.

Hepatitis E

Hepatitis E virus (HEV) is an RNA virus that is now thought to be the most common cause of acute viral hepatitis worldwide. Four major genotypes are described. Genotypes 1 and 2 exclusively infect humans via the faecal–oral route and cause waterborne epidemics, mainly in Asia. Genotypes 3 and 4 are mostly zoonotic (in pigs, wild boars and deer) and are transmitted to humans through undercooked meat. HEV can rarely be transmitted by blood transfusion, and blood donations in the United Kingdom are now routinely screened for hepatitis E.

HEV causes a self-limiting acute hepatitis that does not require any specific treatment. However, it can cause chronic hepatitis, progressing to cirrhosis, in immunocompromised patients, especially organ-transplant recipients. This may require a reduction in the level of immunosuppression and/or treatment with ribavirin.

23.43 Direct-acting antiviral agents for hepatitis C

Drug class	Therapeutic target	Selected drugs
Protease inhibitors (PIs)	Non-structural viral protein NS3/4A (protease that cleaves the HCV polyprotein)	Paritaprevir Grazoprevir Voxilaprevir Glecaprevir
Nucleoside polymerase inhibitors (NPIs)	Non-structural viral protein NS5B (RNA-dependent RNA polymerase needed for viral replication)	Sofosbuvir
Non-nucleoside polymerase inhibitors (NNPIs)	Non-structural viral protein NS5B (RNA-dependent RNA polymerase needed for viral replication)	Dasabuvir
NS5A replication complex inhibitors	Non-structural viral protein NS5A (assembly of viral replication complex)	Velpatasvir Ledipasvir Ombitasvir Elbasvir Pibrentasvir

Infection with genotype 1 or 2 virus during pregnancy carries a high risk of acute liver failure, which has a high mortality. Hepatitis E also causes more severe disease in those with underlying cirrhosis, resulting in decompensation or acute-on-chronic liver failure. Extrahepatic manifestations are increasingly recognised and include neurological problems such as Guillain–Barré syndrome and neuralgic amyotrophy.

Diagnosis of acute infection is usually based on detection of anti-HEV IgM antibodies but it is possible to measure HEV RNA or capsid antigen in the blood and stool (especially in immunocompromised patients).

Other forms of viral hepatitis

Non-A–E hepatitis is the term used to describe hepatitis thought to be due to a virus that is not HAV, HBV, HCV or HEV. Although the viruses above account for the majority of clinically significant hepatitis infections, other viruses can affect the liver. Cytomegalovirus and EBV infection cause abnormal LFTs in most patients and occasionally jaundice occurs. Herpes simplex is a rare cause of hepatitis in adults, most of whom are immunocompromised, but can be very severe in pregnancy. Abnormal LFTs are also common in chickenpox, measles, rubella, acute HIV and COVID-19 infection.

HIV infection and the liver

Several causes of abnormal LFTs occur in HIV infection, as shown in Box 23.44. This topic is discussed in more detail in Chapter 14. Co-infection with HIV and HBV is discussed on page 908.

Liver abscess

Liver abscesses are classified as pyogenic (bacterial), hydatid (protozoal) or amoebic.

Pyogenic liver abscess

Pyogenic liver abscesses are uncommon but important because they are potentially curable but carry significant morbidity and mortality if untreated. The mortality of liver abscesses is 5%–25%. Mortality is higher in those with multiple abscesses, underlying malignancy or other comorbidities, and delayed diagnosis.

Pathophysiology

Infection can reach the liver in several ways (Box 23.45). Pyogenic abscesses are most common in older patients and usually result from ascending infection due to biliary obstruction (cholangitis) or contiguous spread from an empyema of the gallbladder. They can also complicate dental sepsis or colonic pathology, such as cancer, diverticulitis or inflammatory bowel disease causing portal pyaemia. Abscesses complicating suppurative appendicitis used to be common in young adults but are now rare. Immunocompromised or diabetic patients are particularly likely to develop liver abscesses. Multiple abscesses are usually due to biliary obstruction and may be polymicrobial. *Escherichia coli*, *Klebsiella pneumonia* and *Streptococcus anginosus* group are the most common organisms; anaerobes such as *Bacteroides* can often be found when infection has been transmitted from large bowel pathology.

23.44 Causes of abnormal liver blood tests in HIV infection

Hepatitic blood tests

- Chronic hepatitis C
- Chronic hepatitis B
- Antiretroviral drugs
- Cytomegalovirus

Cholestatic blood tests

- Tuberculosis
- Atypical mycobacterium
- Sclerosing cholangitis due to cryptosporidia

23.45 Causes of pyogenic liver abscesses

- Biliary obstruction (cholangitis)
- Haematogenous:
    - Portal vein (intra-abdominal infections)
    - Hepatic artery (bacteraemia)
- Direct extension (cholecystitis)
- Trauma:
    - Penetrating or non-penetrating
- Infection of liver tumour or cyst

Clinical features

Patients are generally ill with fever and sometimes rigors and weight loss. Right upper quadrant abdominal pain is common, sometimes with radiation to the right shoulder. The pain may be pleuritic in nature. Tender hepatomegaly is found in more than 50% of patients. Mild jaundice may be present, becoming severe if large abscesses cause biliary obstruction. Atypical presentations are common and include anorexia, diarrhoea, dyspnoea and pyrexia of unknown origin. Necrotic colorectal metastases can be misdiagnosed as hepatic abscess.

Investigations

A raised white cell count and neutrophilia is common. Alkaline phosphatase is often raised and albumin levels are low. Blood cultures are positive in 50%–80%. The chest X-ray may show a raised right diaphragm and lung collapse, or an effusion at the base of the right lung. Liver imaging is key; ultrasound will detect at least 80% of pyogenic abscesses and CT with contrast will detect over 95%. Needle aspiration under ultrasound guidance confirms the diagnosis and provides pus for culture. Abscesses caused by gut-derived organisms require active exclusion of significant colonic pathology, such as a colonoscopy to exclude colorectal carcinoma.

Management

Pending the results of culture of blood and pus from the abscess, treatment should be commenced with a combination of antibiotics, such as ampicillin, gentamicin and metronidazole. Percutaneous aspiration or drainage with a catheter placed in the abscess under ultrasound guidance is required if the abscess is large or not responding to antibiotics. Any associated biliary obstruction and cholangitis require biliary drainage (preferably endoscopically). Surgical abscess drainage is rarely undertaken, although hepatic resection may be indicated for a chronic persistent abscess or 'pseudotumour'.

Hydatid cysts and amoebic liver abscesses

These are described in Chapter 14.

Leptospirosis

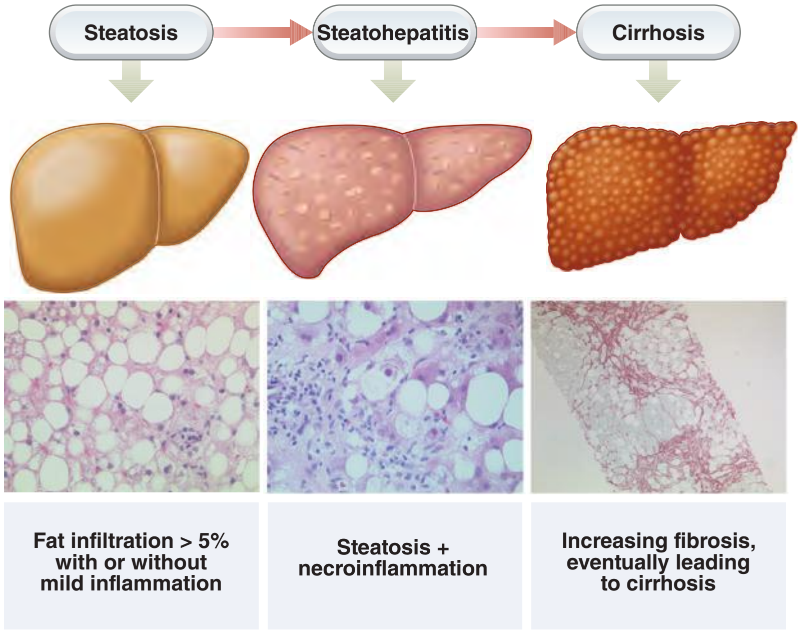
This is described in Chapter 14.

Steatotic liver disease

Steatotic liver disease describes the spectrum of problems that can be caused by the accumulation of lipid within hepatocytes, often related to alcohol consumption or metabolic dysfunction–associated steatotic liver disease (MASLD). Due to the overlapping features, these will be considered together initially with further information specific to each cause later.

Pathophysiology

Steatosis refers to the abnormal accumulation of lipids within the liver. This is the most common manifestation of alcohol misuse and is a



Steatosis
Steatohepatitis
Cirrhosis
Fat infiltration > 5% with or without mild inflammation
Steatosis + necroinflammation
Increasing fibrosis, eventually leading to cirrhosis

Fig. 23.29 Spectrum of steatotic liver disease. The rate of progression of steatotic liver disease to metabolic dysfunction–associated steatotic liver disease and cirrhosis is determined by both environmental and genetic factors, most notably a common variant it the *PNPLA3* gene.

frequent finding in patients with obesity or the metabolic syndrome. These conditions usually cause large droplets of triglycerides within hepatocytes which displace the cytoplasm and distort the nucleus (macrovesicular steatosis).

Similar appearances are also seen with chronic genotype 3 hepatitis C infection and as the result of treatment with some drugs, such as glucocorticoids and tamoxifen. Microvesicular steatosis (multiple small droplets of fat) is less common but occurs in acute fatty liver of pregnancy, certain drug reactions (valproic acid, aspirin and Reye syndrome) or inherited metabolic defects.

Macroscopically, lipid accumulation can cause the liver to enlarge and appear pale or even yellow.

The majority of patients with steatotic liver disease have lipid accumulation but without any resulting inflammation or fibrosis. This may cause abnormal liver enzymes (especially raised GGT) and abnormal appearances on liver imaging but does not result in clinically significant liver disease. A proportion, however, will develop steatohepatitis (lipid accumulation with accompanying inflammation) that can lead to progressive fibrosis and cirrhosis (Fig. 23.29 and Box 23.46).

A number of factors are known to influence the risk of developing fibrosis:

- *Genetics*. Susceptibility to cirrhosis in both alcohol-related liver disease (ArLD) and MASLD is influenced by a common genetic variant coding for an amino acid change from isoleucine to methionine at codon 148 in the adiponutrin (ADPN) protein, which is encoded by the patatin-like phospholipase domain-containing 3 (*PNPLA3*) gene. The ADPN protein is expressed in adipocytes and hepatocytes, but the mechanism by which this variant influences the risk of cirrhosis is still unclear.
- *Metabolic risk factors*. The presence of obesity and diabetes are risk factors for cirrhosis in both ArLD and MASLD, and risk increases with the addition of other features of the metabolic syndrome.
- *Alcohol use*. The amount of alcohol consumed predicts risk of cirrhosis in ArLD, but even lower levels of alcohol appear to increase risk of fibrosis in MASLD.
- *Coffee*. Coffee consumption appears to be protective against both cirrhosis and HCC in steatotic liver disease, although the mechanism is not known.
- *Intestinal microbiome*. Changes in gut microbiota composition are seen in steatotic liver disease and several microbial signatures have been linked to risk of fibrosis.

i 23.46 Clinical syndromes of steatotic liver disease

Fatty liver	
• Asymptomatic abnormal liver enzymes	• Bright (echogenic) liver on ultrasound
Steatohepatitis (10%–35%)	
• As above • Plus some develop 'alcoholic hepatitis': Rapid-onset jaundice Coagulopathy Tender hepatomegaly	• High short-term mortality
Cirrhosis (10%–20% in ArLD, 5% in MASLD)	
• Stigmata of chronic liver disease • Ascites/varices/encephalopathy	• Nodular liver (large, normal or small) • Risk of hepatocellular carcinoma

(ArLD = alcohol-related liver disease; MASLD = metabolic dysfunction–associated steatotic liver disease)

Clinical features

Steatotic liver disease is frequently asymptomatic, although it may be associated with fatigue and mild right upper quadrant discomfort related to capsular stretch. It is commonly identified as an incidental biochemical abnormality during routine blood tests (or screening of at-risk individuals) or on abdominal imaging. Many patients with steatohepatitis are asymptomatic until they present with complications of cirrhosis or portal hypertension. However, some patients with alcohol-related steatohepatitis present with acute jaundice as part of a syndrome known as alcoholic hepatitis. An equivalent to this presentation is not seen in MASLD.

Investigations

Investigations should aim to identify the underlying risk factors and to determine the extent of fibrosis. The clinical history from patient, relatives and friends is important to quantify alcohol use duration and severity. Non-liver manifestations of alcohol excess should be considered, such as chronic pancreatitis, falls and peripheral neuropathy (see Box 29.31). Features of the metabolic syndrome should be looked for and treated. Given the high prevalence of steatotic liver disease, it is also important to exclude any coexistent liver disease (such as viral, autoimmune or inherited causes), as these will increasingly occur in patients with underlying steatosis.

Biochemical tests

There is no single blood test for steatotic liver disease. Serum GGT is often raised. ALT and AST may be normal or modestly raised, usually less than twice the upper limit of normal. A reversed AST/ALT ratio may occur early in alcohol-related liver disease but is indicative of advanced fibrosis in MASLD.

A raised ferritin (with normal transferrin saturations) and raised IgA level are commonly seen in steatotic liver disease. A low-level antinuclear antibody (ANA) is seen in 20%–30% of MASLD patients.

Blood tests cannot reliably distinguish ArLD from MASLD, although a very high GGT and a markedly raised AST/ALT ratio (>2) are more suggestive of alcohol as the cause. A macrocytosis in the absence of anaemia may suggest alcohol excess but is not specific. Blood ethanol testing, carbohydrate-deficient transferrin (CDT) and phosphatidyl ethanol (PEth) may be used as markers of recent alcohol use where the history is in doubt.

Blood tests cannot distinguish steatosis from steatohepatitis but can predict the presence or absence of fibrosis. Calculated scores such as the FIB-4 score (Box 23.47) have a high negative predictive value for advanced fibrosis or cirrhosis. A low score can therefore be used to rule out advanced fibrosis in many patients. Specific serum fibrosis markers such as the Enhanced Liver Fibrosis (ELF) panel may also be used to stratify patients further.

Imaging

Ultrasound scans may confirm steatosis, with the liver appearing 'bright' due to increased echogenicity and sometimes enlarged; however, the sensitivity of ultrasound is limited for mild steatosis, so a normal scan does not exclude the diagnosis. CT, MRI or MR spectroscopy offer greater sensitivity for detecting mild steatosis but are resource-intensive and are not widely used. No routine imaging modality can distinguish steatosis from steatohepatitis. Changes of cirrhosis may be seen in more advanced disease.

Transient elastography

Transient elastography (TE) measurement is often used to assess those at risk of fibrosis. Liver stiffness can predict the likelihood of advanced fibrosis or cirrhosis. Serial changes in liver stiffness have also been shown to predict the risk of liver-related events. However, readings are less reliable in those with a BMI of over 40, and in those with ongoing alcohol excess who may have falsely high readings. Controlled attenuation parameter (CAP) is an ultrasound-based technique which can be performed simultaneously with TE to quantify steatosis non-invasively.

i 23.47 Use of FIB-4 score in predicting advanced fibrosis in MASLD

	Age <65 yr	Age ≥65 yr
Low risk	<1.30	<2.00
Intermediate risk	1.30–2.67	2.00–2.67
High risk	>2.67	>2.67

Online calculator available at gihep.com/calc_fib4.php.
From Vallet-Pichard A, Mallet V, Nalpas B, et al. FIB-4: an inexpensive and accurate marker of fibrosis in HCV infection. comparison with liver biopsy and fibrotest. Hepatology 2007;46(1):32–36.

Liver biopsy

Liver biopsy is not routinely required but can show a spectrum of histological changes (Box 23.48). It remains the 'gold standard' for assessment of the degree of inflammation and fibrosis, although due to the patchy nature of these features, biopsy is prone to sampling error. It can also be helpful to assess for any coexistent pathology if there is diagnostic uncertainty.

Alcohol-related liver disease

Alcohol is one of the most common causes of chronic liver disease worldwide, with consumption continuing to increase post-COVID pandemic in some countries. Almost all heavy drinkers will develop steatotic liver disease, although this is generally asymptomatic and will disappear within 3 months of abstinence. Only a proportion will develop steatohepatitis or cirrhosis.

Alcohol consumption can be quantified in various ways. There is large variability in the strength and amounts of alcoholic drinks (Box 23.49) and even definitions of a 'standard' drink vary widely between countries. The type of alcohol does not affect risk, but rather the total quantity of alcohol consumed. In the UK, a 'unit' of alcohol is defined as 8 g of ethanol. Current UK guidelines suggest drinking less than 14 units of alcohol per week (equivalent to 16 g of ethanol per day) but this threshold is based on a wide range of health issues, including cancer risk. The amount of alcohol required to develop liver disease varies between individuals but probably begins at around 30 g per day (25–30 units per week). For most people, consumption of more than 80 g/day (70 units/week) for more than 5 years is required to confer a significant risk of advanced liver disease. However, the relationship between quantity of alcohol consumed and risk of liver damage is not linear, and many heavy drinkers never develop clinically significant liver disease.

Drinking pattern influences risk, with studies suggesting increased risk of more severe disease both in those who drink on a daily basis

i 23.48 Histological features of steatotic liver disease (ArLD/MASLD)

- Macrovesicular steatosis
- Steatohepatitis:
  - Ballooning degeneration of hepatocytes
  - Neutrophil infiltration
  - Mallory hyaline – more frequent in ArLD
- Fibrosis:
  - Pericellular fibrosis
  - Fibrous septa, leading to cirrhosis
  - Central hyaline sclerosis (perivenular fibrosis) – more frequent in ArLD
  - Lipogranuloma
- Mega-mitochondria

i 23.49 Amounts of alcohol in selected alcohol containing drinks

Alcohol type (% alcohol)	Measure	Amount	Units*
Beer (4%)	Pint	568 mL	2.3
Wine (13%)	Glass Bottle	175 mL 750 mL	2.3 10.0
Alcopops (6%)	Bottle	330 mL	2.0
Sherry (17.5%)	Glass Bottle	125 mL 750 mL	2.2 13
Vodka/rum/gin/whisky (40%)	Small glass Bottle Bottle	25 mL 700 mL 1000 mL	1 28 40

*1 unit = 8 g of alcohol.

and in those with a high daily alcohol intake (termed 'binge' drinking). It is therefore recommended that people should limit the amount they drink in a single day and should have at least two alcohol-free days each week.

Women are more susceptible than men to the toxic effects on the liver for the same level of consumption, and consequently often have lower recommended limits. However, men are more likely to have a harmful pattern of alcohol use.

Genetic factors also predispose to the development of alcohol use disorders. Polymorphisms in genes involved in alcohol metabolism (alcohol dehydrogenase and acetaldehyde dehydrogenase) and in neurotransmitter pathways (GABA receptor A2) are linked to alcohol dependence. Excessive alcohol consumption is also frequently associated with nutritional deficiencies such as thiamin and folate deficiency, which may cause additional health problems.

Pathophysiology

Alcohol reaches peak blood concentrations after about 20 minutes, although this may be influenced by stomach contents. It is metabolised almost exclusively by the liver by one of two pathways (Fig. 23.30).

Approximately 80% of alcohol is metabolised by alcohol dehydrogenase to acetaldehyde, and then by aldehyde dehydrogenase to acetate. This process converts nicotinamide adenine dinucleotide (NAD) to NADH, altering the redox potential of the cell. Up to 20%

Fig. 23.30 Factors involved in the pathogenesis of alcohol-related liver disease. A Main biochemical pathways in alcohol-related liver disease. B Modulating factors in pathogenesis of alcohol-related liver disease. (ADH = alcohol dehydrogenase; DAMPs = damage-associated molecular patterns; FA = fatty acid; MEOS = microsomal ethanol-oxidising system; NAD = nicotinamide adenine dinucleotide; NADH = NAD-hydrogen; NADP = nicotinamide adenine dinucleotide phosphate; NADPH = NADP-hydrogen; ROS = reactive oxygen species; TGF-β = transforming growth factor beta; TNF-α = tumour necrosis factor alpha)

of alcohol is metabolised by the microsomal ethanol-oxidising system (MEOS), predominantly through the inducible cytochrome p450 enzyme CYP2E1, also generating acetaldehyde along with oxygen free radicals. The CYP2E1 enzyme also metabolises acetaminophen, and hence regular heavy drinkers are more susceptible to hepatotoxicity from low doses of paracetamol. Acetaldehyde from either pathway is toxic and causes structural alterations of cellular proteins. This results in altered mitochondrial function and generation of reactive oxygen species, leading to oxidative stress. The altered ratio of reduced/oxidised NAD interrupts beta-oxidation of fatty acids and causes up-regulation of sterol regulatory element-binding protein 1 (SREBP1), promoting fatty acid synthesis.

Damage to hepatocytes leads to stimulation of immune cells by release of damage-associated molecular patterns (DAMPs) such as mitochondrial DNA or necrotic cell debris. Alcohol also affects the gut leading to dysbiosis and increased gut permeability, delivering pathogen-associated molecular patterns (PAMPs) such as lipopolysaccharide and bacterial DNA via the portal vein, which stimulate immune cells, leading to release of tumour necrosis factor alpha (TNF-α) and interleukin (IL)-1, IL-2 and IL-8. All of these cytokines have been implicated in the pathogenesis of liver fibrosis (see Fig. 23.4).

Clinical features

There is a spectrum of alcohol-related liver disease, as shown in Box 23.46 and discussed in more detail below. Alcohol misuse may also cause damage to other organs, and this should be specifically looked for (see Box 29.31).

Alcohol-related steatotic liver disease

Alcohol-related steatotic liver disease usually presents with an incidental finding of elevated transaminases or an echogenic liver on ultrasound. It is generally asymptomatic, has a good prognosis and usually disappears within 3 months of abstinence.

Alcoholic hepatitis

Although alcohol-related liver disease is often asymptomatic until presentation with cirrhosis, a proportion of patients with steatohepatitis present with a clinical syndrome known as alcoholic hepatitis (AH). This presents with rapid-onset jaundice in the context of recent heavy alcohol use, commonly associated with tender hepatomegaly and features of the systemic inflammatory response syndrome. Unlike other types of hepatitis, the ALT level is only mildly raised (<300) and can be normal, but the AST/ALT ratio is often greater than 2. It is commonly associated with a prolonged prothrombin time, which has prognostic value. AH carries a significant risk of death in the short-term, often due to sepsis or renal failure. Severe AH is associated with a 15% 1-month mortality and 50% 1-year mortality. Cirrhosis may coexist in around half of patients with acute alcoholic hepatitis, resulting in ascites or encephalopathy. The jaundice often worsens for the first 1–2 weeks after stopping drinking. It then improves with prolonged abstinence but may take several months to resolve and may not fully reverse if cirrhosis is present. In patients with AH, subsequent return to alcohol use at any level is associated with a dose-related increase in the risk of death.

Specific prognostic scoring systems have been developed for AH. The prothrombin time (PT) and bilirubin are used to calculate a 'modified discriminant function' (mDF), also known as the Maddrey score:

$$mDF = [4.6 \times \mathit{Increase\ in\ PT}\,(sec)] + \mathit{Bilirubin}\,(mg/dL)$$

A value over 32 indicates severe disease. Historically, this group had a 40%–50% 1-month mortality, but this has dropped to 15% in more recent studies, reflecting improved medical management. A second scoring system, the Glasgow Alcoholic Hepatitis Score, uses the age, white cell count and renal function, in addition to PT and bilirubin, to assess prognosis (Box 23.50). A score of 9 or more identifies an even higher risk group with a 60% 1-month mortality.

23.50 The Glasgow Alcoholic Hepatitis Score

Score	1	2	3
Age	<50	>50	
White cell count ($\times 10^9$/L)	<15	>15	
Urea (mmol/L *(BUN mg/dL)*)	<5 (*14*)	>5 (*14*)	
PT ratio	<1.5	1.5–2.0	>2.0
Bilirubin (μmol/L (*mg/dL*))	<125 (*7.4*)	125–250 (*7.4–14.8*)	>250 (*14.8*)

A score of ≥ 9 is associated with a 60% 28-day mortality, compared to 20% for patients with a score of <9.

(BUN = blood urea nitrogen; PT = prothrombin time)

Alcohol-related cirrhosis

Palmar erythema, spider naevi and gynaecomastia are features of cirrhosis but are more common in alcohol-related cirrhosis than in cirrhosis of other aetiologies. Dupuytren contracture (thickening of the palmar fascia) is associated with chronic alcohol excess but is not predictive of cirrhosis.

Management

Cessation of alcohol consumption is the single most important treatment and prognostic factor. In anyone who has had alcoholic hepatitis or cirrhosis, life-long abstinence is advised. Abstinence reduces the risk of further decompensation and death in cirrhosis. In the acute setting, treatment of alcohol withdrawal may be required, and this is discussed in Chapter 29.

Nutrition

Patients with severe alcoholic hepatitis have high calorie requirements, and calorie intake correlates with survival. Enteral feeding via a fine-bore nasogastric tube should be considered in patients unable to meet their requirements. Vitamin supplementation (especially thiamin) is also important to prevent Wernicke encephalopathy.

Medication

The optimal treatment of severe alcoholic hepatitis has been widely debated. The STOPAH study was a large, randomised trial of prednisolone versus pentoxifylline in patients with severe alcoholic hepatitis. This showed no effect of pentoxifylline (a weak anti-TNF agent) on survival. There was a borderline reduction in 28-day mortality with prednisolone, but no ongoing benefit by 3 months or 1 year. Prednisolone was associated with increased rates of sepsis and gastrointestinal bleeding. *N*-acetylcysteine (NAC) may also limit oxidative stress. Although initial trials failed to show any benefit, a single study suggested a benefit of intravenous NAC in patients also treated with prednisolone. If the bilirubin has not fallen 7 days after starting glucocorticoids, the drugs are unlikely to reduce mortality and should be stopped.

Liver transplantation

Alcohol-related cirrhosis is a common indication for liver transplantation in Europe and the United States, with outcomes comparable to other aetiologies. The challenge is to identify patients with an unacceptable risk of returning to harmful alcohol consumption. Some programmes require a 6-month period of abstinence from alcohol before a patient is considered for transplantation. A period of abstinence will allow recovery of liver function sufficient to avoid transplantation in some, as well as identify those at highest risk of early recidivism. However, duration of abstinence is only one factor in predicting risk of relapse, and the length required is debatable. Transplantation for alcoholic hepatitis has been described in highly selected individuals with acceptable short-term outcomes but is seldom performed due to concerns about longer-term risk of recidivism.

Metabolic dysfunction–associated steatotic liver disease

Steatotic liver disease is commonly associated with obesity and the metabolic syndrome. Due to the clinical and histological similarities with ArLD, this was previously described as non-alcoholic fatty liver disease (NAFLD). However, the condition was renamed in 2023 to metabolic dysfunction–associated steatotic liver disease (MASLD) to emphasise the key role of the metabolic syndrome in its pathogenesis. MASLD describes steatotic liver disease in the presence of at least one cardiometabolic risk factor and the absence of harmful alcohol intake (<30 g/day in men, <20 g/day in women), as shown in Figure 23.31.

Rates of obesity and metabolic syndrome continue to increase and have been linked to the availability of low-cost, ultra-processed, high-sugar food and drink, and increasingly sedentary lifestyles. MASLD is now the most common chronic liver disease and is estimated by the World Health Organization to affect around a quarter of all adults. It is observed in most obese individuals, and is strongly associated with type 2 diabetes, hypertension and dyslipidaemia.

As with alcohol, only a proportion of MASLD patients will develop steatohepatitis and fibrosis that can progress to cirrhosis over many years. Fibrosis is the main determinant of liver-related outcome. However, those with less advanced fibrosis are still more likely to have extrahepatic cancers and vascular events so should still be encouraged to address their metabolic risk factors.

Pathophysiology

Hepatic steatosis arises from an imbalance in the rate of import/synthesis and the rate of export/catabolism of fatty acids (FAs). Patients with MASLD have been shown to have both increased FA influx and synthesis, and reduced FA oxidation and reduced very low-density lipoprotein (VLDL) export. The development of inflammation in steatohepatitis may be triggered by oxidative stress due to free radicals produced by FA oxidation, direct lipotoxicity from FAs, endoplasmic reticulum stress or gut-derived endotoxin.

Hepatic fat content tends to diminish as cirrhosis develops and so MASLD is likely to have been under-diagnosed in the setting of advanced liver disease, where it is thought to be the underlying cause of 30%–75% of cases in which no specific aetiology is readily identified (so-called 'cryptogenic cirrhosis').

Management

Given the high prevalence of MASLD, strategies are needed for the identification of those at highest risk of advanced fibrosis. An example of an algorithm for the assessment and risk stratification of patients with MASLD is provided in Figure 23.32.

Non-pharmacological treatment

Current treatment comprises lifestyle interventions to promote weight loss through dietary change and increased physical activity, and discouraging alcohol consumption. Sustained weight reduction of 7%–10% is associated with significant improvement histologically, with reduced fibrosis progression. A Mediterranean diet pattern and avoidance of sugar-sweetened drinks and ultra-processed foods is beneficial.

Pharmacological treatment

Until recently, the main focus of medical treatments has been on treating the associated features of the metabolic syndrome such as diabetes, hypertension and hyperlipidaemia. Although HMG-CoA reductase inhibitors (statins) have not been proven to ameliorate MASLD, there does not appear to be any increased risk of hepatotoxicity or other side-effects, and so they may be used safely to treat dyslipidaemia. Similarly, glucagon-like peptide 1 receptor agonists (GLP1RA), pioglitazone, metformin and sodium-glucose transporter 2 inhibitors are all safe and may be beneficial in patients with diabetes, although they are not directly licensed for MASLD. In patients who are unable to maintain weight loss through lifestyle measures alone, incretin-based weight loss drugs and bariatric surgery have both been shown to reduce liver fat and are potential treatment options.

Positive results with high-dose vitamin E (800 U/day) have been tempered by evidence that high doses may be associated with increased risk of prostate cancer and all-cause mortality, limiting its use.

A number of drugs are in development to specifically target MASLD and liver fibrosis. Resmetirom, a thyroid hormone receptor β-selective agonist, has been shown to reduce steatohepatitis and improve fibrosis in patients with non-cirrhotic MASLD with significant fibrosis, and is the first drug to get FDA approval specifically for MASLD. Obeticholic acid (farnesoid X receptor agonist) has also been shown to improve fibrosis in MASH but was associated with worsening low-density lipoprotein (LDL) cholesterol levels and concerns around possible hepatotoxicity. Other drugs, such as fibroblast growth factor analogues and lanifibranor, are still in phase 3 trials.

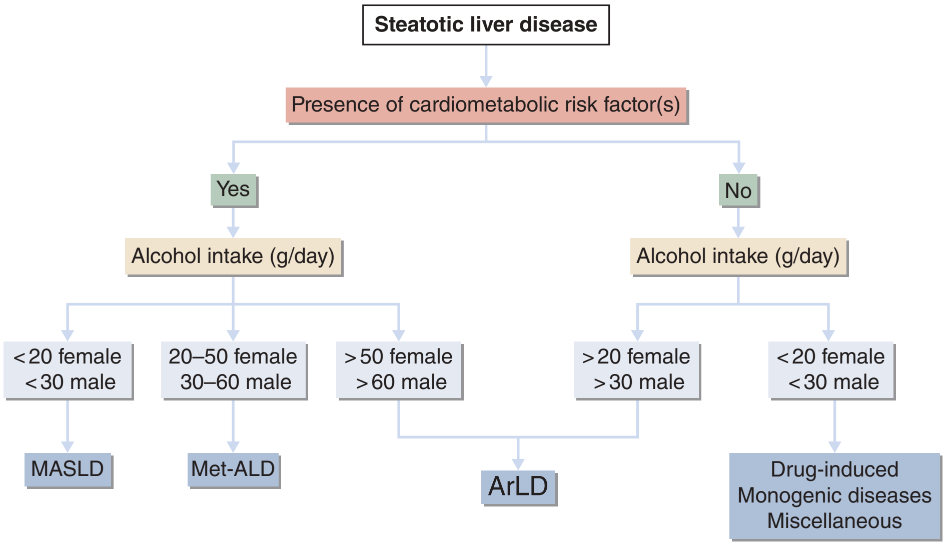

Fig. 23.31 **Classification of metabolic dysfunction–associated liver disease.** In recognition of common risk factors, steatotic liver disease is subdivided into two main categories depending on the presence or absence of cardiometabolic risk factors. Further subgroups are recognised based on age, sex and alcohol intake as shown. (ArLD = alcohol-related liver disease; MASLD = metabolic dysfunction–associated steatotic liver disease; Met-ALD = metabolic dysfunction and alcohol-related liver disease). *Adapted from European Association for the Study of the Liver (EASL); European Association for the Study of Diabetes (EASD); European Association for the Study of Obesity (EASO). Metabolic and alcohol-associated steatotic liver disease (Met-ALD)

Alcohol excess and obesity/metabolic dysfunction frequently coexist and have a synergistic effect on the liver, leading to a specific description for the overlap (see Fig. 23.31). Individuals consuming moderately heavy alcohol (20–50 g/day in women, or 30–60 g/day in men) with at least one cardiometabolic risk factor are diagnosed with Met-ALD. The management of this focuses on dealing with both causative elements.

Autoimmune liver and biliary disease

The liver is an important target for autoimmune injury. The clinical picture is dictated by the nature of the autoimmune process and, in particular, the target cell for immune injury. The disease patterns are quite distinctive for primary hepatocellular injury (autoimmune hepatitis) and biliary epithelial cell injury (primary biliary cholangitis and primary sclerosing cholangitis).

Autoimmune hepatitis

Autoimmune hepatitis (AIH) is a disease of immune-mediated injury targeting hepatocytes, which can present either as an acute severe hepatitis or chronic hepatitis leading to cirrhosis. It is a life-long disease which often runs a relapsing and remitting course. It can develop at any age, with peaks around the second and sixth decades. It is more common in women, with a 5:1 predominance. It has a strong association with other autoimmune diseases (Box 23.51).

Pathophysiology

It is characterised by the presence of serum antibodies and peripheral blood T lymphocytes reactive with self-proteins, and high levels of serum immunoglobulins – in particular, IgG. The reasons for the breakdown in immune tolerance in autoimmune hepatitis remain unclear. There are strong HLA associations (typically DR3 and DR4), indicating an underlying genetic predisposition, with a presumed environmental trigger. Exposure to the antibiotic nitrofurantoin can induce autoimmune hepatitis in a small number of cases, and cross-reactivity to viruses such as HAV and EBV has been proposed as an alternative trigger.

i **23.51 Conditions associated with autoimmune hepatitis**

- Autoimmune thyroiditis
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Primary sclerosing cholangitis
- Coeliac disease
- Type 1 diabetes
- Dermatomyositis
- Coombs-positive haemolytic anaemia
- Ulcerative colitis

Clinical features

Some patients may be asymptomatic, with a raised ALT detected on blood tests. The onset of symptoms is usually insidious, with fatigue, anorexia and arthralgia. The non-specific nature of the early features can lead to the diagnosis being missed in the early disease stages. In about one-quarter of patients the onset is acute, resembling viral hepatitis, but resolution does not occur. This acute presentation can lead to extensive liver necrosis and liver failure. Signs of chronic liver disease, especially spider naevi and hepatosplenomegaly, can be present. Approximately 25% of patients will have cirrhosis at diagnosis, and some will progress to cirrhosis despite treatment.

Investigations

There is no single diagnostic test for autoimmune hepatitis. Liver enzymes typically show raised ALT and AST, although these fluctuate. Serological tests for autoantibodies are often positive (Box 23.52). The most frequently seen autoantibody pattern is high titre of antinuclear and/or anti-smooth muscle antibodies, typically associated with raised IgG levels, frequently seen in young adult females. Disease characterised by the presence of anti-liver–kidney microsomal (LKM) antibodies, recognising cytochrome P450-IID6

23.52 Frequency of autoantibodies in chronic non-viral liver diseases and in healthy people

Disease	Antinuclear antibody (%)	Anti-smooth muscle antibody (%)	Antimitochondrial antibody (%)[1]
Healthy controls	5	1.5	0.01
Autoimmune hepatitis	80	70	15
Primary biliary cholangitis	25	35	95
Cryptogenic cirrhosis	40	30	15

[1] Patients with antimitochondrial antibody frequently have cholestatic liver function tests and may have primary biliary cholangitis (see text).

expressed on the hepatocyte membrane, is typically seen in paediatric populations and can be more resistant to treatment than ANA-positive disease. More recently, a pattern of antibody reactivity with anti-soluble liver antigen (anti-SLA) has been described typically in adult patients, often with aggressive disease and lacking autoantibodies of other specificities.

It should be noted that low titres of these antibodies occur in some healthy people and in patients with other inflammatory liver diseases. Positive ANA tests also occur in connective tissue diseases and other autoimmune diseases (with an identical pattern of homogeneous nuclear staining), while anti-smooth muscle antibody has been reported in infectious mononucleosis, chronic hepatitis C infection and a variety of malignant diseases.

Elevated serum IgG levels support the diagnosis and are associated with response to treatment, but the diagnosis is still possible in the presence of normal IgG levels. If the diagnosis of autoimmune hepatitis is suspected, liver biopsy should be performed both to confirm the diagnosis before commencing long-term immunosuppression and to stage any liver fibrosis. It typically shows an abundance of lymphocytes and plasma cells around the portal tracts (portal lymphoplasmacytic hepatitis), with inflammation extending out from the edge of the portal tracts into the lobule (interface hepatitis). Scoring systems, such as the International Autoimmune Hepatitis Group (IAIHG) criteria, are useful for epidemiological study and for assessing trial eligibility but are complex for normal clinical practice.

Management

Treatment with glucocorticoids is life-saving in autoimmune hepatitis, particularly during exacerbations of active and symptomatic disease. Initially, prednisolone (30–40 mg/day) should be given orally; the dose should then be gradually reduced as the patient and LFTs improve. Budesonide may be used in non-cirrhotic patients if steroid side-effects are problematic. Maintenance therapy is usually with azathioprine (1–2 mg/kg daily), although introduction of this is often delayed by around a month to allow the liver enzymes to settle in case it causes drug-induced hepatotoxicity. Maintenance azathioprine can be used as monotherapy or may be combined with low-dose prednisolone (ideally below 5 mg/day). Second-line therapies are unlicensed with little long-term outcome data. However, mycophenolate mofetil (MMF) appears effective in patients who are azathioprine-intolerant, but less so in azathioprine non-responders. Similarly, tacrolimus appears helpful in refractory disease.

The aims of treatment are to achieve resolution of symptoms and to completely control inflammatory activity to prevent progressive fibrosis, especially in younger patients or those with cirrhosis. As flares may be asymptomatic but increase the risk of cirrhosis or decompensation, disease activity (indicated by rising ALT and IgG levels) should be monitored regularly. Maintenance treatment is required for at least 3 years and is often continued long term, as relapse rates are high if immunosuppression is withdrawn.

Primary biliary cholangitis

Primary biliary cholangitis (PBC, formerly known as primary biliary cirrhosis) is a chronic, progressive cholestatic liver disease that predominantly affects women aged 30 and over. It is strongly associated with the presence of antimitochondrial antibodies (AMAs), which in combination with cholestatic liver enzymes are diagnostic of PBC. It is characterised by granulomatous inflammation of the portal tracts, leading to progressive damage and eventually loss of the small and middle-sized bile ducts. This, in turn, leads to fibrosis and cirrhosis of the liver.

Epidemiology

The prevalence of PBC varies across the world. It is relatively common in northern Europe and North America but is rare in Africa and Asia. There is a strong female-to-male predominance of 9:1; it is also more common among cigarette smokers. Clustering of cases has been reported, suggesting an environmental trigger in susceptible individuals.

Pathophysiology

Immune mechanisms are clearly involved. The condition is closely associated with other autoimmune non-hepatic diseases, such as thyroid disease, and there is a genetic association with HLA-DR8, together with polymorphisms in a number of other genes regulating the nature of the immune response such as IL-12 and its receptor. AMA is directed at pyruvate dehydrogenase complex, a mitochondrial enzyme complex that plays a key role in cellular energy generation. PBC-specific ANAs (such as those directed at the nuclear pore antigen gp210) have a characteristic staining pattern in immunofluorescence assays (selectively binding to the nuclear rim or nuclear dots), distinct from the homogeneous ANA staining seen in autoimmune hepatitis. Increases in serum immunoglobulin levels are frequent but, unlike in autoimmune hepatitis, it is typically IgM that is elevated.

Pathologically, chronic granulomatous inflammation destroys the interlobular bile ducts; progressive lymphocyte-mediated inflammatory damage causes fibrosis, which spreads from the portal tracts to the liver parenchyma and eventually leads to cirrhosis.

Clinical features

Primary biliary cholangitis may be detected incidentally on routine blood tests, but systemic symptoms such as fatigue and generalised itch are common. The severity of these symptoms does not correlate with the severity of the liver disease. Although there may be right upper abdominal discomfort, the typical biliary-type pain, fever and rigors seen with bacterial cholangitis do not occur in PBC. Bone pain or fractures can rarely result from osteomalacia (fat-soluble vitamin malabsorption) or, more commonly, from osteoporosis. Xanthomatous deposits occur in a minority, especially around the eyes. Scratch marks may be found in patients with severe pruritus.

Associated diseases

Autoimmune and connective tissue diseases occur with increased frequency in PBC, particularly Sjögren disease, systemic sclerosis, coeliac disease and thyroid diseases. Hypothyroidism should always be considered in patients with fatigue.

Diagnosis and investigations

The LFTs show a pattern of cholestasis (see Box 23.2). Hypercholesterolaemia is common and worsens as disease progresses but appears not to be associated with increased cardiovascular risk. AMAs are present in over 95% of patients; when they are absent, the diagnosis should not be made without obtaining histological evidence and considering cholangiography (typically MRCP) to exclude other biliary disease. Due to the peripheral nature of the ducts affected by PBC, the biliary tree should appear normal on imaging. ANA and anti-smooth muscle antibodies are present in around 15% of patients (see Box 23.52); autoantibodies found in associated diseases may also be present. Fibrosis stage should be assessed, usually using transient elastography. Liver biopsy is necessary only if there is diagnostic uncertainty. The histological features of PBC correlate poorly with the clinical features; portal hypertension can develop before the histological onset of cirrhosis.

Management

The hydrophilic bile acid ursodeoxycholic acid (UDCA), at a dose of 13–15 mg/kg daily, improves bile flow, replaces toxic hydrophobic bile acids in the bile acid pool and reduces apoptosis of the biliary epithelium. Clinically, UDCA improves LFTs, may slow down histological progression and has few side-effects; it is therefore widely used in the treatment of PBC and should be regarded as the optimal first-line treatment. Eighty percent of patients will have a good biochemical response to UDCA with a reduction in serum alkaline phosphatase to normal or near-normal levels, and this corresponds to very good long-term outcomes. However, a significant minority of patients, especially those presenting under the age of 50 years, show an inadequate response to UDCA, and have an increased risk of developing end-stage liver disease. Obeticholic acid (OCA) is a second-generation bile acid therapeutic that acts as an agonist for the nuclear farnesoid X receptor. It improves alkaline phosphatase in more than half of patients who did not respond to or tolerate UDCA and is licensed for second-line therapy in PBC. Bezafibrate, a peroxisome proliferator-activated receptor alpha (PPAR-α) agonist used predominantly to treat hyperlipidaemia, has also been shown to improve alkaline phosphatase in the majority of UDCA non-responders, although it is not licensed for this use. Emerging alternative treatments include elafibranor (PPAR-α and δ agonist) and seladelpar (PPAR-δ agonist), which have similar effects. However, due to the short-term nature of the studies, these drugs have yet been shown to alter clinically significant outcomes.

Despite the autoimmune aetiology, immunosuppressants, such as glucocorticoids, azathioprine, penicillamine and ciclosporin, have failed to show any overall benefit when given to unselected PBC patients.

Liver transplantation should be considered once liver failure has developed and may also be indicated in patients with intractable pruritus. Serum bilirubin remains the most reliable marker of declining liver function. Transplantation is associated with an excellent 5-year survival of over 80%, although the disease recurs in over one-third of patients at 10 years.

Pruritus

This is the main symptom requiring treatment. The cause is unknown, but up-regulation of opioid receptors and increased levels of endogenous opioids may play a role. First-line treatment is with the anion-binding resin colestyramine, which probably acts by binding potential pruritogens in the intestine and increasing their excretion in the stool. A dose of 4–16 g/day orally is used. The powder is mixed in orange juice and the main dose (8 g) taken before and after breakfast, when maximal duodenal bile acid concentrations occur. Colestyramine may bind other drugs in the gut (most obviously UDCA), and adequate spacing should be used between drugs. Colestyramine is sometimes ineffective and can be difficult for some patients to tolerate. Alternative treatments include rifampicin (150 mg/day, titrated up to a maximum of 600 mg/day as required with close monitoring of LFTs), naltrexone (an opioid antagonist; 25 mg/day initially, increasing up to 300 mg/day), sertraline (a serotonin selective reuptake inhibitor; 75–100 mg/day), plasmapheresis and an extracorporeal liver support device such as a molecular adsorbent recirculation system (MARS).

Fatigue

Fatigue affects about one-third of patients with PBC. The cause is unknown, but it may reflect intracerebral changes due to cholestasis. Unfortunately, once depression, hypothyroidism and coeliac disease have been excluded, there is currently no specific treatment. The impact on quality of life can be substantial.

Malabsorption

Prolonged cholestasis is associated with steatorrhea and malabsorption of fat-soluble vitamins, which should be replaced as necessary. Coeliac disease should be excluded since its incidence is increased in PBC.

Bone disease

Osteopenia and osteoporosis are common, and normal post-menopausal bone loss is accelerated. Baseline bone density should be measured for individuals with a 10-year fracture risk of > 10% and treatment with replacement calcium and vitamin D_3 considered for those with a low dietary calcium intake and vitamin D deficiency. Bisphosphonates should be used if there is evidence of osteoporosis. Osteomalacia can occur but is rare.

Overlap syndromes

Anti-mitochondrial antibody-negative PBC (autoimmune cholangitis)

A few patients demonstrate the clinical, biochemical and histological features of PBC but do not have detectable AMA in the serum. Serum transaminases, serum immunoglobulin levels and titres of ANA tend to be higher than in AMA-positive PBC. The clinical course mirrors classical PBC, however, and these patients should be considered as having a variant of PBC.

Autoimmune hepatitis/PBC overlap

A few patients with AMA and cholestatic LFTs have elevated transaminases, high serum immunoglobulin IgG levels and interface hepatitis on liver histology. In such individuals, a trial of glucocorticoid therapy may be beneficial.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is an immune-mediated cholestatic liver disease characterised by multifocal stricture of the larger bile ducts of the extra- and/or intrahepatic biliary tree, often in association with inflammatory bowel disease. This is also associated with progressive hepatic fibrosis, which can lead to cirrhosis and portal hypertension, along with an increased risk of various cancers (cholangiocarcinoma, gallbladder, colon).

The incidence is about 6.3/100 000 in people of European ancestry. Unlike most other autoimmune diseases, PSC is twice as common in men as women. Most patients present at age 25–40 years, although the condition may be diagnosed at any age and is an important cause of chronic liver disease in children. The generally accepted diagnostic criteria are:

- generalised beading and stenosis of the biliary system on cholangiography (Fig. 23.33)
- absence of choledocholithiasis (or history of bile duct surgery)
- exclusion of bile duct cancer, by prolonged follow-up.

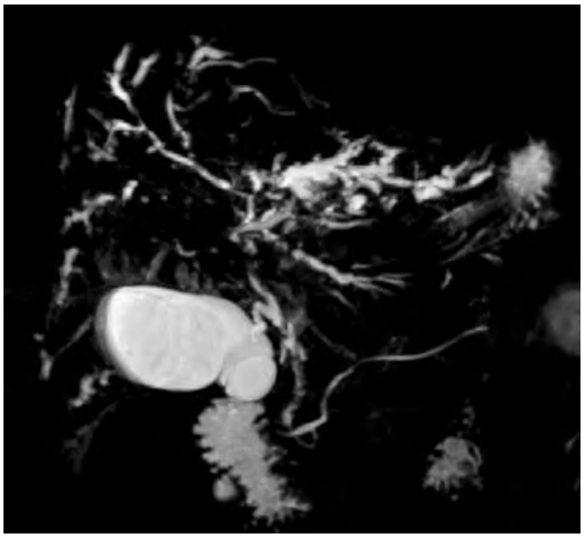

Fig. 23.33 Primary sclerosing cholangitis. Magnetic resonance cholangiopancreatogram showing typical changes of primary sclerosing cholangitis with intrahepatic bile duct beading, stricturing and dilatation. The extrahepatic bile duct is also diffusely strictured.

The term ‘secondary sclerosing cholangitis’ is used to describe the typical changes described above when a clear predisposing factor for duct fibrosis can be identified. The causes of secondary sclerosing cholangitis are shown in Box 23.53.

Pathophysiology

The cause of PSC is unknown but there is a close association with inflammatory bowel disease, particularly ulcerative colitis (Box 23.54). About 70%–80% of PSC patients have coexisting ulcerative colitis, and PSC is the most common form of chronic liver disease in ulcerative colitis. Between 3% and 10% of patients with ulcerative colitis develop PSC, particularly those with extensive colitis or pancolitis. The distribution of PSC-associated colitis is often predominantly right-sided with relative distal sparing and may be less symptomatic than non-PSC inflammatory bowel disease (IBD). The prevalence of PSC is lower in patients with Crohn colitis (about 1%). Patients with PSC and ulcerative colitis are at greater risk of colorectal neoplasia than those with ulcerative colitis alone, and individuals who develop colorectal neoplasia are at greater risk of cholangiocarcinoma.

PSC is thought to be an immunologically mediated disease, triggered in genetically susceptible individuals by toxic or infectious agents, which may gain access to the biliary tract through a leaky, diseased colon. A close link has been identified with HLA haplotype A1-B8-DR3-DRW52A, which is commonly found in association with other organ-specific autoimmune diseases such as autoimmune hepatitis.

Perinuclear antineutrophil cytoplasmic antibodies (pANCA) are detectable in the sera of 60%–80% of patients with PSC with or without ulcerative colitis, and in 30%–40% of patients with ulcerative colitis alone. The antibody is not specific for PSC and is found in about 50% of patients with autoimmune hepatitis as well as other chronic liver diseases, so is of little diagnostic value in isolation.

23.53 Causes of secondary sclerosing cholangitis

- Previous bile duct surgery with stricturing and cholangitis
- Bile duct stones causing cholangitis
- Traumatic or ischaemic bile duct injury
- Critical illness ischaemic cholangiopathy
- Portal hypertensive cholangiopathy
- Intrahepatic infusion of 5-fluorodeoxyuridine
- Insertion of formalin into hepatic hydatid cysts
- Insertion of alcohol into hepatic tumours
- Parasitic infections (e.g. *Clonorchis*)
- Autoimmune pancreatitis/immunoglobulin G4-associated cholangitis
- Acquired immunodeficiency syndrome (AIDS; probably infective as a result of cytomegalovirus or *Cryptosporidium*)

23.54 Comparison of primary biliary cholangitis and primary sclerosing cholangitis

	Primary biliary cholangitis	**Primary sclerosing cholangitis**
Sex (F:M)	9:1	1:2
Age	Older: median age 50–55 years	Younger: median age 20–40 years
Disease associations	Non-organ-specific autoimmune disease such as Sjögren syndrome and autoimmune thyroid disease	Ulcerative colitis
Autoantibody profile	90% AMA +ve	65%–85% pANCA +ve (but this is non-specific and not diagnostic)
Imaging (MRCP)	Normal appearance of ducts	Intrahepatic or extrahepatic biliary strictures

(AMA = antimitochondrial antibody; MRCP = magnetic resonance cholangiopancreatography; pANCA = perinuclear antineutrophil cytoplasmic antibody)

Clinical features

The diagnosis is often made incidentally when persistently raised serum ALP is discovered in an individual with ulcerative colitis. Patients may present with episodes of biliary obstruction, or with symptoms of cirrhosis or portal hypertension. Common symptoms include fatigue, intermittent jaundice, weight loss, right upper quadrant abdominal pain and pruritus. Attacks of acute cholangitis are uncommon and usually follow biliary instrumentation.

Investigations

Biochemical screening usually reveals a cholestatic pattern of LFTs, but ALP and bilirubin levels may vary widely in individual patients during the course of the disease. For example, ALP and bilirubin values increase during acute cholangitis, decrease after therapy and sometimes fluctuate for no apparent reason. Modest elevations in serum transaminases are usually seen, whereas hypoalbuminaemia and clotting abnormalities are found at a late stage only. In addition to pANCA, low titres of antinuclear antibodies and anti-smooth muscle antibodies may be found in PSC but have no diagnostic significance; serum AMA is absent.

The key investigation is MRCP, which is usually diagnostic and reveals multiple irregular strictures and dilatation (see Fig. 23.33). ERCP should be reserved for therapeutic interventions.

On liver biopsy, the characteristic early features of PSC are periductal ‘onion skin’ fibrosis and inflammation, with portal oedema and bile ductular proliferation resulting in expansion of the portal tracts (Fig. 23.34). Later, fibrosis spreads, progressing inevitably to biliary cirrhosis; obliterative cholangitis leads to the so-called ‘vanishing bile duct syndrome’. The link with IBD and associated colon cancer risk is sufficiently strong that all patients diagnosed with PSC should undergo an initial colonoscopy, even in the absence of bowel symptoms.

Management

There is no cure for PSC, but management of cholestasis and its complications and specific treatment of the disease process are indicated. UDCA is widely used, although the evidence to support this is limited. UDCA may have benefit in terms of reducing colon carcinoma risk.

The course of PSC is variable. Overall, the median time from diagnosis to death or transplant is around 20 years. Prognosis is worse in symptomatic patients, possibly reflecting a later disease stage at diagnosis. In recent series, the leading cause of death in PSC is cholangiocarcinoma (58% of deaths), with lower rates attributable to liver failure (30%) and variceal bleeding (9%). Immunosuppressive agents, including prednisolone, azathioprine, methotrexate and ciclosporin, have been tried; results have generally been disappointing. Symptomatic patients often have

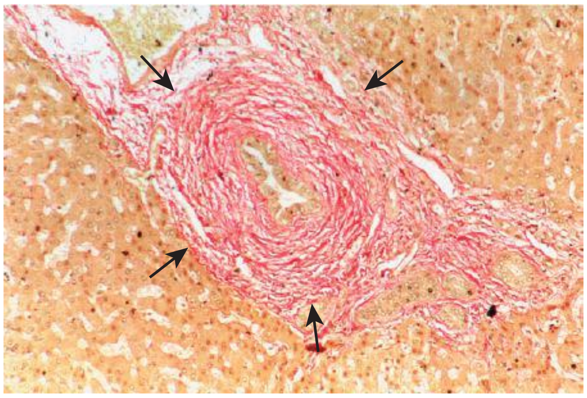

Fig. 23.34 Histological features of primary sclerosing cholangitis. Note onion skin scarring (arrows) surrounding a bile duct.

pruritus. Management is as for PBC. Fatigue appears to be less prominent than in PBC, although it is still present in some patients.

Cancer screening

Patients with PSC should have annual ultrasound scans to screen for gallbladder polyps, to aid early detection of gallbladder cancer. Patients with PSC and colitis should undergo annual colonoscopy to screen for colorectal cancer. There is no established role for routine screening for cholangiocarcinoma with either imaging or serum CA19-9 levels in PSC, due the low specificity and the low likelihood of successful intervention, even with early diagnosis.

Management of complications

Broad-spectrum antibiotics such as ciprofloxacin should be given for acute attacks of cholangitis. If new symptoms develop or liver function tests worsen, non-invasive imaging such as MRCP and/or contrast CT should be performed to assess for a dominant stricture (which may be either inflammatory or malignant). If a dominant stricture is associated with either jaundice or infection, ERCP should be performed for sampling (via brush cytology) to exclude cholangiocarcinoma and to relieve the obstruction, usually through balloon dilatation rather than stenting. Fat-soluble vitamin replacement is necessary in jaundiced patients. Metabolic bone disease (usually osteoporosis) is a common complication that often requires treatment.

Surgical treatment

Surgical resection of the extrahepatic bile duct and biliary reconstruction have a limited role in the management of non-cirrhotic patients with dominant extrahepatic disease. Orthotopic transplantation is the only surgical option in patients with advanced liver disease; 5-year survival is 80%–90% in most centres. Unfortunately, the condition may recur in the graft in around 20% of patients and there are no identified therapies able to prevent this. Cholangiocarcinoma is generally a contraindication to transplantation, although transplantation is being used in some countries for some highly selected patients with localised disease. Colon carcinoma risk persists following transplantation (and may be increased because of immunosuppression), so colonoscopic surveillance should continue. The features of PBC and PSC are compared in Box 23.54.

IgG4-associated cholangitis

This disease (as well as its nomenclature) is closely related to autoimmune pancreatitis (which is present in more than 90% of the patients). IgG4-associated cholangitis (IAC) often presents in middle-aged to older men with obstructive jaundice (due to either hilar stricturing/intrahepatic sclerosing cholangitis or a low bile duct stricture). Cholangiographic appearances can resemble PSC or hilar cholangiocarcinoma. Patients may have past or concurrent evidence of IgG4 disease in other organs (Box 23.55). Serum IgG4 levels are often raised and liver biopsy shows a lymphoplasmacytic infiltrate, with IgG4-positive plasma cells. It is important not to miss the diagnosis as it responds well to glucocorticoid therapy, often with complete normalisation of liver enzymes and resolution of strictures on serial imaging.

i 23.55 Manifestations of IgG4-related disease

- Autoimmune pancreatitis
- Cholangiopathy
- Sialadenitis (especially submandibular gland)
- Dacryoadenitis (lacrimal gland)
- Retroperitoneal fibrosis
- Riedel thyroiditis
- Retro-orbital tumours
- Periaortitis and periarteritis

Liver tumours and other focal liver lesions

Identification of a hepatic mass lesion is common, both in patients with known pre-existing liver disease and as a primary presentation. Although primary and secondary malignant tumours are important potential diagnoses, benign disease is frequent. The critical steps to be taken in diagnosing hepatic mass lesions are:

- determining the presence, nature and severity of any underlying chronic liver disease, as the differential diagnosis is very different in patients with and those without chronic liver disease
- using optimal (usually multiple) imaging modalities.

Primary malignant tumours

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the fifth most common form of cancer worldwide. Its incidence shows significant geographical variability with highest rates in East Asia and sub-Saharan Africa. HCC typically develops in the context of underlying liver disease with 90% of cases associated with chronic liver disease. Globally, chronic viral hepatitis (HBV/HCV) is the most important aetiological factor, with other major contributing factors being alcohol, obesity and aflatoxin. Hepatitis B infection accounts for 60% of cases in Africa and East Asia, where the incidence of HCC is falling. Hepatitis B vaccination has led to a fall in HCC in countries with a high incidence of HBV infection. In Europe and North America, the incidence of HCC has risen. This is thought to have been related to the prevalence of HCV infection, ArLD and MASLD. The risk of HCC is higher in men and rises with age.

Cirrhosis is an important risk factor for the development of HCC. Cirrhosis is present in 80%–90% of patients with HCC worldwide. All aetiological forms of cirrhosis are associated with an increased risk of HCC, with the highest risk in patients with chronic viral hepatitis (HBV/HCV). For chronic hepatitis B infection, reported annual incidence rates for HCC are 0.3%–0.6% in non-cirrhotic patients and 2.2%–3.7% in cirrhosis. The risk of cirrhosis is highest in patients with HCV-associated liver cirrhosis (3%–8%). Overall, the annual risk of HCC development in patients with cirrhosis is 1%–8%. The incidence of HCC is related to the stage of liver cirrhosis. Patients with a higher Child–Pugh score are at increased risk of tumor development. Necroinflammation and regeneration are important factors in promoting cancer development. Persistent inflammation, as reflected by elevated alanine aminotransferase (ALT) levels, is associated with increased HCC occurrence in cirrhotic patients of diverse aetiology.

Macroscopically, the tumour usually appears as a single mass in the absence of cirrhosis, or as a single nodule or multiple nodules in the presence of cirrhosis. It takes its blood supply from the hepatic artery and tends to spread by invasion into the portal vein and its radicals. Lymph node metastases are common, while lung and bone metastases are rare. Well-differentiated tumours can resemble normal hepatocytes and may be difficult to distinguish from normal liver.

Clinical features

Hepatocellular carcinoma may present with symptoms or through screening of high-risk patients. Commonly, liver function deteriorates in those with underlying cirrhosis, with worsening ascites, jaundice or variceal haemorrhage. Other symptoms can include weight loss, anorexia and abdominal pain. This often rapid deterioration may be the first presentation of previously undiagnosed cirrhosis. Examination may reveal hepatomegaly or a right hypochondrial mass. Tumour vascularity can lead to an abdominal bruit, and hepatic rupture with intra-abdominal bleeding may occur. The advanced nature of disease that presents in this way makes curative therapy unlikely. Individuals with HCC found through screening are typically detected early during the course of the disease, significantly increasing the treatment options.

Investigations

Serum markers

Alpha-fetoprotein (AFP) is produced by approximately 50% of HCCs. Levels increase with the size of the tumour and are often normal or only minimally elevated in small tumours detected by ultrasound screening. Serum AFP can also rise in the presence of active hepatitis B and C viral replication; very high levels are seen following acute hepatic necrosis, such as that following paracetamol toxicity. AFP is used in conjunction with ultrasound in screening but, in view of low sensitivity and specificity, levels need to be interpreted with caution. Nevertheless, in the absence of active liver inflammation, a significantly elevated or progressively rising AFP warrants an aggressive search for HCC (normal range is < 10 ng/mL [8 IU/mL]). In HCC patients with elevated AFP levels, serial measurements can be a useful biomarker of disease progression or response to treatment.

Imaging

Ultrasound can detect focal liver lesions as small as 1 cm. The use of ultrasound contrast agents has increased sensitivity and specificity but is highly user dependent. Ultrasound may also show evidence of portal vein involvement and features of coexistent cirrhosis. The diagnosis is usually confirmed on either multi-phase contrast-enhanced CT or MRI, which demonstrate the typical hallmarks of HCC: arterial enhancement with washout on the portal venous phase (Fig. 23.35). Small lesions of less than 2 cm can be difficult to differentiate from hyperplastic nodules in cirrhosis. A combination of imaging modalities (CT and MRI) may be required for indeterminate or probable HCC when the typical radiological features are absent.

Liver biopsy

Histological confirmation is advisable in patients with large tumours who do not have cirrhosis or hepatitis B, in order to confirm the diagnosis and exclude metastatic tumour. Biopsy should be avoided, if possible, in patients who may be eligible for transplantation or surgical resection, because there is a small (1.8%–4%) risk of tumour seeding along the needle tract. In all cases of potential HCC where biopsy is being considered, the impact that a confirmed diagnosis will have on therapy must be weighed against the risks of bleeding.

Role of screening

Screening for HCC, by ultrasound scanning, with or without AFP measurements, every 6 months is indicated in high-risk patients who would be suitable for therapy if diagnosed with HCC. The risk is highest in patients with chronic hepatitis B and cirrhosis due to viral hepatitis and haemochromatosis, and lower in patients with cirrhosis due to Wilson disease and autoimmune hepatitis. Cost-effectiveness studies suggest that HCC surveillance is warranted in cirrhotic patients where there is an annual incidence of HCC of ≥ 1.5% per year. Screening may also be indicated in those with chronic hepatitis B (who carry an increased risk of HCC, even in the absence of cirrhosis). Although many studies investigating the efficacy of HCC surveillance are affected by lead-time and length-time bias, the current evidence base supports the continued use of HCC surveillance. Screening identifies smaller tumours, often less than 3 cm in size, which are more likely to be cured by surgical resection, local ablative therapy or transplantation.

Management

This is different for patients with cirrhosis and those without. In the presence of cirrhosis, treatment options depend on tumour size and number, severity of liver disease (Child–Pugh score) and performance status. An algorithm for managing those with cirrhosis is shown in Figure 23.36.

Hepatic resection

This is the treatment of choice for non-cirrhotic patients. The 5-year survival in this group is about 50%. There is a 50% recurrence rate at 5 years, however, which may be due to a second *de novo* tumour or recurrence of the original tumour. Few patients with cirrhosis are suitable for hepatic resection because of the high risk of hepatic failure. Nevertheless, surgery can be safely performed in cirrhotic patients with small tumours, good liver function (Child–Pugh A) and the absence of clinically relevant portal hypertension (HVPG ≤ 10 mmHg). In experienced centres, advances in surgical technique and pre-operative assessment have permitted liver resection to be performed safely in selected patients with more advanced liver disease and tumour burden.

Liver transplantation

Transplantation has the benefit of curing underlying cirrhosis and removing the risk of a second, de novo tumour in an at-risk patient. The requirement for immunosuppression creates its own risks of reactivation if residual or metastatic disease is present, and assessment of patients for suitability for liver transplantation focuses on the exclusion of extra-hepatic disease and vascular invasion. The 5-year survival following liver transplantation is 75% for patients with single tumours of less than 5 cm in size or three tumours smaller than 3 cm (the Milan criteria). Extended criteria have been developed in a number of countries, including the UK, allowing patients to be transplanted with a greater number of small tumours (≤ 5) or larger single tumours (5–7 cm) that have demonstrated stability after a period of observation (6 months), either with or without locoregional therapy. Downstaging criteria have also been developed to permit transplantation in patients initially outwith standard transplant criteria but who have shown sustained response following locoregional treatment.

Ablative therapy

Ablative therapies use a number of different techniques to achieve localised destruction of tumour tissue. Ultrasound (US) or CT-guided thermal ablative techniques, including radiofrequency ablation (RFA)

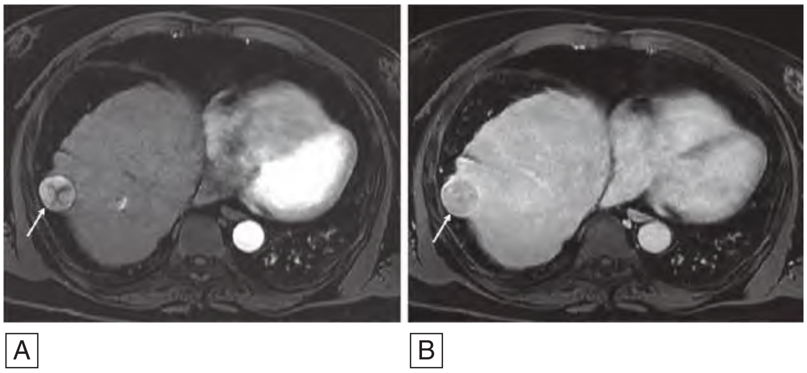

Fig. 23.35 Hepatocellular carcinoma. Contrast-enhanced MRI liver showing a large hepatocellular carcinoma. The tumour (marked by the arrows) demonstrates contrast uptake (enhancement) in the arterial phase **A** and washout in the portal venous phase **B**.

Fig. 23.36 **Management of hepatocellular carcinoma complicating cirrhosis.** Modified Barcelona Clinic Liver Cancer (BCLC) staging system. Patient management is determined by the size and number of tumours, evidence of portal invasion or extrahepatic spread, severity of underlying liver cirrhosis, and a patient's performance status. Preserved liver function refers to Child–Pugh A cirrhosis without ascites. Performance status (PS) (see Box 8.6): 0 = fully active, no symptoms, > 2 = limited self-care, confined to bed or chair for more than 50% of waking hours. *In some countries, including the United Kingdom, transplant may be considered in patients with up to 5 tumours, each less than 3 cm. (HCC = hepatocellular carcinoma; TACE = transarterial chemoembolisation). *Adapted from Reig M, Forner A, Rimola J, et al. BLCL strategy for prognosis, prediction and treatment recommendation: The 2022 update. J Hepatol 2022:76(3);681–693.*

and microwave ablation (MWA), have replaced percutaneous ethanol injection in the treatment of HCC. Alternative techniques include cryoablation and irreversible electroporation. Locoregional ablative therapies may be curative for patients with early HCC. Thermal ablation in single tumours < 3 cm in size is an alternative to surgery based on technical factors (position of the tumour), severity of underlying liver disease and comorbidity. Stereotactic ablative radiotherapy (SABR) can be used as an alternative treatment for HCC that is confined to the liver but cannot be treated by other ablative therapies.

Transarterial chemoembolisation

Transarterial chemoembolisation (TACE) is the most widely used palliative treatment for patients with HCC not amenable to surgery or potentially curative ablative techniques. TACE involves the selective intra-arterial infusion of chemotherapeutic agents followed by embolisation of the tumour feeding vessels with absorbable gelatin powder (Gelfoam) to achieve localised tumour necrosis and devascularisation. Conventional TACE achieves response rates of 52% with 1-year and 3-year survival rates of 70% and 40%, respectively. Modifications of this technique include the use of drug-eluting beads. TACE should not be used in patients with advanced liver or renal dysfunction, vascular invasion or extrahepatic spread. TACE is widely used as a bridging therapy for patients awaiting liver transplant and increasingly has found a role in down-staging therapy in patients being considered for liver transplant. Selective internal radiation therapy (SIRT) involves intra-arterial infusion of radioactive substances or microspheres into the hepatic artery. It can be used as an alternative to TACE or systemic therapy and as a bridging therapy to liver transplant.

Systemic therapy

Systemic therapy is employed for the treatment of intermediate and advanced stage HCC. There have been significant advances in systemic therapy with a number of licensed medications directed against a range of molecular targets. In this rapidly changing field, the combination of the immune checkpoint inhibitor atezolizumab, which blocks programmed death ligand 1 (PD-L1), and the vascular endothelial growth factor (VEGF) inhibitor bevacizumab has replaced the multikinase inhibitors sorafenib and lenvatinib as first-line therapy. The combination of atezolizumab and bevacizumab provides improved median overall survival (19.2 months) in comparison to sorafenib alone (13 months). Systemic therapies can be used sequentially, with second-line therapies also including the tyrosine kinase inhibitors regorafenib and cabozantinib, and the VEGF receptor blocker ramucirumab.

Fibrolamellar carcinoma

Fibrolamellar carcinoma (FLC) is a rare malignancy that is now recognised as clinically distinct from hepatocellular carcinoma. It typically occurs in adolescence and young adulthood, equally in males and females and in the absence of liver cirrhosis. It has characteristic genetic alterations with a chromosome 19 deletion event leading to formation of a chimeric fusion protein (DNAJB1-PRKACA) in almost all cases. FLC tumours are often large at presentation, with histology showing large polygonal hepatoid cells arranged in cords, nests or sheets and surrounded by a dense fibrous stroma. The treatment of choice is surgical resection. However, regional lymph node metastases are present in 30%–50% at presentation, and distant metastatic disease in 30%–40%.

Other primary malignant tumours

Cholangiocarcinoma (bile duct cancer) typically presents with bile duct obstruction rather than as a hepatic mass lesion, although intrahepatic cholangiocarcinoma can present as a focal liver tumour. Cholangiocarcinoma (CCA) is discussed separately below. Hepatoblastoma is rare but is one of the most common primary liver cancers in infants, with most cases occurring in children aged under 3. Hepatoblastoma develops from immature liver precursor cells. Treatment typically involves systemic chemotherapy followed by surgical resection. Liver transplant may be required in some cases. Other rare tumours include haemangioendothelial sarcomas.

Secondary malignant tumours

These are common and usually originate from carcinomas in the lung, breast, abdomen or pelvis. They may be single or multiple. Peritoneal dissemination frequently results in ascites.

Clinical features

The primary neoplasm is asymptomatic in 50% of patients, being detected on either radiological, endoscopic or blood biochemistry screening. There is liver enlargement and weight loss; jaundice may be present.

Investigations

A raised ALP activity is the most common biochemical abnormality but LFTs may be normal. Ascitic fluid, if present, has a high SAAG and protein content and may be blood-stained; cytology sometimes reveals malignant cells. Imaging shows filling defects (Fig. 23.37); laparoscopy may reveal the tumour and facilitates liver biopsy.

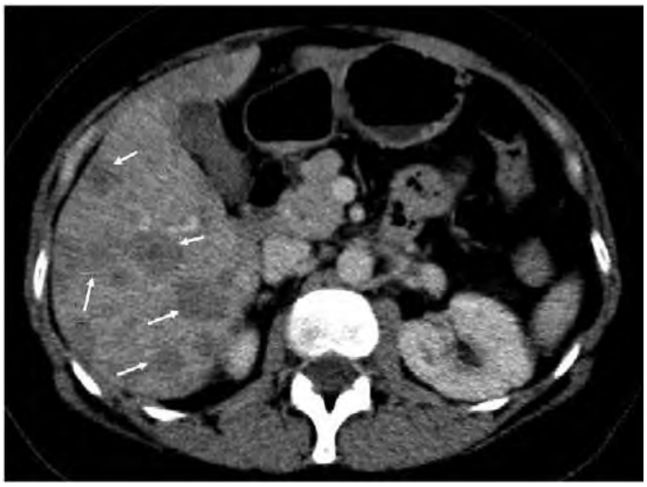

Fig. 23.37 Liver metastases. CT scan of liver showing multiple low attenuation liver lesions typical for metastases (arrows).

Management

Hepatic resection can improve survival for slow-growing colonic carcinoma metastases and is an approach that should be actively explored in patients who are fit for liver resection and have had the primary tumour resected, once extrahepatic disease has been excluded. Patients with neuroendocrine tumours (NETs), such as gastrinomas, insulinomas and glucagonomas, and those with lymphomas may benefit from surgery, hormonal treatment or chemotherapy. Unfortunately, palliative treatment to relieve pain is all that is available for most patients.

Benign tumours

The increasing use of ultrasound scanning has led to more frequent identification of incidental benign focal liver lesions.

Hepatic adenomas

These are rare benign hepatocellular tumours that may present as an abdominal mass or with abdominal pain but now more typically present as an incidental finding on imaging.

They are more common in women (female:male ratio 10:1) and are associated with oral contraceptive, androgen and anabolic steroid use. Hepatic adenomas can increase in size during pregnancy. Large or rapidly growing adenomas can rarely rupture, causing intraperitoneal bleeding. In women, resection is indicated for hepatic adenomas ≥5 cm in diameter or with exophytic protrusion, as this is associated with higher rates of bleeding. Hepatic adenomas <5 cm rarely bleed and there is a low rate of malignant transformation. Management involves avoidance of the oral contraceptive pill and weight loss. Resection is recommended for hepatic adenoma in men, irrespective of size because of a higher rate of malignant transformation.

Haemangiomas

These are the most common benign liver tumours and are present in 1%–20% of the population. Most are smaller than 3 cm and rarely cause symptoms. The diagnosis is usually made by ultrasound, but CT/MRI may show a low-density lesion with delayed arterial filling. Conservative management is appropriate for the majority of cases, with surgery only needed for very large symptomatic lesions or where the diagnosis is in doubt. Transcatheter hepatic embolisation can be considered in selected cases.

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) is a benign polyclonal hepatocellular proliferation resulting from an arterial malformation. FNH is more common in women (female:male ratio 9:1) and typically presents between 35 and 50 years. Most are solitary and <5 cm but 20%–30% are multiple. The lesions are usually asymptomatic. They can be differentiated from adenoma by a focal central scar seen on CT or MRI (Fig. 23.38). Histologically, they consist of nodular regeneration of hepatocytes without fibrosis. In the absence of symptoms, surgical resection is not required. If a confident diagnosis of FNH can be made then follow-up imaging is not required. There is no need to discontinue the oral contraceptive pill or monitor in pregnancy.

Cystic liver disease and liver abscess

Isolated or multiple simple cysts are common in the liver and are a relatively frequent finding on ultrasound screening. They can be associated with polycystic renal disease (Fig. 23.39). They are intrinsically benign and require no therapy, other than in rare cases where the mass effect of very large or multiple cysts causes abdominal discomfort. In such cases, percutaneous or surgical debulking can be attempted but recurrence is typical. Liver transplant may rarely be required in severe cases. Liver abscesses are discussed on page 910.

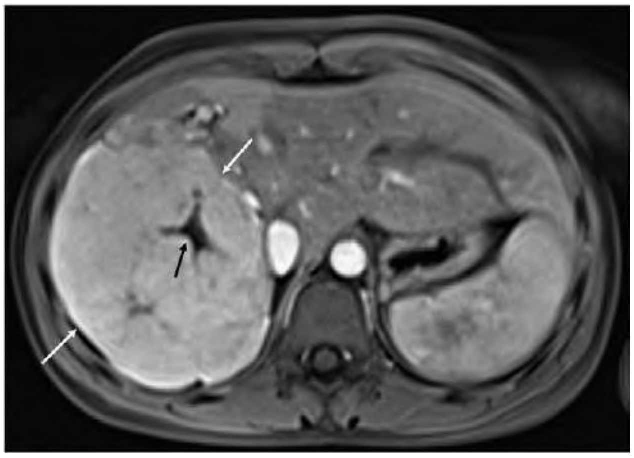

Fig. 23.38 Focal nodular hyperplasia. MRI scan of the liver showing a large enhancing mass within the right lobe of liver (white arrows) with a non-enhancing central scar (black arrow) typical of focal nodular hyperplasia.

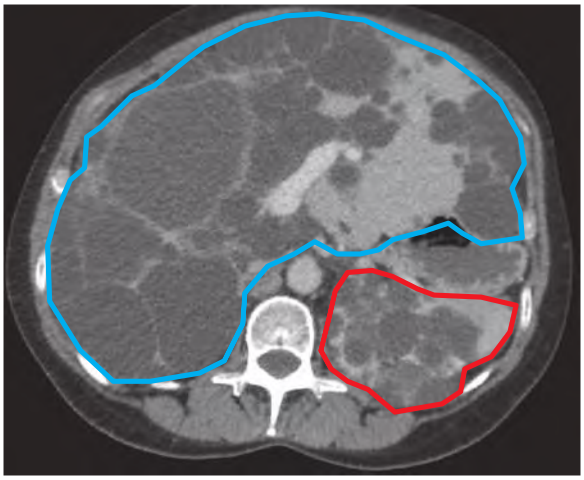

Fig. 23.39 Polycystic liver and kidney disease. CT scan of the abdomen in a patient with polycystic liver and kidney disease. Multiple low attenuation cysts are seen within the liver (highlighted in blue) and left kidney (red). *Courtesy of Dr Hamish Ireland, Royal Infirmary of Edinburgh.*

Drugs and the liver

The liver is the primary site of drug metabolism and an important target for drug-induced injury. Pre-existing liver disease may affect the capacity of the liver to metabolise drugs, and unexpected toxicity may occur when patients with liver disease are given drugs in normal doses. Box 23.56 also shows drugs that should be avoided in patients with cirrhosis, as they can exacerbate known complications of cirrhosis. The possibility of undiagnosed underlying liver injury should always be considered in patients exhibiting unexpected effects following drug exposure.

Drug-induced liver injury

Drug toxicity should always be considered in the differential diagnosis of patients presenting with acute liver failure, jaundice or abnormal liver biochemistry. Drug-induced liver injury (DILI) can be classified as either intrinsic (predictable dose-related toxicity occurring in a large proportion of individuals exposed to a drug) or idiosyncratic (occurring unpredictably in a small proportion of patients exposed to a drug). Typical patterns of drug toxicity are listed in Box 23.57; the most common picture is a mixed cholestatic hepatitis. The presence of jaundice indicates more severe liver damage. Although acute liver failure can occur, most drug reactions are self-limiting and chronic liver damage is rare. Abnormal LFTs often take weeks to normalise following a drug-induced hepatitis, and it may be months before they normalise after a cholestatic hepatitis. Occasionally, permanent bile duct loss (ductopenia) follows a cholestatic drug reaction, such as that due to co-amoxiclav, resulting in chronic cholestasis with persistent symptoms such as itching.

23.56 Drugs to be avoided in cirrhosis

Drug	Problem	Toxicity
Non-steroidal anti-inflammatory drugs	Reduced renal blood flow Mucosal ulceration	Hepatorenal failure Bleeding varices
Angiotensin-converting enzyme inhibitors	Reduced renal blood flow	Hepatorenal failure
Anti-motility agents	Constipation	Hepatic encephalopathy
Narcotics	Constipation, drug accumulation	Hepatic encephalopathy
Anxiolytics	Drug accumulation	Hepatic encephalopathy

23.57 Examples of common causes of drug-induced hepatotoxicity

Pattern	Drug
Cholestasis	High-dose oestrogens Chlorpromazine
Cholestatic hepatitis (mixed injury)	Non-steroidal anti-inflammatory drugs Co-amoxiclav Statins Carbamazepine Terbinafine*
Acute hepatitis	Rifampicin Isoniazid Sertraline Risperidone
Steatohepatitis	Amiodarone
Sinusoidal obstruction syndrome	Busulfan Cyclophosphamide
Fibrosis	Methotrexate
Autoimmune hepatitis-like	Nitrofurantoin Checkpoint inhibitors (nivolumab/pembrolizumab) Methyl-dopa

*Can cause a range of patterns of drug-induced liver injury including acute hepatitis, cholestasis, cholestatic liver injury and vanishing bile duct syndrome.

The key to diagnosis is a detailed drug history (Box 23.58), looking for temporal relationships between drug exposure and onset of liver abnormality (bearing in mind the fact that liver injury can frequently take weeks or even months to develop following exposure). A liver biopsy should be considered if there is suspicion of pre-existing liver disease or if blood tests fail to improve when the suspect drug is withdrawn.

Where drug-induced liver injury is suspected or cannot be excluded, the potential culprit drug should be discontinued unless it is impossible to do so safely.

Types of liver injury

Different histological patterns of liver injury may occur with drug injury.

Cholestasis

Pure cholestasis (selective interference with bile flow in the absence of liver injury) can occur with oestrogens; this was common when high concentrations of oestrogens (50 µg/day) were used as contraceptives. Both

23.58 Diagnosing acute drug-induced liver disease

- Tabulate the drugs taken:
  - Prescribed and self-administered
- Establish whether hepatotoxicity is reported in the literature
- Relate the time the drugs were taken to the onset of illness: 4 days to 8 weeks (usual)
- Establish the effect of stopping the drugs on normalisation of liver biochemistry:
  - Hepatitic liver function tests (2 months)
  - Cholestatic/mixed liver function tests (6 months)
- Exclude other causes:
  - Viral hepatitis
  - Biliary disease
- Consider liver biopsy

Note that challenge tests with drugs to determine causality should be avoided.

the current oral contraceptive pill and hormone replacement therapy can be safely used in chronic liver disease.

Chlorpromazine and antibiotics such as flucloxacillin are examples of drugs that cause cholestatic hepatitis, which is characterised by inflammation and canalicular injury. Co-amoxiclav is the most common antibiotic to cause abnormal LFTs but, unlike other antibiotics, it may not produce symptoms until 10–42 days after it is stopped. Anabolic steroids used by body-builders may also cause a cholestatic hepatitis. NSAIDs exhibit a broad spectrum of liver damage including hepatocellular injury, cholestasis or mixed patterns of drug-induced liver injury.

Hepatocyte necrosis

Many drugs cause an acute hepatocellular necrosis with high serum transaminase concentrations; paracetamol is the best known. Inflammation is not always present but does accompany necrosis in liver injury due to diclofenac (an NSAID) and isoniazid (an anti-tuberculous drug). Granulomas may be seen in liver injury following the use of allopurinol. Acute hepatocellular necrosis has also been described following the use of several herbal remedies, including germander, comfrey and the Chinese herb Jin Bu Huan. Recreational drugs, including cocaine and ecstasy, can also cause severe acute hepatitis.

Steatosis

Microvesicular hepatocyte fat deposition, due to direct effects on mitochondrial beta-oxidation, can follow exposure to tetracyclines and sodium valproate. Macrovesicular hepatocyte fat deposition has been described with tamoxifen, and amiodarone toxicity can produce a steatohepatitis with a similar histological picture to MASLD.

Vascular/sinusoidal lesions

Drugs such as the alkylating agents used in oncology can damage the vascular endothelium and lead to hepatic venous outflow obstruction. Chronic overdose of vitamin A can damage the sinusoids and trigger local fibrosis that can result in portal hypertension.

Hepatic fibrosis

Most drugs cause reversible liver injury, and hepatic fibrosis is very uncommon. Methotrexate, however, as well as causing acute liver injury when it is started, can lead to cirrhosis when used in high doses over a long period of time. Risk factors for drug-induced hepatic fibrosis include pre-existing liver disease and a high alcohol intake.

Autoimmune hepatitis-like

Nitrofurantoin is a commonly used antibiotic for urinary tract infections which can cause a liver injury with the features of autoimmune hepatitis, with raised ALT and IgG levels and antinuclear or anti-smooth muscle antibodies. The immune checkpoint inhibitors nivolumab and pembrolizumab, which target PD-1, are increasingly used as immunotherapy in cancer treatments. A well-recognised side-effect is the development of florid organ-specific autoimmune disease, including an autoimmune hepatitis which can require high-dose glucocorticoids and other immunosuppressive agents to control it.

Inherited liver diseases

The inherited diseases are an important and probably under-diagnosed group of liver diseases. In addition to the 'classical' conditions, such as haemochromatosis and Wilson disease, the important role played by the liver in the expression of the inborn errors of metabolism should be remembered, as should the potential for genetic underpinning for intrahepatic cholestasis.

Haemochromatosis

Haemochromatosis is a condition in which the amount of total body iron is increased; the excess iron is deposited in, and causes damage to, several organs, including the liver. It may be primary or secondary to other diseases (Box 23.59).

Genetic haemochromatosis

In genetic haemochromatosis (GH), iron is deposited throughout the body and total body iron may reach 20–60 g (normally 4 g). The important organs involved are the liver, pancreatic islets, endocrine glands, joints and heart. In the liver, iron deposition occurs first in the periportal hepatocytes, extending later to all hepatocytes, with associated fibrosis and eventually cirrhosis.

Pathophysiology

Body iron content is controlled by regulation of iron absorption from diet and its storage in the reticuloendothelial system. The hormone hepcidin inhibits iron transport by binding to ferroportin on enterocytes and macrophages (see Fig. 24.21). Approximately 90% of GH patients are homozygous for a single point pathogenic variant resulting in a cysteine to tyrosine substitution at position 282 (C282Y) in the HFE protein, which leads to reduced hepcidin levels and ultimately uncontrolled increased iron absorption. This is one of the most frequent genetic disorders in Northern European populations. However, penetrance is variable and fewer than 50% of C282Y homozygotes develop clinical features of haemochromatosis. Iron loss in menstruation and pregnancy can delay the onset of GH in females. A single copy of the C2828Y mutation can also cause GH if also accompanied by a histidine-to-aspartic acid pathogenic variant at position 63 (H63D), referred to as compound heterozygosity. This genotype has a lower risk of iron overload and typically causes a less severe form of haemochromatosis. A number of other rare autosomal recessive pathogenic variants leading to GH are described. The second most common form of inherited iron disorder is ferroportin disease, an autosomal dominant disorder which typically has a milder clinical phenotype than HFE-associated haemochromatosis.

23.59 Causes of haemochromatosis

Primary haemochromatosis

- HFE-associated haemochromatosis (AR)
- Juvenile haemochromatosis (hemojuvelin/hepcidin pathogenic variant, AR)
- Transferrin receptor 2 deficiency (*TFR2* pathogenic variant, AR)
- Ferroportin disease (*SLC40A1* pathogenic variant, AD)

Secondary iron overload

- Transfusional or dietary iron overload
- Iron-loading anaemia (thalassaemia, sideroblastic anaemia, chronic haemolytic anaemias)
- Liver disease (ArLD, MASLD, hepatitis C)

(AD = autosomal dominant, AR = autosomal recessive; ArLD = alcohol-related liver disease; MASLD = metabolic dysfunction–associated steatotic liver disease)

Clinical features

Symptomatic disease usually presents in men over 40 years of age with features of liver disease (often with hepatomegaly), diabetes or heart failure. Fatigue and arthropathy are early symptoms but are frequently absent. Leaden-grey skin pigmentation can sometimes occur due to excess melanin, especially in exposed parts, axillae, groins and genitalia: hence the term ‘bronzed diabetes’. Impotence, loss of libido and testicular atrophy are recognised complications, as are early-onset osteoarthritis targeting unusual sites such as the metacarpophalangeal joints, chondrocalcinosis and pseudogout. Cardiac failure or cardiac dysrhythmia may occur due to iron deposition in the heart.

Investigations

In the absence of inflammation, serum ferritin is proportional to iron stores. The initial approach to diagnosis of haemochromatosis involves assessment of iron stores by measurement of serum ferritin and transferrin saturation. Patients with GH have raised ferritin (> 200 μg/L in women, > 300 μg/L in men) and raised transferrin saturations (> 45% in women, > 50% in men), and this pattern should prompt molecular testing for HFE mutations. If HFE-associated GH is confirmed, those with raised transaminases or a ferritin over 1000 μg/L (100 μg/dL) are at highest risk for liver disease and should also undergo fibrosis assessment (usually with transient elastography). If GH is suspected but HFE genotyping is normal, MRI liver or liver biopsy can be used to assess for significant iron overload to identify patients requiring extended genetic testing. Liver biopsy allows assessment of the distribution of iron, with deposition predominantly within hepatocytes being characteristic of haemochromatosis (Fig. 23.40), while accumulation within reticuloendothelial cells is more suggestive of secondary iron overload. The hepatic iron index (HII) provides quantification of liver iron (μmol of iron per gram dry weight of liver/age in years). An HII of more than 1.9 suggests genetic haemochromatosis. The differential diagnoses for elevated ferritin are systemic inflammatory diseases, alcohol-related liver disease and MASLD. Very significant ferritin elevation can be seen in adult Still disease and acute liver failure secondary to paracetamol overdose and acute severe viral hepatitis.

Management

Treatment consists of weekly venesection of 500 mL blood (250 mg iron) to reduce ferritin to under 50 μg/L (5 μg/dL) and transferrin saturations to under 50%. Thereafter, venesection is continued as required to maintain these parameters (target ferritin 50–100 μg/L). Liver and cardiac problems improve after iron removal, but joint pain is less predictable and can improve or worsen after iron removal. Diabetes does not resolve. First-degree family members should be investigated, preferably by genetic screening, to identify and treat other cases early.

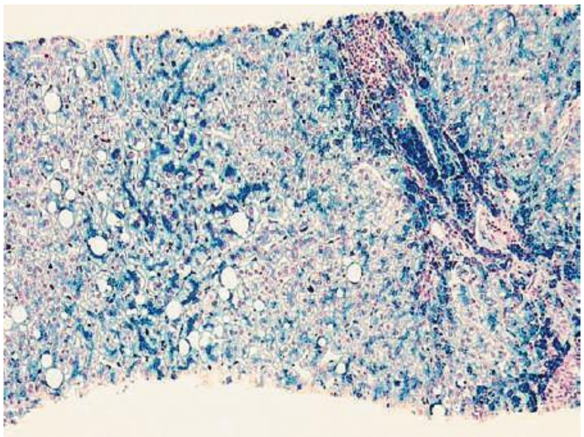

Fig. 23.40 Liver histology in haemochromatosis. This Perls stain shows accumulating iron within hepatocytes, which is stained blue. There is also accumulation of large fat globules in some hepatocytes (macrovesicular steatosis). Iron also accumulates in Kupffer cells and biliary epithelial cells.

Pre-cirrhotic patients with GH have a normal life expectancy, and even cirrhotic patients have a good prognosis compared with other forms of cirrhosis (three-quarters of patients are alive 5 years after diagnosis). This is probably because liver function is often well preserved at diagnosis and improves with therapy. Screening for hepatocellular carcinoma is mandatory in cirrhotic patients because this is the main cause of death, affecting one-third of patients with cirrhosis. Venesection reduces but does not abolish the risk of hepatocellular carcinoma in the presence of cirrhosis.

Secondary haemochromatosis

Many conditions, including chronic haemolytic disorders, sideroblastic anaemia, other conditions requiring multiple blood transfusion (generally over 50 L), porphyria cutanea tarda, dietary iron overload and occasionally alcohol-related cirrhosis, are associated with widespread secondary iron overload. The features are similar to those of primary haemochromatosis, but the history and clinical findings point to the true diagnosis. Some patients are heterozygotes for *HFE* mutations and this may contribute to the development of iron overload.

Wilson disease

Wilson disease (hepatolenticular degeneration) is a rare but important autosomal recessive disorder of copper metabolism caused by a variety of pathogenic variants in the *ATP7B* gene. Pathological copper accumulation leads to damage to liver, brain and other organs.

Pathophysiology

Copper acts as a co-factor for a number of essential enzymes. Dietary absorption is usually balanced by excretion into bile. The *ATP7B* gene encodes a transmembrane copper-transporting ATPase which excretes copper into bile, and loss of function causes excessive copper accumulation. This transporter is also required for synthesis of functional caeruloplasmin, the circulating copper-binding protein. The amount of copper in the body at birth is normal, but thereafter it increases steadily; the organs most affected are the liver, basal ganglia of the brain, eyes, kidneys and skeleton.

At least 700 different pathogenic variants have been described. Most cases are compound heterozygotes with two different pathogenic variants in *ATP7B*. Attempts to correlate the genotype with the mode of presentation and clinical course have not shown any consistent patterns. The large number of culprit pathogenic variants means that, in contrast to haemochromatosis, genetic diagnosis is not routine in Wilson disease, although it may have a role in screening families following identification of the genotype in an index patient.

Clinical features

Symptoms usually arise between the ages of 5 and 45 years. Hepatic disease occurs predominantly in childhood and early adolescence. Neurological damage causes movement disorders and dementia, which tends to present in later adolescence. These features can occur alone or simultaneously. Other manifestations include renal tubular damage and osteoporosis, but these are rarely presenting features.

Liver disease

There is a wide spectrum of acute and chronic presentations of liver disease, including asymptomatic elevated liver enzymes, acute hepatitis, recurrent jaundice and silent progression to cirrhosis. Fulminant liver failure can occur, especially in young women. This causes the liberation of free copper into the blood stream, causing massive haemolysis and renal tubulopathy. The possibility of Wilson disease should be considered in any patient under the age of 40 presenting with recurrent acute hepatitis or chronic liver disease of unknown cause, especially when this is accompanied by haemolytic anaemia.

Neurological disease

Clinical features include a variety of extrapyramidal features, particularly tremor, choreoathetosis, dystonia, parkinsonism and dementia.

Neurological disease typically develops after the onset of liver disease and can be prevented by effective treatment. This increases the importance of diagnosis in the liver phase beyond just allowing effective management of liver disease.

Kayser–Fleischer rings

These constitute the most important single clinical clue to the diagnosis and can be seen in 60% of adults with Wilson disease (less often in children but almost always in neurological Wilson disease) but require slit-lamp examination for correct identification. Kayser–Fleischer rings are characterised by greenish-brown discoloration of the corneal margin appearing first at the upper periphery. They disappear with treatment.

Investigations

The diagnosis of Wilson disease is based on algorithms incorporating symptoms and signs, measures of copper metabolism and DNA analysis. A low serum caeruloplasmin is the best single laboratory clue to the diagnosis. However, advanced liver failure from any cause can also reduce the serum caeruloplasmin, and conversely a normal value does not exclude the diagnosis if there is a high index of suspicion. Other features of disordered copper metabolism should therefore be sought; these include a high free serum copper concentration, a high urine copper excretion of greater than 1.6 µmol/24 hrs (100 µg/24 hrs) and a very high hepatic copper content. Measuring 24-hour urinary copper excretion while giving D-penicillamine may be a useful confirmatory test.

Management

Pharmacological treatment is with either chelating-agents (D-penicillamine or trientine) that increase urinary copper excretion, or zinc salts, which reduce absorption of dietary copper. The copper-binding agent penicillamine is the drug of choice. The dose given must be sufficient to produce cupriuresis and urinary copper excretion should be measured to confirm adequacy of treatment. The dose can be reduced once the disease is in remission, but treatment must continue for life, including throughout pregnancy. Care must be taken to ensure that re-accumulation of copper does not occur. Abrupt discontinuation of treatment must be avoided because this may precipitate acute liver failure. Toxic effects occur in one-third of patients with penicillamine and include rashes, protein-losing nephropathy, lupus-like syndrome and bone marrow depression. If these arise, trientine and zinc are potential alternatives.

Prognosis is excellent with early treatment, and presymptomatic patients compliant with treatment have comparable survival to the general population. Liver transplantation is indicated for fulminant liver failure or for advanced cirrhosis with liver failure. The value of liver transplantation in severe neurological Wilson disease is unclear. Siblings and children must be investigated and treatment should be given to all affected individuals, even if they are asymptomatic.

Alpha-1-antitrypsin deficiency

Alpha-1-antitrypsin (α1-AT) is a serine protease inhibitor (serpin) produced by the liver and secreted into the circulation. One of its main functions is the breakdown of neutrophil elastase. Circulating levels of α1-AT can double during the acute phase response and play a key anti-inflammatory role, preventing damage to normal tissues. Numerous variants of the *SERPINA1* gene have been described, but there are two common pathogenic variants, one of which is referred to as the Z allele and the other the S allele. The wild type is known as the M allele. Ninety-five percent of patients with severe deficiency are homozygotes for the Z allele (PiZZ). Less severe deficiency occurs in compound heterozygotes for the Z and S allele (PiSZ). The abnormal α1-AT forms polymers within the endoplasmic reticulum of hepatocytes, with reduced secretion into the blood. The accumulation of polymers within hepatocytes causes the liver toxicity, whereas the unopposed neutrophil elastase activity causes damage to structural proteins in the lungs. Homozygous individuals for the Z variant (ZZ) have low plasma α1-AT concentrations, although globules containing α1-AT are found in the liver, and these people may develop hepatic and pulmonary disease. Liver manifestations include cholestatic jaundice in the neonatal period (neonatal hepatitis), which can resolve spontaneously; and chronic hepatitis leading to cirrhosis in adults. Alpha-1-antitrypsin deficiency is an exacerbating factor for liver disease of other aetiologies, and the possibility of dual pathology should be considered when severity of disease, such as ArLD, appears disproportionate to the level of underlying insult.

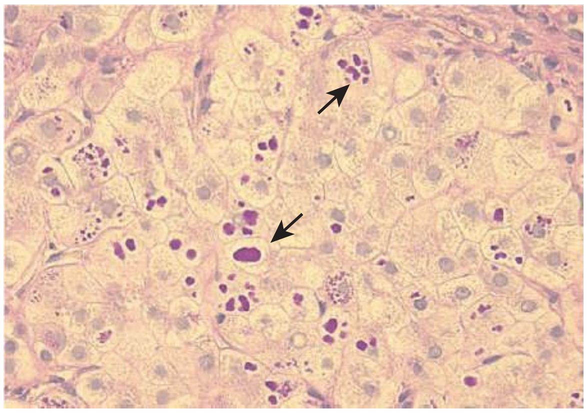

Fig. 23.41 Liver histology in α1-antitrypsin deficiency. Accumulation of periodic acid–Schiff-positive granules (arrows) within individual hepatocytes is shown in this section from a patient with α1-AT deficiency.

Other than potential coexisting pulmonary disease, there are no clinical features that distinguish liver disease due to α1-AT deficiency from liver disease due to other causes, and the diagnosis is made from the low plasma α1-AT concentration and genotyping for the presence of the pathogenic variant. Alpha-1-antitrypsin-containing globules can be demonstrated in the liver (Fig. 23.41), but this is not necessary to make the diagnosis. There is no specific treatment for the associated liver disease yet, although trials of small interfering RNA are in progress. The risk of severe and early-onset emphysema means that all patients should be advised to stop smoking. Alpha-1-antitrypsin augmentation therapy is available in some countries for lung disease.

Gilbert syndrome

Gilbert syndrome is by far the most common inherited disorder of bilirubin metabolism (see Box 23.12). It is an autosomal recessive trait when caused by a pathogenic variant in the promoter region of the gene for UDP-glucuronyl transferase enzyme (*UGT1A1*), which leads to reduced enzyme expression. It can be inherited in a dominant fashion when there is a missense pathogenic variant in the gene. This results in decreased conjugation of bilirubin, which accumulates as unconjugated bilirubin in the blood. The levels of unconjugated bilirubin increase during fasting, as fasting reduces levels of UDP-glucuronyl transferase.

Clinical features

The typical presentation is with isolated elevation of bilirubin, typically, although not exclusively, in the setting of physical stress or illness. There are no stigmata of chronic liver disease other than jaundice. Increased excretion of bilirubin and hence stercobilinogen leads to normal-coloured or dark stools, and increased urobilinogen excretion causes the urine to turn dark on standing as urobilin is formed.

Investigations

The plasma bilirubin is usually less than 100 µmol/L (~6 mg/dL) and the LFTs are otherwise normal. There is no bilirubinuria because the hyperbilirubinaemia is predominantly unconjugated. Hepatic histology is normal, and liver biopsy is not recommended for the investigation of patients with possible Gilbert syndrome. Genetic testing is available. The condition is not associated with liver injury and thus has an excellent prognosis, needs no treatment, and is clinically important only because it may be mistaken for more serious liver disease.

Vascular liver disease

Metabolically, the liver is highly active and has large oxygen requirements. This places it at risk of ischaemic injury in settings of impaired perfusion. The risk is mitigated, however, by the dual perfusion of the liver (via the portal vein as well as hepatic artery), with the former representing a low-pressure perfusion system that offers protection against the potential effects of arterial hypotension. The single outflow through the hepatic vein and the low-pressure perfusion system of the portal vein make the liver vulnerable to venous thrombotic ischaemia in the context of Budd–Chiari syndrome and portal vein thrombosis, respectively.

Hepatic arterial disease

Liver ischaemia

Liver ischaemic injury (ischaemic hepatitis) is relatively common during hypotensive or hypoxic events and is under-diagnosed. The characteristic pattern is one of rising transaminase values in the days following an event associated with hypoxia such as in a patient with prolonged seizures. Ischaemic hepatitis is more common in patients with pre-existing hepatic congestion due to congestive cardiac failure or underlying liver disease. Liver synthetic dysfunction and encephalopathy are uncommon but can occur. Liver failure is very rare. Diagnosis typically rests on clinical suspicion and exclusion of other potential aetiologies. Treatment is aimed at optimising liver perfusion and oxygen delivery. Outcome is dictated by the morbidity and mortality associated with the underlying disease, given that liver ischaemia frequently occurs in the context of other organ ischaemia in high-risk patients.

Liver arterial disease

Hepatic arterial disease is rare outside the setting of liver transplantation and is difficult to diagnose. It can cause significant liver damage. Hepatic artery occlusion may result from inadvertent injury during biliary surgery or may be caused by emboli, neoplasms, polyarteritis nodosa, blunt trauma or radiation. It usually causes severe upper abdominal pain with or without signs of circulatory shock. LFTs show raised transaminases (AST or ALT usually > 1000 U/L), as in other causes of acute liver damage. Patients usually survive if the liver and portal blood supply are otherwise normal.

Hepatic artery aneurysms are extrahepatic in three-quarters of cases and intrahepatic in one-quarter. Atheroma, vasculitis, bacterial endocarditis and surgical or biopsy trauma are the main causes. They usually lead to bleeding into the biliary tree, peritoneum or intestine. CT scans are helpful in identifying the location of the aneurysm, adjacent structures and evidence of rupture. Angiography remains the gold standard for diagnosis. Treatment is radiological or surgical. Any of the vasculitides can affect the hepatic artery, but this rarely causes symptoms.

Hepatic artery thrombosis (HAT) is a recognised complication of liver transplantation and typically occurs in the early post-transplant period. Clinical features are often related to bile duct rather than liver ischaemia because of the dominant role of the hepatic artery in extrahepatic bile duct perfusion. Manifestations can include bile duct anastomotic failure with bile leak or the development of late bile duct strictures (ischaemic cholangiopathy). Diagnosis and initial intervention are radiological in the first instance, with ERCP and biliary stenting being the principal approaches to the treatment of biliary strictures causing significant cholestasis.

Portal venous disease

Portal hypertension

This is dealt with on page 900 of this chapter.

Portal vein thrombosis

Portal venous thrombosis as a primary event is rare but can occur in any condition predisposing to thrombosis. It may also complicate intra-abdominal inflammatory or neoplastic disease and is a recognised cause of portal hypertension. Acute portal venous thrombosis causes abdominal pain and diarrhoea, and may rarely lead to bowel infarction, requiring surgery. Underlying thrombophilia needs to be excluded. Treatment is based on anticoagulation, which is associated with increased recanalisation rates following acute portal vein thrombosis. Interventional thrombolysis and TIPSS can be considered in selected patients with features of intestinal ischaemia or organ failure. Subacute thrombosis can be asymptomatic but may subsequently lead to extrahepatic portal hypertension. Ascites is unusual in non-cirrhotic portal hypertension, unless the albumin is particularly low.

Portal vein thrombosis can arise as a secondary event in patients with cirrhosis and portal hypertension and is a recognised cause of decompensation in patients with previously stable cirrhosis. In individuals showing such decompensation, portal vein patency should be assessed by ultrasound with Doppler flow studies. The role of anticoagulation in patients with chronic portal vein thrombosis is unclear, but it is recommended in potential transplant candidates to reduce the risk of clot propagation. Chronic portal vein thrombosis can be a cause of portal hypertension. Isolated obstruction of the splenic vein, occurring as a complication of pancreatic disease, can lead to left-sided or segmental portal hypertension.

Hepatopulmonary syndrome

This condition is characterised by resistant hypoxaemia ($PaO_2 < 9.3$ kPa (70 mmHg)), due to intrapulmonary vascular dilatation and shunt in patients with cirrhosis and portal hypertension. Clinical features include finger clubbing, cyanosis and a characteristic reduction in arterial oxygen saturation on standing (orthodeoxia). The hypoxia is the result of changes in the alveolar microcirculation with vascular dilatation exacerbating ventilation/perfusion (V/Q) mismatch and the development of direct AV shunts. Nitric oxide (NO) over-production may be important in pathogenesis. The hepatopulmonary syndrome can be treated by liver transplantation but, if severe ($PaO_2 < 6.7$ kPa (50 mmHg)), is associated with an increased operative risk.

Portopulmonary hypertension

This unusual complication of portal hypertension is similar to primary pulmonary hypertension (Chapter 17). It is defined as pulmonary hypertension with increased pulmonary vascular resistance and a normal pulmonary artery wedge pressure in a patient with portal hypertension. The condition is caused by vasoconstriction and obliteration of the pulmonary arterial system and leads to breathlessness and fatigue.

Hepatic venous disease

Obstruction to hepatic venous blood flow can occur in the small central hepatic veins, the large hepatic veins, the inferior vena cava or the heart. The clinical features depend on the cause and on the speed with which obstruction develops and can mimic many other forms of chronic liver disease, sometimes leading to delayed diagnosis. Congestive hepatomegaly and ascites are the most consistent features. The possibility of hepatic venous obstruction should always be considered in patients with an atypical liver presentation.

Budd–Chiari syndrome

This uncommon condition is caused by thrombosis of the larger hepatic veins and sometimes the inferior vena cava. Many patients have haematological disorders such as myelofibrosis, primary proliferative polycythaemia, paroxysmal nocturnal haemoglobinuria, or antithrombin III, protein C or protein S deficiencies (Ch. 24). Pregnancy and oral contraceptive use, obstruction due to tumours (particularly carcinomas of the liver, kidneys or adrenals), congenital venous webs and occasionally inferior vena caval stenosis are the other main causes. The underlying cause cannot be found in about 30% of patients, although this percentage is falling as new diagnostic tools have emerged, such as testing for pathogenic *JAK2* variants in myelofibrosis. Hepatic congestion affecting the centrilobular areas is followed by centrilobular fibrosis, and eventually cirrhosis supervenes in those who survive long enough.

Clinical features

Acute venous occlusion causes rapid development of upper abdominal pain, marked ascites and occasionally acute liver failure. More gradual occlusion causes gross ascites and, often, upper abdominal discomfort. Hepatomegaly, frequently with tenderness over the liver, is almost always present. Peripheral oedema occurs only when there is inferior vena cava obstruction. Features of cirrhosis and portal hypertension develop in those who survive the acute event.

Investigations

The LFTs vary considerably, depending on the presentation, and can show the features of acute hepatitis. Ascitic fluid analysis shows a protein concentration above 25 g/L (2.5 g/dL) in the early stages; however, this often falls later in the disease. Doppler ultrasound may reveal obliteration of the hepatic veins and reversed flow or associated thrombosis in the portal vein. CT may show enlargement of the caudate lobe, as this often has a separate venous drainage system that is not involved in the disease. CT and MRI may also demonstrate occlusion of the hepatic veins and inferior vena cava. Liver biopsy demonstrates centrilobular congestion with fibrosis, depending on the duration of the illness. Venography is needed only if CT and MRI are unable to demonstrate the hepatic venous anatomy clearly.

Management

Predisposing causes should be treated as far as possible; where recent thrombosis is suspected, thrombolysis with recombinant tissue plasminogen activator or streptokinase, followed by heparin and oral anticoagulation, should be considered. Long-term anticoagulation is required. Ascites is initially treated medically but often with only limited success. Short hepatic venous strictures can be treated with angioplasty or hepatic vein stenting. In the case of more extensive hepatic vein occlusion, many patients can be managed successfully by insertion of a covered TIPSS, followed by anticoagulation. Surgical shunts, such as portacaval shunts, are rarely performed now that TIPSS is available. Approximately 40% of patients will require TIPSS following failure of medical management. Survival at 1 year and 5 years following TIPSS is 88% and 78%, respectively. Occasionally, a web can be resected or an inferior vena cava stenosis dilated. Progressive liver failure is an indication for liver transplantation and life-long anticoagulation.

Sinusoidal obstruction syndrome

Sinusoidal obstruction syndrome (SOS; previously known as veno-occlusive disease) is a rare condition characterised by widespread occlusion of the small central hepatic veins. Pyrrolizidine alkaloids in *Senecio* and *Heliotropium* plants used to make teas, as well as cytotoxic drugs and hepatic irradiation, are all recognised causes. SOS may develop in 10%–20% of patients following haematopoietic stem cell transplantation (usually within the first 20 days) and carries a 90% mortality in severe cases. Pathogenesis involves obliteration and fibrosis of terminal hepatic venules due to deposition of red cells, haemosiderin-laden macrophages and coagulation factors. In this setting, SOS is thought to relate to pre-conditioning therapy with irradiation and cytotoxic chemotherapy. The clinical features are similar to those of the Budd–Chiari syndrome (see above). Investigations show evidence of venous outflow obstruction histologically but, in contrast to Budd–Chiari, the large hepatic veins appear patent radiologically. Transjugular liver biopsy (with portal pressure measurements) may facilitate the diagnosis. Treatment involves supportive care/fluid management to maintain intravascular filling. In severe cases, defibrotide, a drug that binds to vascular endothelial cells, promoting fibrinolysis and suppressing coagulation, is recommended.

Cardiac disease

Hepatic damage, due to congestion and ischaemia, may develop in all forms of right heart failure. The clinical features are predominantly cardiac in nature. Very rarely, long-standing cardiac failure or pericardial disease (constrictive pericarditis), with resultant hepatic congestion gives rise to cardiac cirrhosis. Liver cirrhosis is also a recognised complication of some forms of congenital heart disease. Fontan-associated liver disease develops in patients with diverse forms of congenital cardiac disease resulting in a single functioning ventricle, treated with the Fontan procedure. Chronic hepatic congestion resulting from passive filling of the pulmonary arterial circulation results in progressive liver fibrosis and cirrhosis. Severe left ventricular dysfunction is a cause of ischaemic hepatitis. Cardiac causes of acute and chronic liver disease are typically under-diagnosed. Treatment is principally that of the underlying heart disease with supportive treatment for the liver component.

Nodular regenerative hyperplasia of the liver

This is the most common cause of non-cirrhotic portal hypertension in developed countries; it is characterised by small hepatocyte nodules throughout the liver without fibrosis, which can result in sinusoidal compression. It is believed to be due to damage to small hepatic arterioles and portal venules. It occurs in older people and is associated with many conditions, including connective tissue disease, haematological diseases and immunosuppressive drugs, such as azathioprine. The condition is usually asymptomatic but occasionally presents with portal hypertension or with an abdominal mass. The diagnosis is made by liver biopsy, which, in contrast to cirrhosis, shows nodule formation in the absence of fibrous septa. Liver function is good and the prognosis is very favourable. Management is based on treatment of the portal hypertension.

Pregnancy and the liver

The inter-relationship between liver disease and pregnancy can be a complex one and a source of real anxiety for both patient and clinician. Three possibilities need to be borne in mind when treating a pregnant woman with a liver abnormality:

- This represents a worsening of pre-existing chronic liver or biliary disease (although pregnancy may be the first time a woman's liver biochemistry has been tested, so this may not have previously been diagnosed).
- This represents a genuine first presentation of liver disease that is not intrinsically related to pregnancy.
- This represents a genuine pregnancy-associated liver injury process.

It is critical to obtain information relating to liver disease risk factors and pre-pregnancy liver status to establish whether any abnormality was present before pregnancy. In general, the earlier in pregnancy that liver abnormality presents, the more likely it is to represent either pre-existing liver disease or non-pregnancy-related acute liver disease. Equally, the best outcome for both mother and baby results from optimising the physical condition of the mother, and in situations of deteriorating liver function (which can be steep in late pregnancy) consideration should always be given to early delivery if the fetus is viable. Joint management between hepatologists and obstetricians is essential.

Intercurrent and pre-existing liver disease

Acute hepatitis A can occur during pregnancy but has no effect on the fetus. Chronic hepatitis B requires identification in pregnancy because of long-term health implications for the mother and the effectiveness of perinatal vaccination (with or without pre-delivery maternal antiviral therapy) in reducing neonatal acquisition of chronic hepatitis B. Maternal transmission of hepatitis C occurs in 1% of cases and there is no convincing evidence that the mode of delivery affects this. Hepatitis E (genotypes 1 and 2) is reported to progress to acute liver failure much more commonly in pregnancy, with a 20% maternal mortality. Pregnancy may be associated with either worsening or improvement of autoimmune hepatitis, although improvement during pregnancy and rebound post-partum is the most common pattern seen. Complications of portal hypertension may be a particular issue in the second and third trimesters.

Gallstones are more common during pregnancy and may present with cholecystitis or biliary obstruction. The diagnosis can usually be made with ultrasound. In biliary obstruction due to gallstones, therapeutic ERCP can be safely performed but lead protection for the fetus is essential and X-ray screening must be kept to a minimum.

Pregnancy-associated liver disease

Several conditions occur only during pregnancy, may recur in subsequent pregnancies and resolve after delivery of the baby, and these are discussed in Chapter 30. The causes of abnormal LFTs in pregnancy, which include pregnancy-associated liver disease, are shown in Box 23.60.

Liver transplantation

Liver transplantation is an effective treatment for end-stage liver disease. However, the number of procedures is limited by cadaveric donor availability, and 5%–15% of those listed for liver transplantation die while awaiting a donor liver. The main complications of liver transplantation relate to long-term immunosuppression, rejection or disease recurrence in the liver graft.

Indications and contraindications

More than 30 000 liver transplants are performed worldwide each year. The main indications vary between regions. In Europe, the majority of liver transplants are for decompensated cirrhosis (56%), most frequently due to alcohol, hepatitis C or MASLD, followed by hepatocellular carcinoma (17%), with 8% for acute liver failure. Figure 23.42 shows indications for transplantation in the UK. In Asia, the most common indication is hepatocellular carcinoma related to hepatitis B. Patterns are changing over time, with reducing need for transplant in hepatitis C as a result of improved antiviral therapy but increasing for MASLD as the result of increased prevalence of this disorder. Liver transplantation is increasingly being undertaken in older patients, with 30% of liver transplants in Europe now in patients aged over 60 years, but only a very small number aged over 70 years.

Transplant may be undertaken to improve survival in advanced liver disease or to alleviate symptoms. Common indications for elective transplant assessment are listed in Box 23.61. There are various criteria for HCC based on the size and number of lesions and level of serum alpha-fetoprotein (as these factors predict risk of recurrence post-transplant). Current UK guidelines allow transplant for a single lesion ≤5 cm, or up to five lesions ≤3 cm, provided there is no macrovascular invasion or extrahepatic spread. Larger lesions may be suitable if stable following treatment.

Specific criteria exist for patients with acute liver failure, depending on aetiology.

23.60 Abnormal liver function tests in pregnancy

- **Liver function tests**: alkaline phosphatase (ALP) levels and albumin normally fall in pregnancy. ALP levels can rise due to the contribution of placental ALP.
- **Pre-existing liver disease**: pregnancy is uncommon in cirrhosis because cirrhosis causes relative infertility. Varices can enlarge in pregnancy, and ascites should be treated with amiloride rather than spironolactone. Penicillamine for Wilson disease and azathioprine for autoimmune liver disease should be continued throughout pregnancy. Autoimmune liver disease can flare up post-partum.
- **Incidental**: viral, autoimmune and drug-induced hepatitis must be excluded in the presence of an elevated alanine aminotransferase (ALT). Immunoglobulin/vaccination given to the fetus at birth prevents transmission of hepatitis B to the fetus if the mother is infected. Gallstones are more common in pregnancy and post-partum and are a cause of a raised ALP level. Biliary imaging with ultrasound and magnetic resonance cholangiopancreatography is safe. Endoscopic retrograde cholangiopancreatography to remove stones can be performed safely with shielding of the fetus from radiation.
- **Pregnancy-related liver diseases**: occur predominantly in the third trimester and resolve post-partum. Maternal and fetal mortality and morbidity are reduced by expediting delivery.

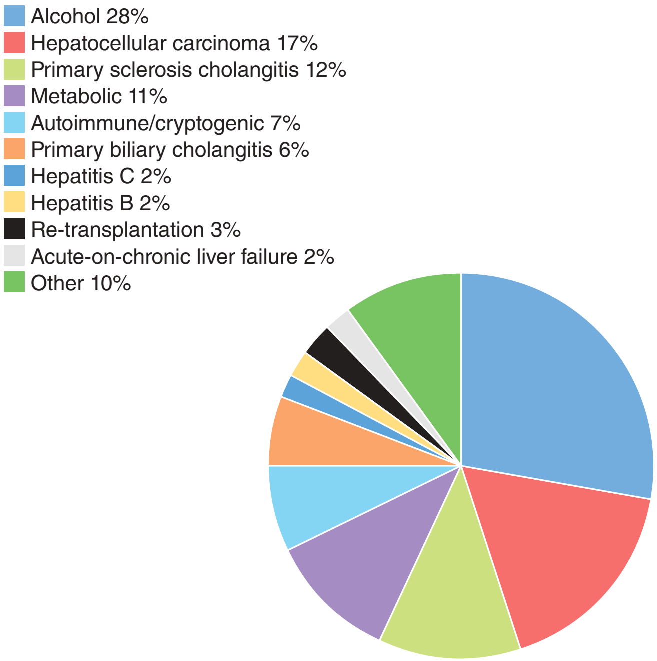

Fig. 23.42 Indications for elective adult liver transplantation in the UK, 2022-2023.

23.61 Potential indications for liver transplant in cirrhosis

Complications

- First episode of bacterial peritonitis
- Diuretic-resistant ascites
- Recurrent variceal haemorrhage
- Hepatocellular carcinoma
- Persistent hepatic encephalopathy

Poor liver function

- Bilirubin > 100 μmol/L (5.8 mg/dL) in primary biliary cholangitis
- MELD score > 12 (Box 23.32)
- UKELD score ≥ 49
- Child–Pugh grade C (Box 23.31)

(MELD = Model for End-stage Liver Disease; UKELD = United Kingdom Model for End-stage Liver Disease)

The main contraindications to transplantation are extrahepatic sepsis or malignancy, continued alcohol or other substance misuse, and significant cardiorespiratory disease.

Patients are matched for ABO blood group and body size but do not require HLA matching with donors, as the liver is a relatively immune-privileged organ compared with the heart or kidneys.

Organ allocation is often based on greatest need, estimating short-term mortality using the MELD or UKELD scores (see Box 23.32). The United Kingdom has recently moved to a national allocation system based on Transplant Benefit Score, which uses donor and recipient variables to calculate the difference between the mortality without transplant (need) and the predicted 5-year survival with transplant (utility), to identify those with the greatest net benefit.

Approaches to increase the availability of donor organs include:

- *Split liver transplantation*. Due to the liver's regenerative capacity, a cadaveric donor liver can be split into two, with the larger right lobe used in an adult and the smaller left lobe used in a child.
- *Living donor transplantation*. This is normally performed using the left lateral segment or the right lobe from a healthy donor. The donor mortality is significant, at 0.5%–1%. Pre-operative assessment includes looking at donor liver size and psychological status.
- *Use of marginal grafts*. Higher-risk livers (older donors, steatotic livers, non-heart-beating donors) are being used in selected patients. Novel organ perfusion technologies may help to improve graft selection and outcomes in this group.
- *Increased donation*. Improved infrastructure to support organ donation, increased public awareness of transplantation and changes to consent process ('opt-out', or presumed consent) may all increase donation rates.

Complications

Early complications

Primary graft non-function

This is due to a severe ischaemia–reperfusion injury, resulting in irreversible graft failure and requiring early re-transplantation in around 1%–2% of recipients. Factors that increase the likelihood of primary non-function include increasing donor age, degree of steatosis in the liver and the length of ischaemia.

Technical complications

These include hepatic artery thrombosis, which may necessitate re-transplantation. Anastomotic biliary strictures can also occur; these may respond to endoscopic stenting or require surgical reconstruction. Portal vein thrombosis following transplant is rare.

Rejection

Life-long immunosuppression is required in most liver transplant recipients, although at lower levels than with kidney or heart/lung transplants. Immunosuppression is maximal in the early post-operative period, with reducing levels over time. A number of different regimens are used but the majority include a calcineurin inhibitor (usually tacrolimus) with or without an antimetabolite (azathioprine or mycophenolate) or tapering glucocorticoids. Some patients can eventually be maintained on a single agent. Acute cellular rejection occurs in 15%–25% of patients, commonly presenting as raised liver enzymes at 5–30 days post-transplant but can arise later. This normally responds to 3 days of high-dose intravenous methylprednisolone.

Infections

Bacterial infections, such as pneumonia and wound infections, can occur in the first few weeks after transplantation. Opportunistic infections are also seen, and prophylaxis against fungal infections and *Pneumocystis jirovecii* may be given during the first few months. Cytomegalovirus (primary infection or reactivation) is common in the 3 months after transplantation and can cause fevers, bone marrow suppression and hepatitis. Patients who have never had cytomegalovirus infection but who receive a liver from a donor who has been exposed are at greatest risk and need to be monitored for CMV viraemia or given prophylactic antiviral therapy, such as valganciclovir, in the early post-transplant period. Patients with latent tuberculosis should receive prophylaxis against reactivation.

Late complications

Late complications are mostly consequences of long-term immunosuppression. These include malignancy (especially skin cancers and lymphoma), renal failure and cardiovascular disease. Weight gain is common following liver transplantation, leading to obesity and diabetes. Chronic rejection is rare, occurring in only 5% of cases. Recurrence of the initial disease can occur, especially with autoimmune liver diseases or hepatocellular carcinoma.

Prognosis

Current UK data show 1-year survival for patients transplanted for cirrhosis of 94%, with 5-year survival of 84%. Outcomes are worse in patients transplanted for acute liver failure as they often have multi-organ failure at the time of transplantation, and in patients transplanted for hepatocellular carcinoma, due to disease recurrence.

Cholestatic and biliary disease

The concepts of biliary and cholestatic disease, and the important distinctions between them, can be a source of confusion. Cholestasis relates to impaired bile flow, usually detected as a biochemical abnormality (typically, elevation of ALP and elevation in serum bile acid levels and bilirubin). This can be due to failure of bile acid transport across the hepatocyte membrane, or physical obstruction of the bile duct. Biliary disease relates to pathology at any level from the small intrahepatic bile ducts to the sphincter of Oddi. Although there is very significant overlap between cholestatic and biliary disease, there are scenarios where cholestasis can exist without biliary disease (transporter disease or pure drug-induced cholestasis) and where biliary disease can exist without cholestasis (when disease of the bile duct does not impact on bile flow).

Chemical cholestasis

Pure cholestasis can occur as an inherited condition (p. 925), as a consequence of cholestatic drug reactions (p. 924) or as acute cholestasis of pregnancy. A more frequent, but less recognised, acquired biochemical cholestasis occurs in sepsis (cholangitis lenta). This biochemical phenomenon is one of the causes of LFT abnormality in sepsis. Also termed subacute non-suppurative cholangitis, it is characterised by inspissated bile plugs in dilated bile ductules in the absence of mechanical obstruction. It does not require specific treatment and has a prognostic significance conferred by the underlying septic process.

Pathogenic variants in biliary transporters on either the hepatocyte basolateral or canalicular membranes have been shown to cause inherited intrahepatic biliary disease of varying severity in children/adolescents and increasingly in adults (see Fig. 23.7).

Progressive familial intrahepatic cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is an inherited disease presenting in childhood characterised by itch, failure to thrive and jaundice (with raised ALP) progressing to biliary cirrhosis. PFIC can be caused by pathogenic variants in the bile salt transporter genes *ATP8B1* encoding FIC1 (PFIC1) *or ABCB11* encoding BSEP (PFIC2). The disease can also occur as the result of pathogenic variants in other genes. Management involves dietary support and medication to treat itch and malabsorption, biliary diversion surgery and/or liver transplant for liver failure.

Benign recurrent intrahepatic cholestasis

Benign recurrent intrahepatic cholestasis (BRIC) refers to a group of genetically heterogeneous disorders that are inherited in an autosomal recessive manner. BRIC can be caused by pathogenic variants in the same genes implicated in the pathogenesis of PFIC (see above). It is characterised by recurrent episodes of cholestatic jaundice lasting weeks to months. These episodes may be triggered by infections or drugs such as oral contraceptives or can occur spontaneously. It usually presents in adolescence. Prodromal symptoms include pruritus, nausea, vomiting and weight loss. Patients are asymptomatic between episodes. Blood tests typically show conjugated hyperbilirubinaemia with elevated ALP levels. Cholangiography shows no evidence of biliary obstruction. Liver biopsy shows cholestasis during episodes but is normal between episodes. Treatment is purely supportive to relieve symptoms and the long-term prognosis is good.

Intrahepatic biliary disease

Inflammatory and immune disease

The small intrahepatic bile ducts appear to be specifically vulnerable to immune-mediated injury, and ductopenic injury ('vanishing bile duct syndrome') can be a feature of a number of chronic conditions, including graft-versus-host disease (GVHD), sarcoidosis and, in the setting of liver transplantation, chronic rejection. Intrahepatic small bile duct injury occurs most frequently in primary biliary cholangitis, an autoimmune cholestatic disease, and less frequently in primary sclerosing cholangitis (see Box 23.54).

Caroli disease

Caroli disease and Caroli syndrome are rare congenital disorders characterised by multifocal saccular dilatation of the intrahepatic bile ducts. Bile duct ectasia may involve the entire liver, a lobe or a single segment. In Caroli disease, biliary ectasia occurs in isolation. However, in the more common variant, Caroli syndrome, the bile duct dilatation is associated with congenital hepatic fibrosis. The molecular pathogenesis is incompletely understood. Most cases are transmitted in an autosomal recessive manner and are associated with autosomal recessive polycystic kidney disease (ARPKD). In both conditions, focal dilatation of bile ducts leads to cholestasis with formation of biliary sludge and intraductal calculi. Recurrent attacks of cholangitis require antibiotic therapy and predispose to hepatic abscess formation. There is an increased risk of cholangiocarcinoma affecting 2.5%–16% of patients. Prognosis is generally poor. Localised disease may be treated by segmental liver resection. Patients with diffuse disease complicated by recurrent biliary sepsis or portal hypertension may require liver transplantation.

Congenital hepatic fibrosis

Congenital hepatic fibrosis (CHF) is a rare developmental disorder characterised by broad bands of fibrous tissue linking portal tracts and irregular-shaped proliferating bile ducts, resulting from ductal plate malformation. CHF may be inherited in an autosomal recessive manner and is associated with a range of disorders with multisystem involvement, including: Caroli syndrome, polycystic kidney disease, Joubert syndrome and Bardet–Biedl syndrome. The renal tubules may show cystic dilatation (medullary sponge kidney) and renal cysts/renal failure may develop. The condition typically presents in childhood or early adulthood, although late presentation is described. Patients may present with symptoms of portal hypertension, including painful splenomegaly and variceal bleeding with preserved hepatic function, or with symptoms of cholestasis and recurrent cholangitis (Caroli syndrome). However, patients frequently present with symptoms related to other organ systems such as renal abnormalities, renal impairment and neurological symptoms.

Cystic fibrosis

The term cystic fibrosis–associated liver disease (CFLD) encompasses the range of liver disease seen in patients with cystic fibrosis. Liver function test abnormalities are common, with persistent abnormalities affecting 40% of patients with cystic fibrosis. Biliary cirrhosis develops in 5%–10% of individuals by adolescence/early adulthood, when complications such as variceal haemorrhage may occur. Non-cirrhotic portal hypertension may develop as a consequence of pre-sinusoidal obliterative portal venopathy. UDCA may improve liver biochemistry but there is no strong evidence that it can influence disease progression. Deficiency of fat-soluble vitamins (A, D, E and K) may need to be treated in view of biliary and pancreatic disease.

Extrahepatic biliary disease

Diseases of the extrahepatic biliary tree typically present with the clinical features of impaired bile flow (jaundice, itch and fat malabsorption). Obstructive disease is frequently a consequence of ductal gallstones, sometimes with associated infection or inflammatory strictures, or post-surgical strictures. Malignant diseases (cholangiocarcinoma or carcinoma of the head of pancreas) should be considered in all patients with extrahepatic biliary obstruction. PSC frequently involves the extrahepatic biliary tree and its differential, IgG4 disease, is an important and potentially treatable cause of disease.

Choledochal cysts

Choledochal cysts are uncommon congenital cysts of the biliary tree (Fig. 23.43). They are usually diagnosed in the first decade of life. The majority cause diffuse dilatation of the common bile duct (type I). Others represent true diverticulae of the common bile duct (type II), dilatation of the intraduodenal bile duct at the pancreaticobiliary junction (type III) or dilatation of the intrahepatic and/or the extrahepatic biliary ducts (type IV). Type IV choledochal cysts are subdivided into those affecting the intrahepatic and extrahepatic ducts (type IVA) or multiple cysts affecting extrahepatic ducts with normal intrahepatic ducts (type IVB). Type V choledochal cysts refer to one or more cystic dilatations of intrahepatic ducts with normal extrahepatic ducts, with multiple cystic dilatations of intrahepatic ducts referred to as Caroli disease. Children may present with abdominal mass, jaundice or biliary peritonitis from cyst rupture. Adults more commonly present with jaundice, abdominal pain and cholangitis. Liver abscess and biliary cirrhosis may develop. There is an increased incidence of cholangiocarcinoma. Cyst excision with hepaticojejunostomy is the treatment of choice.

Secondary biliary cirrhosis

Secondary biliary cirrhosis develops after prolonged large duct biliary obstruction due to gallstones, benign bile duct strictures or sclerosing cholangitis (see below). Carcinomas rarely cause secondary biliary

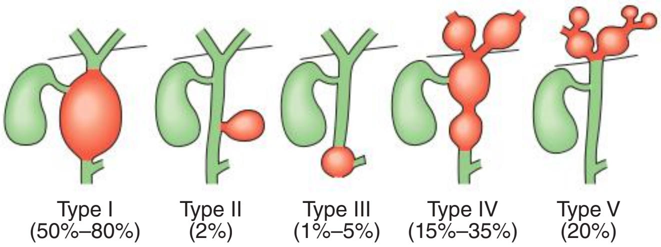

Fig. 23.43 **Classification and frequency of choledochal cysts.** *Adapted from the Todani Classification of Choledochal Cysts (1977).*

cirrhosis because few patients survive long enough. The clinical features are those of chronic cholestasis with episodes of ascending cholangitis or even liver abscess. Cirrhosis, ascites and portal hypertension are late features. Relief of biliary obstruction may require endoscopic or surgical intervention. Cholangitis requires treatment with antibiotics, which can be given continuously or on a rotational basis if attacks recur frequently.

Gallstones

Gallstone formation is the most common disorder of the biliary tree and it is unusual for the gallbladder to be diseased in the absence of gallstones. In high-income countries, gallstones occur in 7% of males and 15% of females aged 18–65 years, with an overall prevalence of 11%. In individuals under 40 years there is a 3:1 female preponderance, whereas in older people the sex ratio is about equal. Gallstones are less frequent in Asia and Africa. There has been much debate over the role of diet in cholesterol gallstone disease; an increase in dietary cholesterol, fat, total calories and refined carbohydrate and lack of dietary fibre have all been implicated as predisposing factors.

Pathophysiology

Gallstones are conventionally classified into cholesterol or pigment stones, although the majority are of mixed composition. Gallstones contain varying quantities of calcium salts, including calcium bilirubinate, carbonate, phosphate and palmitate, which are radio-opaque. Gallstone formation is multifactorial, and the factors involved are related to the type of gallstone (Boxes 23.62, 23.63).

Cholesterol gallstones

Cholesterol is held in solution in bile by its association with bile acids and phospholipids in the form of micelles and vesicles. Biliary lipoproteins may also have a role in solubilising cholesterol. In gallstone disease, the liver produces bile that contains an excess of cholesterol because there is either a relative deficiency of bile salts or a relative excess of cholesterol ('lithogenic' bile). Abnormalities of bile salt synthesis and circulation, cholesterol secretion and gallbladder function may make production of lithogenic bile more likely.

23.62 Risk factors and mechanisms for cholesterol gallstones

Increased cholesterol secretion

- Old age
- Female gender
- Pregnancy
- Obesity
- Rapid weight loss

Impaired gallbladder emptying

- Pregnancy
- Gallbladder stasis
- Fasting
- Total parenteral nutrition
- Spinal cord injury

Decreased bile salt secretion

- Pregnancy

23.63 Composition of and risk factors for pigment stones

Black	Brown
Composition	
Polymerised calcium bilirubinates*	Calcium bilirubinate crystals*
Mucin glycoprotein	Mucin glycoprotein
Calcium phosphate	Cholesterol
Calcium carbonate	Calcium palmitate/stearate
Cholesterol	
Risk factors	
Haemolysis	Infected bile
Age	Stasis
Hepatic cirrhosis	
Ileal resection/disease	

*Major component.

Pigment stones

Brown, crumbly pigment stones are almost always the consequence of bacterial or parasitic biliary infection. They are common in Asia, where infection allows bacterial β-glucuronidase to hydrolyse conjugated bilirubin to its free form, which then precipitates as calcium bilirubinate. The mechanism of black pigment gallstone formation in high-income countries is not satisfactorily explained. Haemolysis is important as a contributing factor for the development of black pigment stones that occur in chronic haemolytic disease.

Biliary sludge

This describes gelatinous bile that contains numerous microspheroliths of calcium bilirubinate granules and cholesterol crystals, as well as glycoproteins; it is an important precursor to the formation of gallstones in the majority of patients. Biliary sludge is frequently formed under normal conditions but then either dissolves or is cleared by the gallbladder; only in about 15% of patients does it persist to form cholesterol stones. Fasting, parenteral nutrition and pregnancy are also associated with sludge formation.

Clinical features

Only 10%–20% of individuals with gallstones develop clinical evidence of gallstone disease. However, once symptoms occur, they are likely to recur. Symptomatic stones within the gallbladder (Box 23.64) manifest as either biliary pain (biliary colic) or cholecystitis (see below). If a gallstone becomes acutely impacted in the cystic duct, the patient will experience pain. The term 'biliary colic' is a misnomer because the pain does not rhythmically increase and decrease in intensity like other forms of colic. Typically, the pain occurs suddenly and persists for several hours; if it continues for more than 6 hours, a complication such as cholecystitis or pancreatitis may be present. Pain is usually felt in the epigastrium (70% of patients) or right upper quadrant (20%) and radiates to the interscapular region or the tip of the right scapula, but other sites include the left upper quadrant and the lower chest. The pain can mimic intrathoracic disease, oesophagitis, myocardial infarction or aortic dissection.

Combinations of fatty food intolerance, dyspepsia and flatulence not attributable to other causes have been referred to as 'gallstone dyspepsia'. These symptoms are now recognised as being caused by gallstones and are best regarded as functional dyspepsia. Acute and chronic cholecystitis is described below.

A mucocele may develop if there is slow distension of the gallbladder from continuous secretion of mucus; if this material becomes infected, an empyema supervenes. Calcium may be secreted into the lumen of the hydropic gallbladder, causing 'limey' bile, and if calcium salts are precipitated in the gallbladder wall, the radiological appearance of 'porcelain' gallbladder results.

23.64 Clinical features and complications of gallstones

Clinical features

- Asymptomatic (80%)
- Biliary colic
- Acute cholecystitis
- Chronic cholecystitis

Complications

- Empyema of the gallbladder
- Porcelain gallbladder
- Choledocholithiasis
- Acute pancreatitis
- Fistulae from gallbladder to duodenum/colon
- Pressure on/inflammation of the common hepatic duct by a gallstone in the cystic duct (Mirizzi syndrome)
- Gallstone ileus
- Cancer of the gallbladder

23.65 Gallbladder disease in old age

- **Gallstones**: by the age of 70 years, prevalence is around 30% in women and 19% in men
- **Acute cholecystitis**: tends to be severe, may have few localising signs and is associated with a high frequency of empyema and perforation. If such complications supervene, mortality may reach 20%
- **Cholecystectomy**: mortality after urgent cholecystectomy for acute uncomplicated cholecystitis is not significantly higher than in younger patients.
- **Endoscopic sphincterotomy and removal of common duct stones**: well tolerated by older patients, with lower mortality than surgical common bile duct exploration.
- **Cancer of the gallbladder**: a disease of old age, with a 1-year survival of 10%.

Gallstones in the gallbladder (cholecystolithiasis) migrate to the common bile duct (choledocholithiasis; p. 935) in approximately 10%–20% of patients and can cause biliary colic. Rarely, stones can fistulate between the gallbladder and the gastric duodenum or colon. If this occurs, air will be seen in the biliary tree on plain abdominal X-rays. If a stone larger than 2.5 cm in diameter has migrated into the gut, it may then impact either at the terminal ileum or sigmoid colon. The resultant intestinal obstruction may be followed by 'gallstone ileus'. Gallstones impacted in the cystic duct may cause obstruction to the common hepatic duct and the clinical picture of extrahepatic biliary obstruction (Mirrizi syndrome) with its important differential of malignant bile duct stricture). The more common cause of jaundice due to gallstones is a stone passing from the cystic duct into the common bile duct (choledocholithiasis), which may also result in cholangitis or acute pancreatitis. It is usually very small stones that precipitate acute pancreatitis, due to oedema at the ampulla as the stone passes into the duodenum. No stone is seen within the bile duct in 80% of cases of presumed gallstone pancreatitis, suggesting stone passage. Previous stone passage is also the likely cause of most cases of benign papillary fibrosis, which is most commonly seen in patients with previous or present gallstone disease. It presents with biliary pain (often following cholecystectomy) with cholestatic LFTs and biliary dilatation, or acute pancreatitis, and is treated by ERCP and sphincterotomy.

Cancer of the gallbladder is increasing in frequency but in over 85% of cases is associated with the presence of gallstones. Previously, the diagnosis was typically made as an incidental histological finding following cholecystectomy for gallstone disease. Increasing awareness of the risk of gallbladder carcinoma and of the role played by polyps in the natural history has led to an increase in screening activity and prospective diagnosis. Biliary disease is common in the elderly and can be challenging to manage in frail patients (Box 23.65).

Investigations

Ultrasound is the investigation of choice for diagnosing gallstones. Most stones are diagnosed by transabdominal ultrasound, which has more than 84% sensitivity and 99% specificity for gallbladder stones (see Fig. 23.8). Other imaging modalities such as CT, MRCP (Fig. 23.44) and, increasingly, EUS are excellent modalities for detecting complications of gallstones (distal bile duct stone or gallbladder empyema) but are inferior to ultrasound in defining their presence in the gallbladder. When recurrent attacks of otherwise unexplained acute pancreatitis occur, they may result from 'microlithiasis' in the gallbladder or common bile duct which are best assessed by EUS.

Management

Asymptomatic gallstones found incidentally in the gallbladder should not be treated because the majority will never cause symptoms. Symptomatic gallstones are best treated surgically by laparoscopic cholecystectomy; the severity of symptoms should be balanced against the individual patient surgical risk in order to decide whether surgery is warranted. Asymptomatic common bile duct stones should also be removed due to the high risk of complications (Box 23.66).

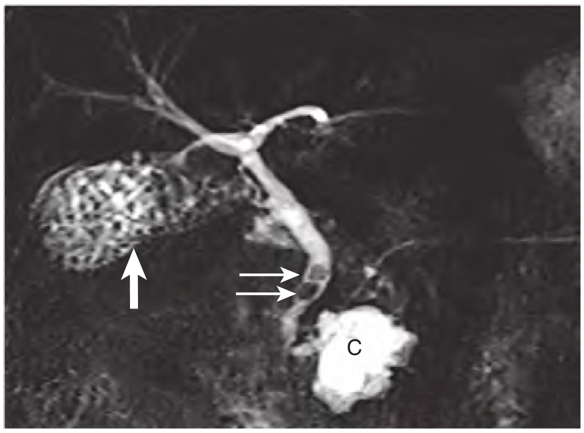

Fig. 23.44 Gallstones. Magnetic resonance cholangiopancreatogram showing multiple small stones in the gallbladder (large arrow), two larger stones in the distal common bile duct (smaller arrows) and also a cystic lesion in the head of pancreas (C).

23.66 Treatment of gallstones

Gallbladder stones

- Cholecystectomy: laparoscopic or open
- Oral bile acids: chenodeoxycholic or ursodeoxycholic (low rate of stone dissolution)

Bile duct stones

- Endoscopic sphincterotomy and stone extraction
- Surgical bile duct exploration
- Lithotripsy (endoscopic or extracorporeal shock wave, ESWL)

Cholecystitis

Acute cholecystitis

Pathophysiology

Acute cholecystitis is almost always associated with obstruction of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a biliary tumour, or may follow endoscopic bile duct stenting. The pathogenesis is unclear but the initial inflammation is possibly chemically induced. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually, and in older patients or those with diabetes mellitus, a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle-cell disorder and diabetes mellitus.

Clinical features

The cardinal feature is pain in the right upper quadrant but also in the epigastrium, the right shoulder tip or the interscapular region. Differentiation between biliary colic and acute cholecystitis may be difficult; features suggesting cholecystitis include severe and prolonged pain, fever and leucocytosis.

Examination shows right hypochondrial tenderness with guarding, worse on inspiration (Murphy sign) and occasionally a gallbladder mass (30% of cases). Fever is present but rigors are unusual and suggest cholangitis. Jaundice occurs in less than 10% of patients and is usually due to coexistent stones in the common bile duct, or to compression or even stricturing of the common bile duct following stone impaction in the cystic duct (Mirizzi syndrome). Gallbladder perforation occurs in 10%–15% of cases and gallbladder empyema may arise.

Investigations

Peripheral blood leucocytosis is common, except in older patients, in whom the signs of inflammation may be minimal. Minor increases of transaminases and amylase may be encountered. Amylase should be measured to detect acute pancreatitis, which may be a potentially serious complication of gallstones. Only when the amylase is higher than 1000 U/L can pain be confidently attributed to acute pancreatitis, since moderately elevated levels of amylase can occur with many other causes of abdominal pain. Serum lipase is favoured in the United States. Plain X-rays of the abdomen and chest may show radio-opaque gallstones, and rarely intrabiliary gas due to fistulation of a gallstone into the intestine; they are important in excluding lower lobe pneumonia and a perforated viscus. Ultrasonography detects gallstones and gallbladder thickening due to cholecystitis, but gallbladder empyema or perforation is best assessed by CT.

Management

Medical

Medical management consists of pain relief, antibiotics and intravenous fluids. Moderate pain can be treated with NSAIDs but more severe pain should be managed with opiates. A cephalosporin (such as cefuroxime) or piperacillin/tazobactam is the usual antibiotic of choice, but metronidazole is normally added in severely ill patients and local prescribing practice may vary. Cholecystitis usually resolves with medical treatment, but the inflammation may progress to an empyema or perforation and peritonitis.

Surgical

Urgent surgery is the optimal treatment when cholecystitis progresses in spite of medical therapy and when complications such as empyema or perforation develop. The operation should be carried out within 5 days of the onset of symptoms. Delayed surgery after 2–3 months is no longer favoured. When cholecystectomy is likely to be technically difficult due to extensive inflammatory change, percutaneous gallbladder drainage can be performed, with subsequent cholecystectomy 4–6 weeks later. Recurrent biliary colic or cholecystitis is frequent if the gallbladder is not removed.

Chronic cholecystitis

Chronic inflammation of the gallbladder is almost invariably associated with gallstones. The usual symptoms are those of recurrent attacks of upper abdominal pain, often at night and following a heavy meal. The clinical features are similar to those of acute calculous cholecystitis but milder. Patients may recover spontaneously or following analgesia and antibiotics. They are usually advised to undergo elective laparoscopic cholecystectomy.

Acute cholangitis

Acute cholangitis is caused by bacterial infection of bile ducts and occurs in patients with other biliary problems, such as choledocholithiasis (see below), biliary strictures or tumours, or after ERCP. Jaundice, fever (with or without rigors) and right upper quadrant pain are the main presenting features (Charcot triad). Treatment is with antibiotics, relief of biliary obstruction and removal (if possible) of the underlying cause.

Choledocholithiasis

Stones in the common bile duct (choledocholithiasis) occur in 10%–15% of patients with gallstones (Fig. 23.45) which have usually migrated from the gallbladder. Primary bile duct stones are rare but can develop within the common bile duct many years after a cholecystectomy and are sometimes related to biliary sludge arising from dysfunction of the sphincter of Oddi. In South-East Asia, primary common bile duct stones are thought to follow bacterial infection secondary to parasitic infections with *Clonorchis sinensis*, *Ascaris lumbricoides* or *Fasciola hepatica*.

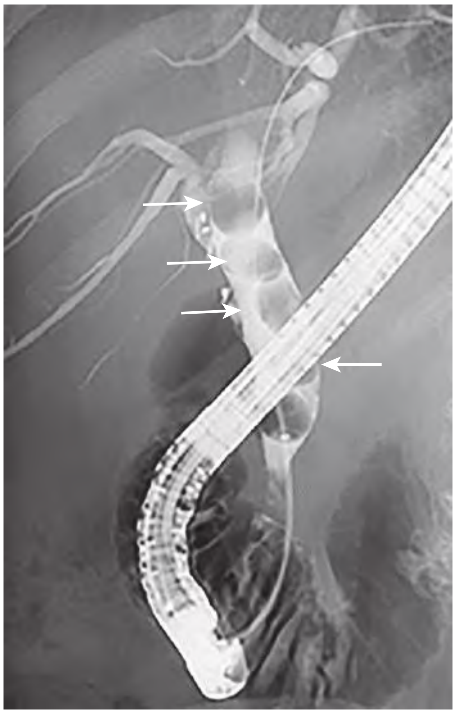

Fig. 23.45 Endoscopic retrograde cholangiopancreatogram. Common bile duct stones are indicated by arrows.

Common bile duct stones can cause bile duct obstruction and may be complicated by cholangitis due to secondary bacterial infection, sepsis, liver abscess and biliary stricture.

Clinical features

Choledocholithiasis may be asymptomatic, may be found incidentally by operative cholangiography at cholecystectomy or on abdominal imaging, or may manifest as biliary colic, jaundice, cholangitis or pancreatitis. If the gallbladder is still present, it is usually small, fibrotic and impalpable.

Investigations

The LFTs show a cholestatic pattern. If cholangitis is present, the patient usually has a leucocytosis and may have a high ALT. Initial imaging is with transabdominal ultrasound which often shows dilated extrahepatic and intrahepatic bile ducts, together with gallbladder stones (see Fig. 23.8), but does not always reveal the cause of the obstruction in the common bile duct; 50% of bile duct stones are missed on ultrasound, particularly those in the distal common bile duct. MRCP and EUS (Fig. 23.46) both have a high sensitivity for ductal stones and can also help to define biliary anatomy prior to intervention, but MRCP is preferred as it is non-invasive.

Management

Cholangitis should be treated with analgesia, intravenous fluids and broad-spectrum antibiotics, such as cefuroxime and metronidazole (local prescribing practice may vary). Blood cultures should be taken before antibiotics are administered. Decompression of the biliary tree and stone removal are required to prevent further episodes. ERCP with biliary sphincterotomy and stone extraction is the treatment of choice and is successful in about 90% of patients (see Fig. 23.45). In some complex cases, cholangioscopy with electrohydraulic lithotripsy may be required. If ERCP fails, other approaches include percutaneous transhepatic drainage and combined ('rendezvous') endoscopic procedures, extracorporeal shock wave lithotripsy (ESWL) and surgery.

Surgical treatment of choledocholithiasis is performed less frequently than ERCP. The common bile duct may be explored laparoscopically, either transcystic (via the gallbladder) or transductal, or at laparotomy.

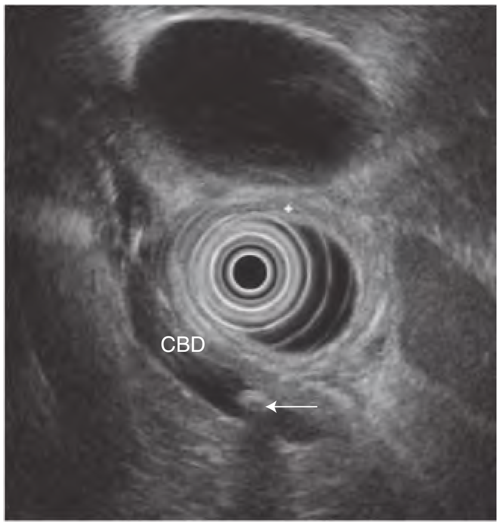

Fig. 23.46 **Endoscopic ultrasonography (EUS) imaging.** The EUS shows a prominent common bile duct (CBD) containing a small stone (arrow) causing acoustic shadowing.

Recurrent pyogenic cholangitis

This disease occurs predominantly in South-east Asia. Biliary sludge, comprising calcium bilirubinate concretions and stones accumulate in the intrahepatic bile ducts, with secondary bacterial infection. Patients present with recurrent attacks of upper abdominal pain, fever and cholestatic jaundice. Investigation of the biliary tree demonstrates that both the intrahepatic and the extrahepatic portions are filled with soft biliary mud. Eventually, the liver becomes scarred and liver abscesses and secondary biliary cirrhosis develop. The condition is difficult to manage and requires drainage of the biliary tract with extraction of stones, antibiotics and, in certain patients, partial resection of damaged areas of the liver.

Tumours of the gallbladder and bile duct

Carcinoma of the gallbladder

This is an uncommon tumour, occurring more often in females and usually in those over the age of 70 years. More than 90% are adenocarcinomas; the remainder are anaplastic or, rarely, squamous tumours. Gallstones are present in 70%–80% of cases and are thought to be important in the aetiology of the tumour. Individuals with a calcified gallbladder ('porcelain gallbladder') are at high risk of malignant change, and gallbladder polyps greater than 1 cm in size are associated with increased risk of malignancy; preventative cholecystectomy should be considered in such patients. Chronic infection with *Salmonella*, especially in areas where typhoid is endemic, is also a risk factor.

Carcinoma of the gallbladder may be diagnosed incidentally and is found in 0.2%–3% of gallbladders removed at cholecystectomy for gallstone disease. It may manifest as repeated attacks of biliary pain and, later, persistent jaundice and weight loss. A gallbladder mass may be palpable in the right hypochondrium. LFTs show cholestasis, and calcification of the gallbladder wall may be found on X-ray. The tumour can be diagnosed by ultrasonography and staged by CT. The treatment is surgical excision, but local extension of the tumour beyond the wall of the gallbladder into the liver, lymph nodes and surrounding tissues is common at diagnosis. Only a minority of pre-operatively diagnosed gallbladder cancers are suitable for resection. Adjuvant chemotherapy with capecitabine or gemcitabine/cisplatin should be considered in all patients with locally advanced disease. Subsequent radiation therapy can also be considered following capecitabine. Patients with unresectable locally advanced or metastatic disease and good performance status can be given chemotherapy. The current standard of care is the checkpoint inhibitor durvalumab with gemcitabine plus cisplatin, or gemcitabine with cisplatin alone. The combination chemotherapy regime FOLFOX (leucovorin, 5-flurouracil and oxaliplatin) can be used as second-line chemotherapy. Targeted chemotherapy and immunotherapy is available in some centres for tumours with specific genetic alterations. Survival is generally short, death typically occurring within 1 year in patients presenting with symptoms.

Cholangiocarcinoma

Cholangiocarcinoma (CCA) is an uncommon tumour that can arise anywhere in the biliary tree, from the intrahepatic bile ducts (20%–25% of cases) and the confluence of the right and left hepatic ducts at the liver hilum (50%–60%) to the distal common bile duct (20%). It accounts for only 1.5% of all cancers but the incidence is increasing. The cause is unknown but the tumour is associated with gallstones, primary and secondary sclerosing cholangitis, Caroli disease and choledochal cysts (see Fig. 23.43). In South-east Asia, chronic liver fluke infection (*Clonorchis sinensis*) is a major risk factor for the development of CCA in men. Primary sclerosing cholangitis carries a lifetime risk of CCA of 5%–20%, although only 5% of CCAs relate to primary sclerosing cholangitis. Cirrhosis is a risk factor for intrahepatic cholangiocarcinoma. Chronic biliary inflammation appears to be a common factor in the development of biliary dysplasia and cancer that is shared by all the predisposing causes.

Tumours typically invade the lymphatics and adjacent vessels, with a predilection for spread within perineural sheaths. The presentation is usually with obstructive jaundice. About 50% of patients also have upper abdominal pain and weight loss. The diagnosis is made using a combination of CT and MRI (see Fig. 23.10) but can be difficult to confirm in patients with sclerosing cholangitis. Serum levels of the tumour marker CA19-9 are elevated in up to 80% of cases, although this may occur in biliary obstruction of any cause. In the setting of biliary obstruction, ERCP may result in positive biliary cytology. The sensitivity of biliary brushing cytology is low (20%–43%) but can be improved with analysis for chromosomal aneuploidy using fluorescent in situ hybridisation (FISH). Endoscopic ultrasound–fine needle aspiration (EUS–FNA) of bile duct masses or lymph nodes is sometimes possible, and in specialist centres cholangioscopy with biopsy is now established. CCAs can be treated surgically in about 20% of patients, which improves 5-year survival from less than 5% to 20%–40%. Surgery involves excision of the extrahepatic biliary tree with or without a liver resection and a Roux loop reconstruction. Adjuvant chemotherapy is recommended. Currently, 6 months of capecitabine is the standard of care in this rapidly changing field. Liver transplant was not previously recommended as a treatment for CCA due to high recurrence rate and poor long-term survival. However, neoadjuvant chemoradiotherapy or chemotherapy alone (with gemcitabine and cisplatin) followed by liver transplant is effective in highly selected patients with perihilar CCA. Similarly, in some specialised centres, liver transplant can now be considered for very early intrahepatic CCA (< 2 cm) where resection is precluded either because of tumour location or underlying liver disease. Thermal ablation can also be considered in patients with unresectable/inoperable single small (< 2 cm) intrahepatic CCA.

Most patients with CCA are treated with stent insertion across the malignant biliary stricture, using endoscopic or percutaneous transhepatic techniques to relieve jaundice (Fig. 23.47). Patients with unresectable disease and good performance status/preserved liver function may receive chemotherapy using a combination of gemcitabine and cisplatin with a checkpoint inhibitor/immunotherapy agent (durvalumab). Selected patients may benefit from combined chemotherapy and radiotherapy. Locoregional therapies with chemotherapy may be effective for some patients with locally advanced unresectable tumours. Palliation with endoscopic photodynamic therapy has provided encouraging results for extrahepatic CCA.

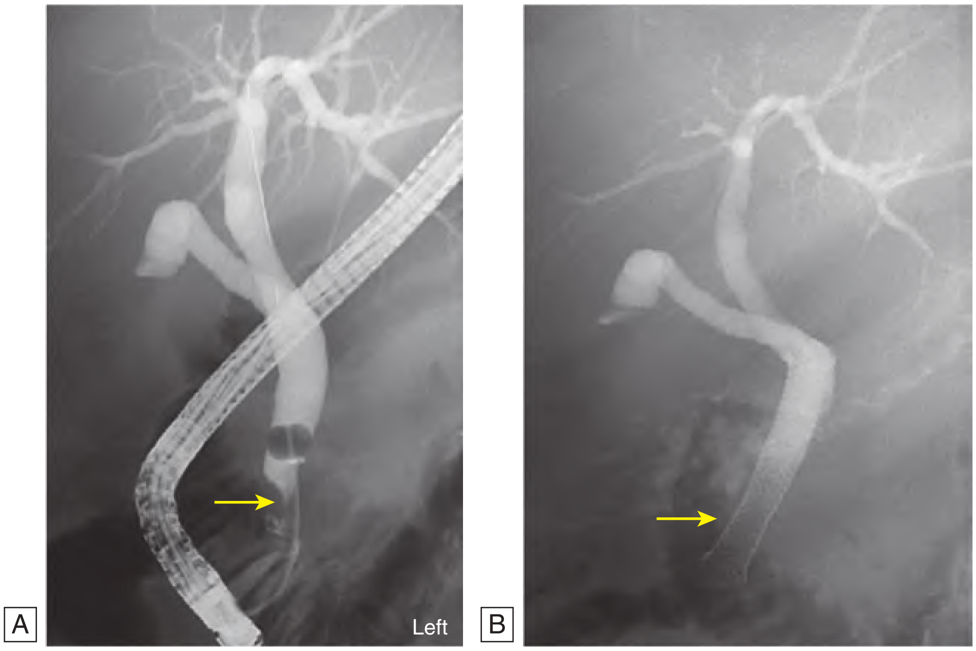

Fig. 23.47 **Cholangiocarcinoma.** A Endoscopic retrograde cholangiopancreatogram showing a malignant distal biliary stricture (arrow) and dilated duct above this. B A self-expanding metallic stent (SEMS) has been placed across the stricture to relieve jaundice (arrow).

Carcinoma at the ampulla of Vater

Nearly 40% of all adenocarcinomas of the small intestine arise in relationship to the ampulla of Vater and present with pain, anaemia, vomiting and weight loss. Jaundice may be intermittent or persistent. The diagnosis is made by duodenal endoscopy and biopsy of the tumour, but staging by CT/MRI and EUS is essential. Ampullary carcinoma must be differentiated from carcinoma of the head of the pancreas and a CCA because these last two conditions both have a worse prognosis. Imaging may show a 'double duct sign' with dilatation of both the common bile duct and pancreatic duct due to obstruction at the ampulla. EUS is the most sensitive method of assessing and staging ampullary or periampullary tumours.

Curative surgical treatment can be undertaken by pancreaticoduodenectomy, and the 5-year survival may be as high as 50% for locally confined disease. If resection is impossible, palliative surgical bypass or stenting may be necessary.

Benign gallbladder tumours

These are uncommon, often asymptomatic and usually found incidentally at operation or postmortem. Cholesterol polyps, sometimes associated with cholesterolosis, papillomas and adenomas, are the main types.

Miscellaneous biliary disorders

Functional gallbladder disorder

Functional gallbladder disorder refers to symptoms of biliary-type pain in the absence of gallstones, sludge or microlithiasis. Gallstone disease needs to be excluded by means of abdominal US and/or EUS to exclude microlithiasis. Other diagnostic tests may be required to exclude peptic ulcer disease, pancreatitis or musculoskeletal syndromes. Cholecystokinin-stimulated hepatobiliary scintigraphy can be used to evaluate gallbladder ejection fraction.

Symptoms suggestive of functional gallbladder disorder often improve spontaneously, so urgent surgical intervention is not required. Management involves patient education and reassurance. Pharmacological therapy with analgesia, neuromodulators and antispasmodics may be beneficial. Cholecystectomy can improve symptoms in many patients with recurrent functional biliary pain. It is suggested that a low gallbladder ejection fraction (< 40%) may identify a subset of patients likely to benefit from surgery, but the evidence is contradictory.

Post-cholecystectomy syndrome

Post-cholecystectomy syndrome refers to a complex of heterogeneous symptoms including abdominal pain and dyspepsia that recur and/or persist following cholecystectomy. It occurs in 10%–30% of patients depending on how the condition is defined, how actively symptoms are sought and what the original indication for cholecystectomy was. The syndrome occurs most frequently in women, in patients who have had symptoms for more than 5 years before cholecystectomy, and in cases when the operation was undertaken for non-calculous gallbladder disease. An increase in bowel frequency resulting from bile acid diarrhoea occurs in about 5%–10% of patients after cholecystectomy and often responds to colestyramine (4–8 g daily). Severe post-cholecystectomy syndrome occurs in only 2%–5% of patients. The main causes are listed in Box 23.67.

i 23.67 Causes of post-cholecystectomy symptoms

Immediate post-surgical

- Bleeding
- Biliary peritonitis
- Abscess
- Bile duct trauma/transection
- Fistula

Biliary

- Common bile duct stones
- Benign stricture
- Tumour
- Cystic duct stump syndrome
- Disorders of the ampulla of Vater (e.g. benign papillary fibrosis; sphincter of Oddi dysfunction)

Extrabiliary

- Functional dyspepsia
- Peptic ulcer
- Pancreatic disease
- Gastro-oesophageal reflux
- Irritable bowel syndrome
- Functional abdominal pain

The usual symptoms include right upper quadrant pain, flatulence, fatty food intolerance and occasionally jaundice and cholangitis. The LFTs may be abnormal and sometimes show cholestasis. Ultrasonography is used to detect biliary obstruction, and EUS or MRCP to seek common bile duct stones. If retained bile duct stones are excluded, sphincter of Oddi dysfunction should be considered (see below). Other investigations that may be required include upper gastrointestinal endoscopy, small bowel radiology and pancreatic function tests. The possibility of a functional illness should also be considered.

Functional biliary sphincter disorders

Functional biliary sphincter disorders is now the preferred term for a group of disorders known collectively as sphincter of Oddi dysfunction (SOD). The sphincter of Oddi is a small smooth-muscle sphincter situated at the junction of the bile duct and pancreatic duct in the duodenum. It has been believed that SOD was characterised by an increase in contractility that produces a benign non-calculous obstruction to the flow of bile or pancreatic juice. This may cause pancreaticobiliary pain, deranged LFTs or recurrent pancreatitis. Classification systems, based on clinical history, laboratory results, findings on investigation and response to interventions, are difficult because of the fluctuating nature of symptoms and the well-recognised placebo effect of interventions. SOD was previously classified into types I–III, but these have been replaced by newer terminology (Boxes 23.68, 23.69).

Clinical features

Patients with functional biliary sphincter disorders, who are predominantly female, present with symptoms and signs suggestive of either biliary or pancreatic disease:

- *Patients with biliary sphincter of Oddi disorders* experience recurrent, episodic biliary-type pain. They have often had a cholecystectomy but the gallbladder may be intact.
- *Patients with pancreatic sphincter of Oddi disorders* usually present with unexplained recurrent attacks of pancreatitis.

23.68 Classification of biliary sphincter of Oddi dysfunction (SOD)

Organic stenosis (formerly SOD type I)

- Biliary-type pain
- Abnormal liver enzymes (ALP or ALT/AST > twice normal on two or more occasions)
- Dilated common bile duct (> 12 mm diameter on US or > 10 mm on cholangiography)
- Delayed drainage of ERCP contrast beyond 45 mins

Functional sphincter of Oddi disorder (formerly SOD type II)

- Biliary-type pain
- Absence of bile duct stones or other structural abnormalities
- Elevated liver enzymes or dilated bile duct (but not both)

Functional biliary-type pain (formerly SOD type III)

- Biliary-type pain with no other abnormalities

(ALP = alkaline phosphatase; ALT = alanine aminotransferase; AST = aspartate aminotransferase; ERCP = endoscopic retrograde cholangiopancreatography; US = ultrasound)

23.69 Criteria for pancreatic sphincter of Oddi dysfunction

- Recurrent attacks of acute pancreatitis – pancreatic-type pain with amylase or lipase 3 times normal and/or imaging evidence of acute pancreatitis
- Other aetiologies of acute pancreatitis excluded
- Normal pancreas at endoscopic ultrasound
- Abnormal sphincter manometry

Investigations

The diagnosis is established by excluding gallstones, including microlithiasis, and by demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is sphincter of Oddi manometry but this is associated with a high rate of procedure-related pancreatitis and is not routinely used in many centres. Hepatobiliary scintigraphy may have value in the second-line investigation of post-cholecystectomy syndrome.

Management

All patients with organic stenosis should be treated with endoscopic sphincterotomy. The results are good but patients should be warned that there is a high risk of complications, particularly acute pancreatitis (10%–15%). In contrast, ERCP and sphincterotomy should be avoided in patients with functional biliary-type pain as it is of no benefit. Medical therapy with nifedipine and/or low-dose amitriptyline may be tried. Pancreatic SOD can be treated with biliary sphincterotomy, carried out in specialist centres, but this should be undertaken with caution and careful consideration due to the risk of causing ERCP-related pancreatitis.

Prophylactic pancreatic duct stenting in patients undergoing ERCP for sphincter of Oddi disorders may be used in carefully selected patients. Prophylactic administration of rectal NSAIDs, such as a single dose of diclofenac 100 mg, is recommended because this significantly reduces the risk of procedure-related acute pancreatitis.

Cholesterolosis of the gallbladder

In this condition, lipid deposits in the submucosa and epithelium appear as multiple yellow spots on the pink mucosa, giving rise to the description ‘strawberry gallbladder’. Cholesterolosis of the gallbladder is usually asymptomatic. Larger polypoid deposits occur in a third of cases leading to the formation of cholesterol polyps that can detach resulting in complications similar to small gallstones, including right upper quadrant pain. Small, fixed filling defects may be visible on ultrasonography; the radiologist can usually differentiate between gallstones and cholesterolosis. The condition is usually diagnosed at cholecystectomy; if the diagnosis is made radiologically, cholecystectomy may be indicated, depending on symptoms.

Adenomyomatosis of the gallbladder

Adenomyomatosis is a benign acquired condition in which there is hyperplasia of the muscle and mucosa of the gallbladder. The projection of pouches of mucous membrane through weak points in the muscle coat produces Rokitansky–Aschoff sinuses. Segmental, fundal and more unusually diffuse forms exist. There is much disagreement over whether adenomyomatosis is a cause of right upper quadrant pain or other gastrointestinal symptoms. It is usually asymptomatic. It is diagnosed pre-operatively on ultrasound by mural thickening and ‘comet tail’ artefacts. On MR cholangiogram a characteristic ‘pearl necklace’ appearance is described. Localised adenomyomatosis in the region of the gallbladder fundus causes the appearance of a ‘Phrygian cap’. Most patients are treated by cholecystectomy but only after other diseases in the upper gastrointestinal tract have been excluded.

IgG4-associated cholangitis

This often presents with obstructive jaundice and is described in more detail previously in this chapter.

Multiple Choice Questions

23.1. A 52-year-old homeless man with a history of alcohol dependency is admitted to hospital with a 2-month history of weight loss, fever, cough and abdominal distension. Liver ultrasound scan shows moderate ascites with normal liver appearance with patent portal/hepatic veins and no focal lesions. A diagnostic ascitic tap is performed:

Microscopy: WCC 350 cells/mm^3, polymorphs 100 cells/mm^3, lymphocytes 250 cells/mm^3. No organisms seen.
Ascitic protein: 28 g/L
Ascitic albumin: 19 g/L
Serum albumin: 26 g/L
Cytology: inflammatory cells only.

What is the most likely cause of this patient's ascites?

A. Spontaneous bacterial peritonitis
B. Tuberculosis
C. Budd–Chiari syndrome
D. Pancreatic cancer
E. Alcohol-related liver disease with cirrhosis

Answer: B.

Tuberculosis is a cause of high-protein ascites with a low serum-ascites albumin gradient (SAAG) (< 11 g/L). Elevated lymphocytes are typically seen on ascites microscopy. Acid-fast bacilli (AFB) may be seen, but prolonged TB culture may be required for definitive diagnosis. Budd–Chiari syndrome is a cause of ascites with high SAAG (> 11 g/L). Disseminated malignancy with peritoneal involvement is a cause of exudative ascites with low SAAG (< 11 g/L), but normal CT imaging and ascites cytology makes this diagnosis less likely. Ascites due to liver cirrhosis has a high SAAG (> 11 g/L). Spontaneous bacterial peritonitis is diagnosed by the finding of elevated polymorphs (> 250 cells/mm^3) in ascitic fluid.

23.2. A 56-year-old woman with autoimmune hepatitis and cirrhosis is admitted with agitation and confusion. Examination reveals a flapping tremor and a diagnosis of hepatic encephalopathy is made. Which of the following would be suitable first-line therapy?

A. Dietary protein restriction
B. Oral lactulose
C. Rifaximin
D. L-ornithine L-aspartate (LOLA)
E. Benzodiazepines

Answer: B.

Hepatic encephalopathy is caused by disturbed brain function provoked by gut-derived neurotoxins that are normally metabolised by the liver and excluded from the systemic circulation. Treatment aims to reduce toxin production in the bowel. First-line therapy is with lactulose (15–30 mL 3 times daily) to promote regular bowel motions. Rifaximin is a non-absorbable antibiotic that reduces bacterial load in the gut and is helpful in treating recurrent episodes of encephalopathy. L-ornithine L-aspartate (LOLA) is an amino acid supplement that may be useful in reducing ammonia levels and improving encephalopathy in patients with refractory disease. Dietary protein restriction is no longer recommended in the treatment of encephalopathy and may worsen nutritional state. Sedative drugs including opiates and benzodiazepines may precipitate/worsen encephalopathy in cirrhotic patients and should be avoided in these patients.

23.3. An 18-year-old man presents to his family doctors having noticed mild jaundice after being treated with a course of oral amoxicillin for lower respiratory tract infection. Abdominal ultrasound is normal. His liver biochemistry reveals:

Bilirubin 60 μmol/L
Direct bilirubin 9 μmol/ L
ALT 23 U/L
ALP 82 U/L
GGT 35 U/L
Albumin 40 g/L

What is the most likely diagnosis?

A. Drug-induced liver injury
B. Primary sclerosing cholangitis
C. Gilbert syndrome
D. Dubin–Johnson syndrome
E. Hepatitis E infection

Answer: C.

Gilbert syndrome is an inherited disorder of bilirubin metabolism characterised by isolated elevation of bilirubin, usually in the context of physical stress or illness. It presents with isolated elevation of unconjugated bilirubin (indirect bilirubin) and otherwise normal liver enzymes. Drug-induced liver injury may present with jaundice, but there would be additional liver enzyme disturbance following either a hepatitic, cholestatic or mixed pattern. Dubin–Johnson syndrome is an inherited disorder of bilirubin metabolism associated with conjugated (direct) hyperbilirubinaemia. Hepatitis E infection may present with jaundice in association with an acute hepatitis with elevated transaminase levels (ALT/AST).

23.4. A 42-year-old man presents with abnormal liver enzymes, on a background of early-onset emphysema. His serum α1-antitrypsin level is 0.03 g/L (normal range 1.1–2.1 g/L). Which of the following statements about α1-antitrypsin deficiency is true?

A. Most liver disease is due to the PiMM genotype
B. Lung disease occurs due to the accumulation of abnormally folded protein in alveolar cells
C. Inheritance is autosomal dominant
D. It can present as neonatal jaundice
E. A liver biopsy is required for diagnosis

Answer: D.

Alpha-1-antitrypsin deficiency can present in a range of ways, from neonatal cholestatic jaundice through to adult-onset cirrhosis. Inheritance is autosomal recessive. The normal genotype is PiMM and most disease is due to PiZZ. Liver disease occurs due to accumulation of abnormally folded protein in hepatocytes, whereas lung disease is a result of unopposed neutrophil elastase activity. Diagnosis is usually based on serum α1-antitrypsin levels and genotyping.

23.5. A 56-year-old man with alcohol-related cirrhosis is admitted with ascites and hepatic encephalopathy, and is noted to have loss of muscle mass. The Na is 131 mmol/L (normal range 135–145). Which of the following would you advise the patient?

A. Salt intake should be increased in view of hyponatraemia
B. Fluid intake should be restricted
C. Protein intake should be restricted in view of encephalopathy
D. Calorie intake should be 15–20 kcal/kg per day
E. A bedtime snack is recommended

Answer: E.

Malnutrition is common in cirrhosis. A bedtime snack will avoid prolonged fasting which can trigger catabolism. Calorie intake should be at least 35 kcal/kg per day, with a protein intake of 1.2–1.5 g/kg. A no-added-salt diet is recommended in ascites, and fluid restriction is rarely needed (and may exacerbate renal impairment in this case).

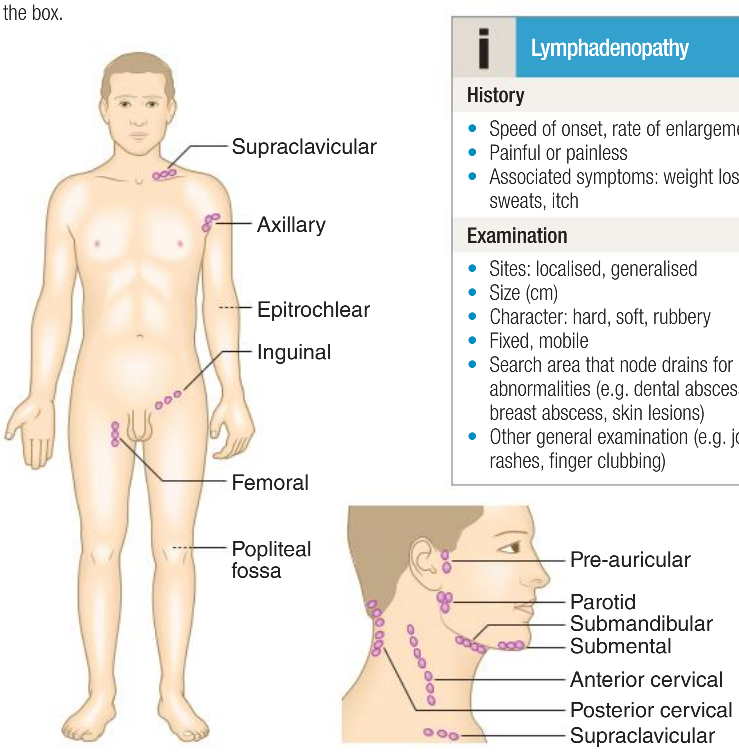
Abnormalities detected in the blood are caused not only by primary diseases of the blood and lymphoreticular systems, but also by diseases affecting other systems of the body. The clinical assessment of patients with haematological abnormalities must include a general history and examination, as well as a search for symptoms and signs of specific primary haematological and other disorders that result in abnormalities of red cells, white cells, platelets, coagulation, lymph nodes and lymphoreticular tissues.

6 Lymphadenopathy

Lymphadenopathy can be caused by benign or malignant disease. The clinical points to clarify are shown in the box.



i Lymphadenopathy

History

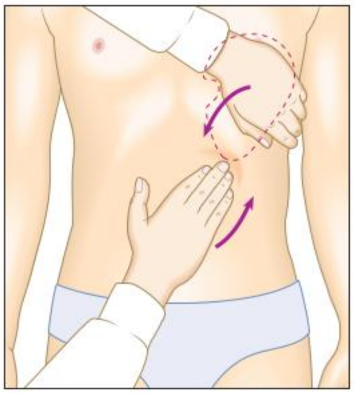
- Speed of onset, rate of enlargement
- Painful or painless
- Associated symptoms: weight loss, night sweats, itch

Examination

- Sites: localised, generalised
- Size (cm)
- Character: hard, soft, rubbery
- Fixed, mobile
- Search area that node drains for abnormalities (e.g. dental abscess, breast abscess, skin lesions)
- Other general examination (e.g. joints, rashes, finger clubbing)

8 Examination of the spleen

- Move your hand up from the right iliac fossa, towards the left upper quadrant on expiration.
- Keep your hand still and ask the patient to take a deep breath through the mouth to feel the spleen edge being displaced downwards.
- Place your left hand around the patient's lower ribs and approach the costal margin to pull the spleen forwards.
- To help palpate a spleen that is only slightly enlarged, roll the patient on to the right side and examine as before.



i Characteristics of the spleen

- Notch
- Superficial
- Dull to percussion
- Cannot get examining hand between ribs and spleen
- Moves well with respiration

Anaemia

Symptoms and signs help to indicate the clinical severity of anaemia. A full history and examination are needed to identify the underlying cause.

i Anaemia

Non-specific symptoms

- Tiredness
- Lightheadedness
- Breathlessness
- Development/worsening of ischaemic symptoms, e.g. angina or claudication

Non-specific signs

- Mucous membrane pallor
- Tachypnoea
- Raised jugular venous pressure
- Tachycardia
- Flow murmurs
- Ankle oedema
- Postural hypotension

Bleeding

Bleeding can be due to congenital or acquired abnormalities in the coagulation system. History and examination help to clarify the severity and the underlying cause of the bleeding problem.

i Bleeding

History

- Site of bleed
- Duration of bleed
- Precipitating causes, including previous surgery or trauma
- Family history
- Drug history
- Age at presentation
- Other medical conditions, e.g. liver disease

Examination

There are two main patterns of bleeding:

1. Mucosal bleeding
   Reduced number or function of platelets (e.g. bone marrow failure or aspirin) or von Willebrand factor (e.g. von Willebrand disease)
      Skin: petechiae, bruises
      Gum and mucous membrane bleeding
      Fundal haemorrhage
      Post-surgical bleeding
2. Coagulation factor deficiency/dysfunction (e.g. haemophilia or anticoagulant)
      Bleeding into joints (haemarthrosis) or muscles
      Bleeding into soft tissues
      Retroperitoneal haemorrhage
      Intracranial haemorrhage
      Post-surgical bleeding

Disorders of the blood cover a wide spectrum of illnesses, ranging from some of the most common disorders affecting humans (anaemias) to relatively rare conditions such as leukaemias and congenital coagulation disorders. Although the latter are uncommon, advances in cellular and molecular biology have had major impacts on their diagnosis, treatment and prognosis. Haematological changes occur because of diseases affecting any system and give important information in the diagnosis and monitoring of many conditions.

Functional anatomy and physiology

Blood flows throughout the body in the vascular system, and consists of:

- red cells, which transport oxygen from the lungs to the tissues
- white cells, which defend against infection
- platelets, which interact with blood vessels and clotting factors to maintain vascular integrity and prevent bleeding
- plasma, which contains proteins with many functions, including antibodies and coagulation factors.

Haematopoiesis

Haematopoiesis describes the formation of blood cells, an active process that must maintain normal numbers of circulating cells and be able to respond rapidly to increased demands such as bleeding or infection. During development, haematopoiesis occurs in the yolk sac, liver and spleen, and subsequently in red bone marrow in the medullary cavity of all bones. In childhood, red marrow is progressively replaced by fat (yellow marrow) so that, in adults, normal haematopoiesis is restricted to the vertebrae, pelvis, sternum, ribs, clavicles, skull, upper humeri and proximal femora. However, red marrow can expand in response to increased demands for blood cells.

Bone marrow contains a range of immature haematopoietic precursor cells and a storage pool of mature cells for release at times of increased demand. Haematopoietic cells interact closely with surrounding connective tissue stroma, made up of reticular cells, macrophages, fat cells, blood vessels and nerve fibres (Fig. 24.1). In normal marrow, nests of red cell precursors cluster around a central macrophage, which provides iron and phagocytoses nuclei from red cells prior to their release into the circulation. Megakaryocytes are large cells that produce and release platelets into vascular sinuses. White cell precursors are clustered next to the bone trabeculae; maturing cells migrate into the marrow spaces towards the vascular sinuses. Plasma cells are antibody-secreting mature B cells that normally represent less than 5% of the marrow population and are scattered throughout the intertrabecular spaces.

Stem cells

All blood cells are derived from pluripotent haematopoietic stem cells. These comprise only 0.01% of the total marrow cells, but they can self-renew (i.e. make more stem cells) or differentiate to produce a hierarchy of lineage-committed progenitor cells. The resulting primitive progenitor cells cannot be identified morphologically, so they are named according to the types of cell (or colony) they form during cell culture experiments. CFU–GM (colony-forming unit – granulocyte, monocyte) is a progenitor cell that produces granulocytic and monocytic lines, CFU–E produces erythroid cells, and CFU–Meg produces megakaryocytes and ultimately platelets (Fig. 24.2).

Growth factors, produced in bone marrow stromal cells and elsewhere, control the survival, proliferation, differentiation and function of stem cells and their progeny. Some, such as interleukin-3 (IL-3), stem cell factor (SCF) and granulocyte, macrophage colony-stimulating factor (GM–CSF), act on a wide number of cell types at various stages of differentiation. Others, such as erythropoietin, granulocyte colony-stimulating factor (G–CSF) and thrombopoietin (Tpo), are lineage-specific. Some of these growth factors are synthesised by recombinant DNA technology and used as treatments (see below).

Bone marrow also contains stem cells that can differentiate into non-haematological cells. Mesenchymal stem cells differentiate into skeletal muscle, cartilage, cardiac muscle and fat cells, while others differentiate into nerves, liver and blood vessel endothelium. This is termed stem cell plasticity and may have exciting clinical applications (Ch. 3).

Blood cells and their functions

Red cells

Red cell precursors formed in the bone marrow from the erythroid (CFU–E) progenitor cells are called erythroblasts or normoblasts (Fig. 24.3). These divide and acquire haemoglobin, which turns the cytoplasm pink; the nucleus condenses and is extruded from the cell. The first non-nucleated red cell is a reticulocyte, which still contains ribosomal material in the cytoplasm, giving these large cells a faint blue tinge ('polychromasia'). Reticulocytes lose their ribosomal material and mature over 3 days, during which time they are released into the circulation. Increased numbers of circulating reticulocytes (reticulocytosis) reflect increased erythropoiesis. Proliferation and differentiation of red cell precursors is stimulated by

erythropoietin, a polypeptide hormone produced by renal interstitial peritubular cells in response to hypoxia. Failure of erythropoietin production in patients with renal failure causes anaemia, which can be treated with exogenous recombinant erythropoietin or similar pharmacological agents called erythropoiesis-stimulating agents, e.g. darbepoetin.

Normal mature red cells circulate for about 120 days. They are 8 μm biconcave discs lacking a nucleus, but filled with haemoglobin, which delivers oxygen to the tissues. To pass through the smallest capillaries, the red cell membrane is deformable, with a lipid bilayer to which a 'skeleton' of filamentous proteins is attached via special linkage proteins

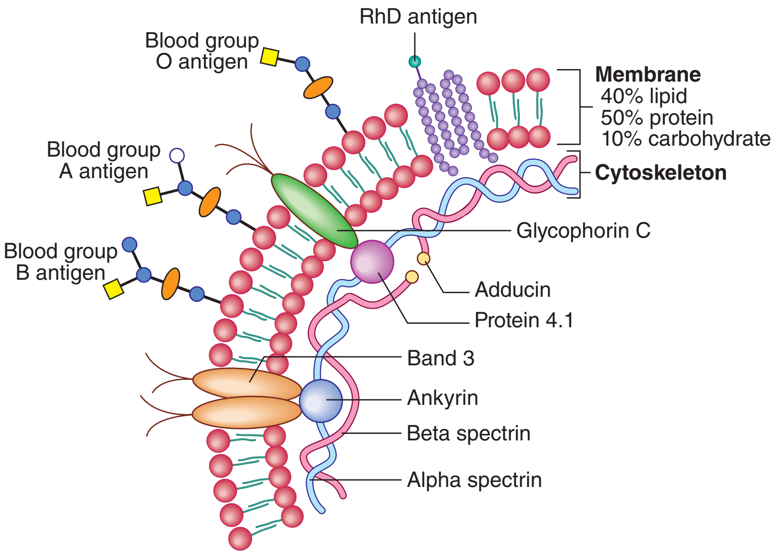

Fig. 24.4 Normal structure of red cell membrane. Red cell membrane flexibility is conferred by attachment of cytoskeletal proteins. Important transmembrane proteins include Band 3 (an ion transport channel) and glycophorin C (involved in cytoskeletal attachment and gas exchange, and a receptor for *Plasmodium falciparum* in malaria). Antigens on the red blood cell determine an individual's blood group. There are currently 45 blood group systems (groups of carbohydrate or protein antigens controlled by a single gene or by multiple closely linked loci); the most important clinically are the ABO and Rhesus (Rh) systems (p. 960). The ABO genetic locus has three main allelic forms: A, B and O. The A and B alleles encode glycosyltransferases that introduce *N*-acetylgalactosamine (open circle) and *D*-galactose (blue circle), respectively, on to antigenic carbohydrate molecules on the membrane surface. People with the O allele produce an O antigen, which lacks either of these added sugar groups. Rh antigens are transmembrane proteins.

(Fig. 24.4). Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 24.8D). Red cells are exposed to osmotic stress in the pulmonary and renal circulation; in order to maintain homeostasis, the membrane contains ion pumps, which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 24.4). The ABO and Rhesus systems are the most commonly recognised, but over 400 blood group antigens have been described.

Haemoglobin

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment molecule termed haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A (αα/ββ) represents over 90% of adult haemoglobin, whereas haemoglobin F (αα/γγ) is the predominant type in the fetus. Each haem molecule contains a ferrous ion (Fe^{2+}), to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains 'swing' closer together; they move apart as oxygen is lost. In the 'open' deoxygenated state, 2,3-bisphosphoglycerate (2,3-BPG), a product of red cell metabolism, binds to the haemoglobin molecule and lowers its oxygen affinity. These complex interactions produce the sigmoid shape of the oxygen dissociation curve (Fig. 24.5). The position of this curve depends on the concentrations of 2,3-BPG, H$^+$ ions and CO$_2$; increased levels shift the curve to the right and cause oxygen to be released more readily, e.g. when red cells reach hypoxic tissues. Haemoglobin F is unable to bind 2,3-BPG and has a left-shifted oxygen dissociation curve, which, together with the low pH of fetal blood, ensures fetal oxygenation. Strong oxidising agents, such as dapsone, can convert the ferrous iron in haemoglobin to its ferric state (Fe^{3+}). The resultant methaemoglobin also has a left-shifted oxygen dissociation curve, which can result in tissue hypoxia (see Fig. 11.1).

Genetic mutations affecting the haem-binding pockets of globin chains or the 'hinge' interactions between globin chains result in haemoglobinopathies or unstable haemoglobins. Alpha globin chains are produced by two genes on chromosome 16, and beta globin chains by a single gene on chromosome 11; imbalance in the production of globin chains results in the thalassaemias (p. 983). Defects in haem synthesis cause the porphyrias (Ch. 19).

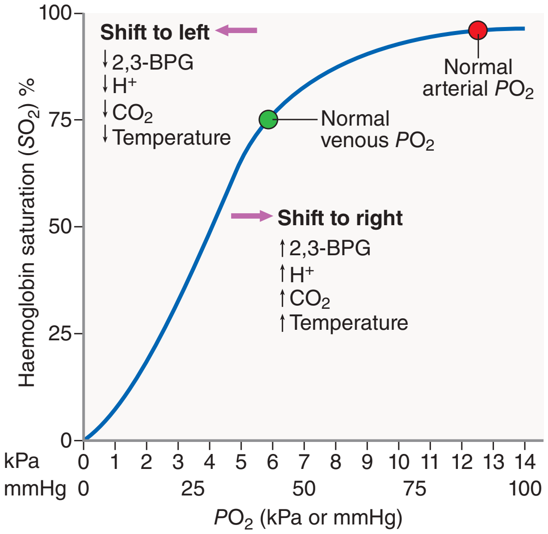

Fig. 24.5 The haemoglobin–oxygen dissociation curve. Factors are listed that shift the curve to the right (more oxygen released from blood) and to the left (less oxygen released) at given PO_2. To convert kPa to mmHg, multiply by 7.5. (2,3-BPG = 2,3-bisphosphoglycerate).

Destruction

Red cells at the end of their lifespan of approximately 120 days are phagocytosed by the reticulo-endothelial system. Amino acids from globin chains are recycled and iron is removed from haem for reuse in haemoglobin synthesis. The remnant haem structure is degraded to bilirubin and conjugated with glucuronic acid before being excreted in bile. In the small bowel, bilirubin is converted to stercobilin; most of this is excreted, but a small amount is reabsorbed and excreted by the kidney as urobilinogen. Increased red cell destruction due to haemolysis or ineffective haematopoiesis results in jaundice and increased urinary urobilinogen. Free intravascular haemoglobin is toxic and is normally bound by haptoglobins, which are plasma proteins produced by the liver.

White cells

White cells or leucocytes in the blood consist of granulocytes (neutrophils, eosinophils and basophils), monocytes and lymphocytes (see Fig. 24.12). Granulocytes and monocytes are formed from bone marrow CFU–GM progenitor cells during myelopoiesis. The first recognisable granulocyte in the marrow is the myeloblast, a large cell with a small amount of basophilic cytoplasm and a primitive nucleus with open chromatin and nucleoli. As the cells divide and mature, the nucleus segments and the cytoplasm acquire specific neutrophilic, eosinophilic or basophilic granules (see Fig. 24.3). This takes about 14 days. The cytokines G–CSF, GM–CSF and M–CSF are involved in the production of myeloid cells, and recombinant G–CSF can be used clinically to hasten recovery of blood neutrophil counts after chemotherapy.

Myelocytes or metamyelocytes are normally found only in the marrow, but may appear in the circulation in response to infection or toxic states. The appearance of more primitive myeloid precursors in the blood is often associated with the presence of nucleated red cells and is termed a 'leucoerythroblastic' picture; this indicates a serious disturbance of marrow function.

Neutrophils

Neutrophils, the most common white blood cells in the blood of adults, are 10–14 μm in diameter, with a multilobular nucleus containing 2–5 segments and granules in their cytoplasm. Their main function is to recognise, ingest and destroy foreign particles and microorganisms (see Ch. 4). A large storage pool of mature neutrophils exists in the bone marrow. Every day, some 10^{11} neutrophils enter the circulation, where cells may be circulating freely or attached to endothelium in the marginating pool. These two pools are equal in size; factors such as exercise or catecholamines increase the number of cells flowing in the blood. Neutrophils spend 6–10 hours in circulation before being removed, principally by the spleen. Alternatively, they pass into the tissues, and either are consumed in the inflammatory process or undergo apoptotic cell death and phagocytosis by macrophages.

Eosinophils

Eosinophils represent 1%–6% of the circulating white cells. They are a similar size to neutrophils but have a bilobed nucleus and prominent orange granules on Romanowsky staining. Eosinophils are phagocytic and their granules contain a peroxidase capable of generating reactive oxygen species and proteins involved in the intracellular killing of protozoa and helminths (Ch. 14). They are also involved in allergic reactions (e.g. atopic asthma, Ch. 17; see also Ch. 4).

Basophils

These cells are less common than eosinophils, representing less than 1% of circulating white cells. They contain dense black granules that obscure the nucleus. Mast cells resemble basophils but are found only in tissues. These cells are involved in hypersensitivity reactions (Ch. 4).

Monocytes

Monocytes are the largest of the white cells, with a diameter of 12–20 μm and an irregular nucleus in abundant pale blue cytoplasm containing occasional cytoplasmic vacuoles. These cells circulate for a few hours and then migrate into tissue, where they become macrophages, Kupffer cells or antigen-presenting dendritic cells. The former phagocytose debris, apoptotic cells and microorganisms (see Box 4.1).

Lymphocytes

Lymphocytes are derived from pluripotent haematopoietic stem cells in bone marrow. There are two main types: T cells (which mediate cellular immunity) and B cells (which mediate humoral immunity) (Ch. 4). Lymphoid cells that migrate to the thymus develop into T cells, whereas B cells develop in the bone marrow.

The majority (about 80%) of lymphocytes in the circulation are T cells. Lymphocytes are heterogeneous, the smallest being the size of red cells and the largest the size of neutrophils. Small lymphocytes are circular with scanty cytoplasm, but the larger cells are more irregular with abundant blue cytoplasm. Lymphocyte subpopulations have specific functions and lifespan can vary from a few days to many years. Cell surface antigens ('cluster of differentiation' (CD) antigens), which appear at different points of lymphocyte maturation and indicate the lineage and maturity of the cell, are used to classify lymphomas and lymphoid leukaemias.

Haemostasis

Blood must be maintained in a fluid state to function as a transport system, but must be able to solidify to form a clot following vascular injury to prevent excessive bleeding, a process known as haemostasis. Successful haemostasis is localised to the area of tissue damage and is followed by removal of the clot and tissue repair. This is achieved by complex interactions between the vascular endothelium, platelets, von Willebrand factor, coagulation factors, natural anticoagulants and fibrinolytic enzymes (Fig. 24.6 and see Fig. 24.19). Dysfunction of any of these components may result in haemorrhage or thrombosis.

Platelets

Platelets are formed in the bone marrow from megakaryocytes. Megakaryocytic progenitor cells (CFU–Meg) divide to form megakaryoblasts, which undergo a process called 'endomitotic reduplication', in which there is division of the nucleus but not the cell. This creates mature megakaryocytes, large cells with several nuclei and cytoplasm containing platelet granules. Large numbers of platelets then fragment off from each megakaryocyte into the circulation. The formation and maturation of megakaryocytes is stimulated by thrombopoietin produced in the liver. Platelets circulate for 8–10 days before they are destroyed in the reticulo-endothelial system. Some 30% of peripheral platelets are normally pooled in the spleen and do not circulate.

Under normal conditions, platelets are discoid, with a diameter of 2–4 μm (Fig. 24.7). The surface membrane invaginates to form a tubular network, the canalicular system, which provides a conduit for the discharge of the granule content following platelet activation. Drugs that inhibit platelet function and thrombosis include aspirin (cyclo-oxygenase inhibitor), clopidogrel, prasugrel and ticagrelor (adenosine diphosphate (ADP)-mediated activation inhibitors), dipyridamole (phosphodiesterase inhibitor), and abciximab, tirofiban and eptifibatide (which prevent fibrinogen binding to glycoprotein IIb/IIIa (αiib β3 integrin); see Fig. 24.19).

Clotting factors

The coagulation system consists of a cascade of soluble inactive zymogen proteins designated by Roman numerals. When proteolytically cleaved and activated, each is capable of activating one or more components of the cascade. Activated factors are designated by the suffix 'a'. Some of these reactions require phospholipid and calcium. Coagulation occurs by two pathways: it is initiated by the extrinsic (or tissue factor) pathway and amplified by the 'intrinsic pathway' (see Fig. 24.6D).

Clotting factors are synthesised by the liver, although factor V is also produced by platelets and endothelial cells. Factors II, VII, IX and X require post-translational carboxylation to allow them to participate in coagulation. The carboxylase enzyme responsible for this in the liver is vitamin K–dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase is inhibited by warfarin, and this is the basis of the anticoagulant effect of coumarins (p. 968). Inherited (e.g. haemophilia) and acquired (e.g. liver failure) causes of coagulation factor deficiency are associated with bleeding.

Fig. 24.6 The stages of normal haemostasis. **A** *Stage 1. Pre-injury conditions encourage flow.* The vascular endothelium produces substances (including nitric oxide, prostacyclin and heparans) to prevent adhesion of platelets and white cells to the vessel wall. Platelets and coagulation factors circulate in a non-activated state. **B** *Stage 2. Early haemostatic response: platelets adhere; coagulation is activated.* At the site of injury, the endothelium is breached, exposing subendothelial collagen. Small amounts of tissue factor (TF) are released. Platelets bind to collagen via a specific receptor, glycoprotein Ia (GPIa), causing a change in platelet shape and its adhesion to the area of damage by the binding of other receptors (GPIb and GPIIb/IIIa) to von Willebrand factor and fibrinogen, respectively. Coagulation is activated by the tissue factor (extrinsic) pathway, generating small amounts of thrombin. **C** and **D** *Stage 3. Fibrin clot formation: platelets become activated and aggregate; fibrin formation is supported by the platelet membrane; stable fibrin clot forms.* The adherent platelets are activated by many pathways, including binding of adenosine diphosphate (ADP), collagen, thrombin and adrenaline (epinephrine) to surface receptors. The cyclo-oxygenase pathway converts arachidonic acid from the platelet membrane into thromboxane A_2, which causes aggregation of platelets. Activation of the platelets results in release of the platelet granule contents, enhancing coagulation further (see Fig. 24.7). Thrombin plays a key role in the control of coagulation: the small amount generated via the TF pathway massively amplifies its own production; the 'intrinsic' pathway becomes activated and large amounts of thrombin are generated. Thrombin directly causes clot formation by cleaving fibrinopeptides (FPs) from fibrinogen to produce fibrin. Fibrin monomers are cross-linked by factor XIII, which is also activated by thrombin. Having had a key role in clot formation and stabilisation, thrombin then starts to regulate clot formation in two main ways: (a) activation of the protein C (PC) pathway (a natural anticoagulant), which reduces further coagulation; (b) activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which inhibits fibrinolysis (see **E** and **F**). **E** *Stage 4. Limiting clot formation: natural anticoagulants reverse activation of coagulation factors.* Once haemostasis has been secured, the propagation of clot is curtailed by anticoagulants. Antithrombin is a serine protease inhibitor synthesised by the liver, which destroys activated factors such as XIa, Xa and thrombin (IIa). Its major activity against thrombin and Xa is enhanced by heparin and fondaparinux, explaining their anticoagulant effect. Tissue factor pathway inhibitor (TFPI) binds to and inactivates VIIa and Xa. Activation of PC occurs following binding of thrombin to membrane-bound thrombomodulin; activated protein C (aPC) binds to its co-factor, protein S (PS), and cleaves Va and VIIIa. PC and PS are vitamin K–dependent and are depleted by coumarin anticoagulants such as warfarin. **F** *Stage 5. Fibrinolysis: plasmin degrades fibrin to allow vessel recanalisation and tissue repair.* The insoluble clot needs to be broken down for vessel recanalisation. Plasmin, the main fibrinolytic enzyme, is produced when plasminogen is activated, e.g. by tissue plasminogen activator (tPA) or urokinase in the clot. Plasmin hydrolyses the fibrin clot, producing fibrin degradation products, including the D-dimer. This process is highly regulated; the plasminogen activators are controlled by an inhibitor called plasminogen activator inhibitor (PAI), the activity of plasmin is inhibited by α_2-antiplasmin and α_2-macroglobulin, and fibrinolysis is further inhibited by the thrombin-activated TAFI.

Fig. 24.7 Normal platelet structure. The platelet surface is populated by glycoproteins, which bind to key structures including fibrinogen, collagen and von Willebrand factor and cell surface receptors for thrombin, ADP and adrenaline (epinephrine). Through internal signalling pathways, platelet activation causes degranulation of alpha and dense granules, which ultimately results in platelet aggregation. Blockade of these pathways by drugs such as aspirin, clopidogrel, ticagrelor, tirofiban and abciximab forms the basis of antiplatelet therapy. (ADP = adenosine diphosphate; GP = glycoprotein)

Investigation of diseases of the blood

The full blood count

To obtain a full blood count (FBC), anticoagulated blood is processed through automated blood analysers that use a variety of technologies (particle-sizing, radiofrequency and laser instrumentation) to measure the haematological parameters. These include numbers of circulating cells, the proportion of whole blood volume occupied by red cells (the haematocrit, Hct), and the red cell indices that give information about the size of red cells (mean cell volume, MCV) and the amount of haemoglobin present in the red cells (mean cell haemoglobin, MCH). Blood analysers can differentiate types of white blood cell and give automated counts of neutrophils, lymphocytes, monocytes, eosinophils and basophils. It is important to appreciate, however, that a number of conditions can lead to spurious results (Box 24.1). The reference ranges for a number of common haematological parameters in adults are given in Chapter 33 and the effects of age are shown in Box 24.6, below.

Blood film examination

Although technical advances in full blood count analysers have resulted in fewer blood samples requiring manual examination, scrutiny of blood components prepared on a microscope slide (the 'blood film') can often yield valuable information (Box 24.2 and Fig. 24.8). Analysers cannot identify abnormalities of red cell shape and content (e.g. Howell–Jolly bodies, basophilic stippling, malaria parasites) or fully define abnormal white cells such as blasts.

Bone marrow examination

In adults, bone marrow for examination is usually obtained from the posterior iliac crest. After a local anaesthetic, marrow can be sucked out from the medullary space, stained and examined under the microscope (bone marrow aspirate). In addition, a core of bone may be removed (trephine biopsy), fixed and decalcified before sections are cut for staining (Fig. 24.9). Bone marrow aspirate is used to assess the composition and morphology of haematopoietic cells or abnormal infiltrates. Further investigations may be performed, such as cell surface marker analysis (immunophenotyping), chromosome (karyotyping) and molecular studies, including next-generation sequencing (NGS) to identify mutated genes as part of the assessment of malignant diseases and bone marrow failure syndromes. Marrow can be cultured for suspected tuberculosis. A trephine biopsy is superior for assessing marrow cellularity, marrow fibrosis, and infiltration by abnormal cells such as metastatic carcinoma.

Investigation of coagulation

Bleeding disorders

In patients with clinical evidence of a bleeding disorder (p. 943), there are recommended screening tests (Box 24.3). Physiological activation of coagulation is predominantly by tissue factor, with amplification of the process by the small amounts of thrombin formed as a result. For ease of description, the terms extrinsic, intrinsic and common pathways are still used (see Fig. 24.6D).

i 24.1 Spurious full blood count results from autoanalysers

Result	Explanation
Increased haemoglobin	Lipaemia, jaundice, very high white cell count
Reduced haemoglobin	Improper sample mixing, blood taken from vein into which an infusion is flowing
Increased red cell volume (mean cell volume, MCV)	Cold agglutinins, non-ketotic hyperosmolarity
Increased white cell count	Nucleated red cells present
Reduced platelet count	Clot in sample, platelet clumping

Coagulation tests measure the time to clot formation in vitro in a platelet poor plasma sample after the clotting process is initiated by activators and calcium. The result of the test sample is compared with normal controls. The tissue factor ('extrinsic') pathway (see Fig. 24.6D) is assessed by the prothrombin time (PT), and the 'intrinsic' pathway by the activated partial thromboplastin time (APTT), sometimes known as the partial thromboplastin time with kaolin (PTTK). Coagulation is delayed by deficiencies of coagulation factors and by the presence of inhibitors of coagulation, such as heparin and lupus anticoagulants. The approximate reference ranges and causes of abnormalities are shown in Box 24.3. If both the PT and APTT are prolonged, this indicates either deficiency or inhibition of the final common pathway (which includes factors X, V, prothrombin and fibrinogen) or global coagulation factor deficiency involving more than one factor, as occurs in disseminated intravascular coagulation (DIC; pp. 236 and 1013). Further specific tests may be performed based on interpretation of the clinical scenario and results of these screening tests. A mixing test with normal plasma allows differentiation between a coagulation factor deficiency (the prolonged time corrects) and the presence of an inhibitor of coagulation (the prolonged time does not correct); the latter may be a chemical (heparins) or an antibody (most often a lupus anticoagulant, but occasionally a specific inhibitor of one of the coagulation factors, typically factor VIII). Von Willebrand disease may present with a normal APTT; further investigation of suspected cases is detailed on page 1009).

Platelet function has historically been assessed by the bleeding time, measured as the time to stop bleeding after a standardised incision. However, most centres have abandoned the use of this test. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists, such as adrenaline (epinephrine), collagen, thrombin, arachidonic acid and ADP, agglutination in response to ristocetin or by measuring the constituents of the intracellular granules, e.g. adenosine triphosphate, adenosine diphosphate and their ratio to each other (ATP/ADP).

In disseminated intravascular coagulation (DIC), platelets and coagulation factors are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with consumption of fibrinogen and generation of fibrin degradation products (D-dimers). Note, however, that fibrinogen is an acute phase protein that may also be elevated in inflammatory disease (p. 66).

Monitoring anticoagulant therapy

The International Normalised Ratio (INR) is validated only to assess the therapeutic effect of coumarin anticoagulants, including warfarin. INR is the ratio of the patient's PT to that of a normal control, raised to the power of the international sensitivity index of the thromboplastin used in the test (ISI, derived by comparison with an international reference standard material). Concentrations of the direct oral anticoagulants (DOACs) cannot be accurately assessed from the PT or the APTT, with which they have a variable and generally poor correlation, but can be measured using appropriately calibrated specific assays.

Monitoring of heparin therapy is, on the whole, required only with unfractionated heparins (UFH). Therapeutic anticoagulation prolongs the APTT relative to a control sample by a ratio of approximately 1.5–2.5. Many laboratories now prefer to measure UFH activity by an appropriately calibrated anti-Xa assay. Low-molecular-weight heparins have such a predictable dose response that monitoring of the anticoagulant effect is not required, except in patients with renal impairment (glomerular filtration rate less than 30 mL/min). When monitoring is indicated, an anti-Xa assay is used.

24.2 How to interpret red cell appearances

Microcytosis (reduced average cell size, MCV <76 fL) A

- Iron deficiency
- Thalassaemia
- Sideroblastic anaemia

Macrocytosis (increased average cell size, MCV > 100 fL) B

- Vitamin B_{12} or folate deficiency
- Liver disease, alcohol
- Hypothyroidism
- Myelodysplastic syndromes
- Drugs (e.g. zidovudine, trimethoprim, phenytoin, methotrexate, hydroxycarbamide)

Target cells (central area of haemoglobinisation) C

- Liver disease
- Thalassaemia
- Post-splenectomy
- Haemoglobin C disease

Spherocytes (dense cells, no area of central pallor) D

- Autoimmune haemolytic anaemia
- Post-splenectomy
- Hereditary spherocytosis

Red cell fragments (intravascular haemolysis) E

- Microangiopathic haemolysis, e.g. haemolytic urea syndrome (HUS), thrombotic thrombocytopenic purpura (TTP)
- Disseminated intravascular coagulation (DIC)

Nucleated red blood cells (normoblasts) F

- Marrow infiltration
- Severe haemolysis
- Myelofibrosis
- Acute haemorrhage

Howell–Jolly bodies (small round nuclear remnants) G

- Hyposplenism
- Post-splenectomy
- Dyshaematopoiesis

Basophilic stippling (abnormal ribosomal RNA appears as blue dots) H

- Dyshaematopoiesis
- Lead poisoning

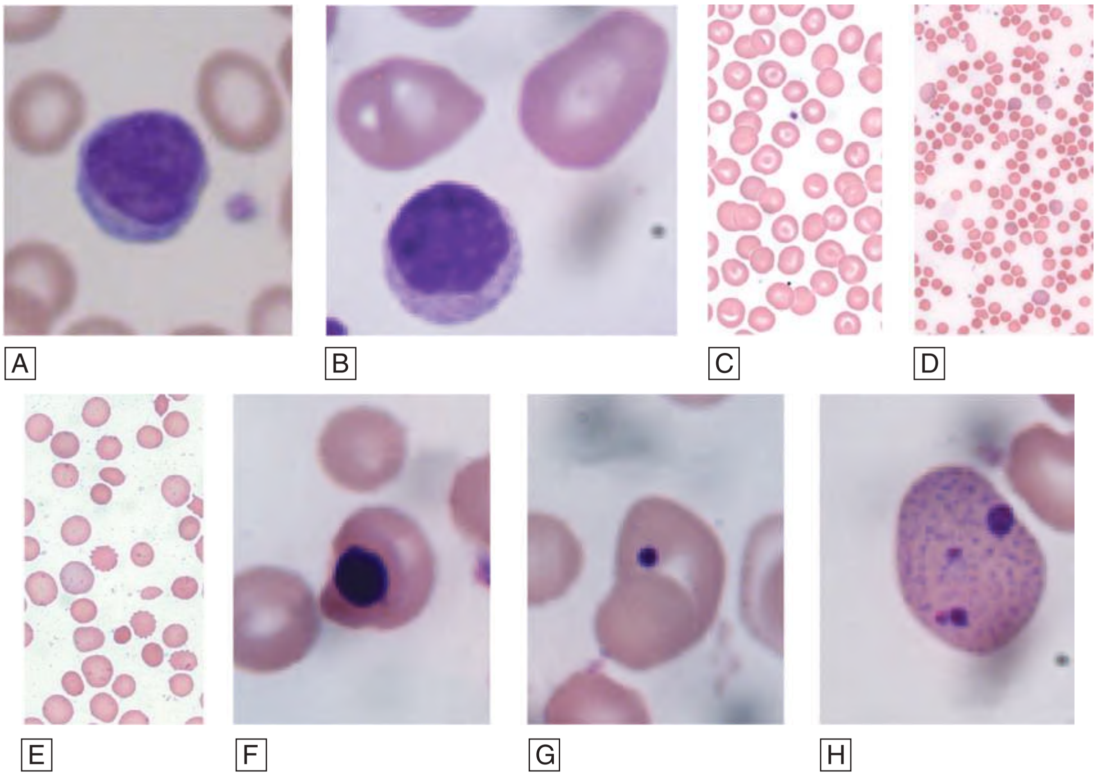

Fig. 24.8 **Appearance of red blood cells.** **A** Microcytosis. **B** Macrocytosis. **C** Target cells. **D** Spherocytes and polychromasia. **E** Red cell fragments. **F** Nucleated red blood cells. **G** Howell–Jolly bodies. **H** Basophilic stippling.

(MCV = mean cell volume)

Thrombotic disorders

Measurement of plasma levels of D-dimers derived from fibrin degradation is useful in excluding the diagnosis of active venous thrombosis in some patients (see Fig. 10.7).

A variety of tests exist that may help to explain an underlying propensity to thrombosis, especially venous thromboembolism (thrombophilia) (Box 24.4). Examples of possible indications for testing are given in Box 24.5. In most patients, the results of these tests do not affect clinical management (p. 1009), but they may influence the duration of anticoagulation (e.g. antiphospholipid antibodies, p. 1012), justify family screening in inherited thrombophilias (p. 1012), or suggest additional management strategies to reduce thrombosis risk (e.g. in myeloproliferative disease and paroxysmal nocturnal haemoglobinuria; p. 961). Anticoagulants can interfere with some of these assays. For example, warfarin reduces protein C and S levels and affects measurement of lupus anticoagulant. Heparin interferes with antithrombin and lupus anticoagulant assays and the DOACs all affect the measurement of lupus anticoagulant as well as other specific coagulation assays. Therefore, these tests, when required, should be performed when the patient is not taking anticoagulants or, if required, during temporary discontinuation to facilitate accurate measurement.

Box 24.6 lists some considerations specific to all haematological investigations in old age.

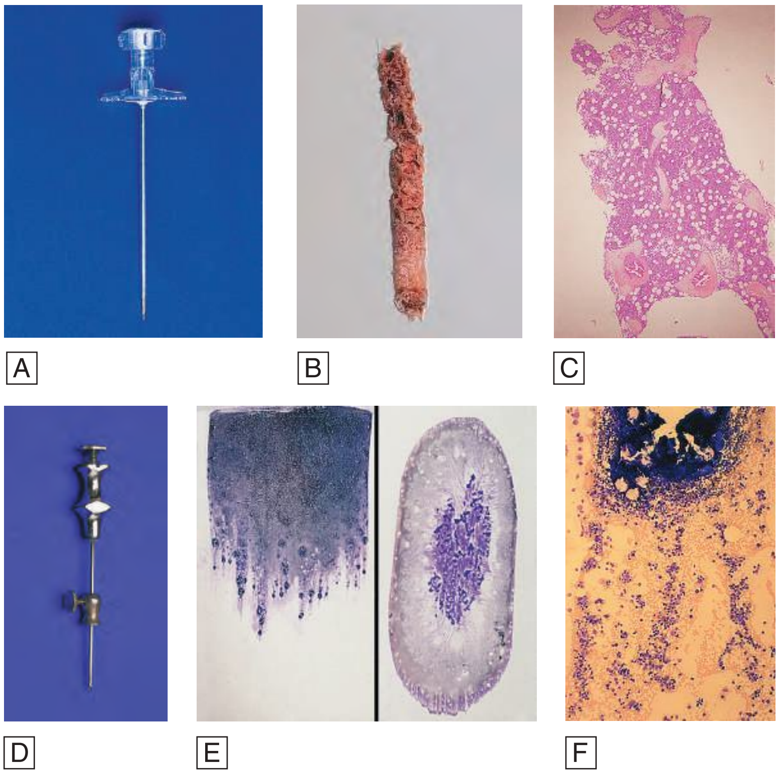

Fig. 24.9 Bone marrow aspirate and trephine. **A** Trephine biopsy needle. **B** Macroscopic appearance of a trephine biopsy. **C** Microscopic appearance of stained section of trephine. **D** Bone marrow aspirate needle. **E** Stained macroscopic appearance of marrow aspirate: smear (left) and squash (right). **F** Microscopic appearance of stained marrow particles and trails of haematopoietic cells.

24.3 Coagulation screening tests[1]

Investigation	Reference range[2]	Situations in which tests may be abnormal
Platelet count	150–400 $\times 10^9$/L	Thrombocytopenia
Prothrombin time (PT)	9–12 secs	Deficiencies of factors II, V, VII or X Severe fibrinogen deficiency, DIC
Activated partial thromboplastin time (APTT)	26–36 secs	Deficiencies of factors II, V, VIII, IX, X, XI, XII Severe fibrinogen deficiency Unfractionated heparin therapy Antibodies against clotting factors Lupus anticoagulant Multiple factor deficiency, e.g. DIC
Fibrinogen concentration	1.5–4.0 g/L	Hypofibrinogenaemia, e.g. liver failure, DIC

[1] N.B. International Normalised Ratio (INR) is used only to monitor coumarin therapy and is not a coagulation screening test. [2] Ranges are approximate and may vary between laboratories. (DIC = disseminated intravascular coagulation)

Presenting problems in blood disease

Anaemia

Anaemia refers to a state in which the level of haemoglobin in the blood is below the reference range appropriate for age and sex. Other factors, including pregnancy and altitude, also affect haemoglobin levels and must be taken into account when considering whether an individual is anaemic. The clinical features of anaemia reflect diminished oxygen supply to the tissues (p. 943). A rapid onset of anaemia (e.g. due to blood loss) causes more profound symptoms than gradually developing

24.4 Investigation of possible thrombophilia

Full blood count

Plasma levels

- Antithrombin
- Protein C
- Protein S (free)
- Antiphospholipid antibodies, lupus anticoagulant, anticardiolipin antibody/anti-β_2-GP1

Thrombin/reptilase time (for dysfibrinogenaemia)

Genetic testing

- Factor V Leiden
- Prothrombin G20210A
- *JAK-2 V617F* mutation
- *CALR* mutations
- *MPL 515* mutation

Flow cytometry

- Screen for GPI-linked cell surface proteins (CD14, 16, 55, 59), deficient in paroxysmal nocturnal haemoglobinuria

(CD = cluster of differentiation; GP1 = glycoprotein 1; GPI = glycerol phosphatidyl inositol)

24.5 Possible indications for thrombophilia testing*

- Venous thrombosis < 45 years
- Recurrent venous thrombosis
- Family history of unprovoked or recurrent thrombosis
- Combined arterial and venous thrombosis
- Venous thrombosis at an unusual site:
  - Cerebral venous thrombosis
  - Hepatic vein (Budd–Chiari syndrome)
  - Portal vein, mesenteric vein, splenic vein

*Antiphospholipid antibodies should be sought where clinical criteria for antiphospholipid syndrome (APS) are fulfilled (p. 1012). Thrombophilia testing may explain the diagnosis without necessarily affecting management and this limits the clinical value of such an approach.

24.6 Haematological investigations in old age

- **Blood cell counts and film components**: not altered in general by ageing alone, although haemoglobin concentrations fall with increasing age.
- **Ratio of bone marrow cells to marrow fat**: falls.
- **Neutrophils**: maintained throughout life, although leucocytes may be less readily mobilised by bacterial invasion in old age.
- **Lymphocytes**: functionally compromised by age due to a T-cell-related defect in cell-mediated immunity.
- **Clotting factors**: no major changes, although mild congenital deficiencies may be first noticed in old age.
- **Erythrocyte sedimentation rate (ESR)**: raised above the reference range, but usually in association with chronic or subacute disease. In truly healthy older people, the ESR range is very similar to that in younger people (see Ch. 4).
- **Clonal haematopoiesis**. Myeloid gene panels are more likely to demonstrate clonal haematopoiesis of indeterminate potential (CHIP) based on acquired gene mutations in the blood cells of older patients. This may occur as frequently as 20% of people aged over 80 years despite having normal blood counts.

24.7 Causes of anaemia

Decreased or ineffective marrow production

- Lack of iron, vitamin B_{12} or folate
- Hypoplasia/myelodysplasia
- Invasion by malignant cells
- Renal failure
- Anaemia of chronic disease

Normal marrow production but increased removal of cells

- Blood loss
- Haemolysis
- Hypersplenism

anaemia. Individuals with cardiorespiratory disease are more susceptible to symptoms of anaemia.

The clinical assessment and investigation of anaemia should gauge its severity and define the underlying cause (Box 24.7).

Clinical assessment

- *Iron deficiency anaemia* (p. 971) is the most common type of anaemia worldwide. A thorough gastrointestinal history is important, looking in particular for symptoms of blood loss. Menorrhagia is a common cause of anaemia in pre-menopausal females, so women should always be asked about menstrual periods.
- *A dietary history* should assess the intake of iron, B_{12} and folate, which may become deficient in comparison to needs (e.g. in pregnancy or during periods of rapid growth; see also Chs 5 and 31).
- *Past medical history* may reveal a disease that is known to be associated with anaemia, such as rheumatoid arthritis (anaemia of inflammation (AI)), or previous surgery (e.g. resection of the stomach or small bowel, which may lead to malabsorption of iron and/or vitamin B_{12}).
- *Family history and ethnic background* may raise suspicion of haemolytic anaemias, such as haemoglobinopathies, oxidative enzymopathies and membranopathies. Pernicious anaemia, an autoimmune disorder, may also run in families, but is not associated with a clear Mendelian pattern of inheritance.
- *A drug history* may reveal the ingestion of drugs that cause or worsen blood loss (e.g. anticoagulants, antiplatelet drugs and anti-inflammatory drugs), haemolysis (e.g. sulphonamides and anti-malarial drugs) or aplasia (e.g. chloramphenicol, mercaptopurine).

On examination, as well as the general physical findings of anaemia shown on page 943, there may be specific findings related to the aetiology of the anaemia; for example, a right iliac fossa mass due to an underlying caecal carcinoma. Haemolytic anaemias can cause jaundice. Vitamin B_{12} deficiency may be associated with neurological signs, including peripheral neuropathy, dementia and signs of subacute combined degeneration of the spinal cord (see Box 27.95). Sickle-cell disorder (p. 981) may result in leg ulcers, stroke or features of pulmonary hypertension. Anaemia may be multifactorial, and the lack of specific symptoms and signs does not rule out silent pathology.

Investigations

Schemes for the investigation of anaemias are often based on the size of the red cells, which is most accurately indicated by the MCV in the FBC. Commonly, in the presence of anaemia:

- A normal MCV (normocytic anaemia) suggests either acute blood loss or the anaemia of chronic disease, also known as the anaemia of inflammation (ACD/AI) (Fig. 24.10).
- A low MCV (microcytic anaemia) suggests iron deficiency or thalassaemia or sometimes ACD/AI (see Fig. 24.10).
- A high MCV (macrocytic anaemia) suggests vitamin B_{12} or folate deficiency or myelodysplasia (Fig. 24.11).

Specific types of anaemia and their management are described later in this chapter.

High haemoglobin

Patients with a persistently raised haematocrit (Hct) (>0.52 males, >0.48 females) for more than 2 months should be investigated. 'True' polycythaemia (or absolute erythrocytosis) indicates an excess of red cells, while 'relative', 'apparent' or 'low volume' polycythaemia is due to a decreased plasma volume. Causes of polycythaemia are shown in Box 24.8. These involve increased erythropoiesis in the bone marrow, either due to a primary increase in marrow activity, or in response to increased erythropoietin (Epo) levels in chronic hypoxaemia, or due to inappropriate secretion of Epo. Some athletes improperly use Epo to increase oxygen-carrying capacity and thus enhance their physical performance.

Apparent erythrocytosis with a raised Hct, normal red cell mass (RCM) and reduced plasma volume may be associated with hypertension, smoking, alcohol and diuretic use (Gaisböck syndrome).

Clinical assessment and investigations

Males and females with Hct values of over 0.60 and over 0.56, respectively, can be assumed to have an absolute erythrocytosis. A clinical history and examination including measurement of oxygen saturation will identify most patients with polycythaemia secondary to hypoxia. The presence of hypertension, smoking, excess alcohol consumption and/or diuretic use is consistent with low-volume polycythaemia (Gaisböck syndrome). In polycythaemia vera (PV), the acquired *V617F* mutation is found in the *JAK-2* gene (a kinase) in over 90% of cases; in the remainder, mutations in exon 12 of the same gene may be rarely identified. Patients with PV have an increased risk of arterial thromboses, particularly stroke, and venous thromboembolism. They may also have aquagenic pruritus (itching after exposure to water), hepatosplenomegaly and gout (due to high red cell turnover).

If *JAK-2* mutations are absent and there is no obvious secondary cause, a measurement of red cell mass is required to confirm an absolute erythrocytosis, followed by further investigations to exclude hypoxia, and causes of inappropriate erythropoietin secretion.

Leucopenia (low white cell count)

A reduction in the total numbers of circulating white cells is called leucopenia. This may be due to a reduction in all types of white cell or in individual cell types (usually neutrophils or lymphocytes). Leucopenia may occur in isolation or as part of a reduction in all three haematological lineages (pancytopenia; p. 959).

24.8 Classification and causes of erythrocytosis

	Absolute erythrocytosis	Relative (low-volume) erythrocytosis
Haematocrit	High	High
Red cell mass	High	Normal
Plasma volume	Normal	Low
Causes	*Primary* Myeloproliferative disorder Polycythaemia rubra vera (primary proliferative polycythaemia) *Secondary* High erythropoietin due to tissue hypoxia: High altitude Cardiorespiratory disease High-affinity haemoglobins Inappropriately increased erythropoietin: Renal disease (hydronephrosis, cysts, carcinoma) Other tumours (hepatoma, bronchogenic carcinoma, uterine fibroids, phaeochromocytoma, cerebellar haemangioblastoma) Exogenous testosterone therapy Exogenous erythropoietin administration: Performance-enhancing drug-taking in athletes	Diuretics Smoking Obesity Alcohol excess Gaisböck syndrome

Neutropenia

A reduction in neutrophil count (usually $<1.5 \times 10^9$/L but dependent on age and race) is called neutropenia. The main causes are listed in Box 24.9 and Figure 24.12. Drug-induced neutropenia is not uncommon (Box 24.10). Clinical manifestations range from no symptoms to overwhelming sepsis. The risk of bacterial infection is related to the degree of neutropenia, with counts lower than 0.5×10^9/L considered to be critically low. Fever is the first and often only manifestation of infection. A sore throat, perianal pain or skin inflammation may be present. The lack of neutrophils allows the patient to become septicaemic and shocked within hours if immediate antibiotic therapy does not commence. Management is discussed on page 317 and on page 178.

Lymphopenia

This is an absolute lymphocyte count of less than 1×10^9/L. The causes are shown in Box 24.9. Although minor reductions may be asymptomatic, deficiencies in cell-mediated immunity may result in infections (with organisms such as fungi, viruses and mycobacteria) and a propensity to lymphoid and other malignancies (particularly those associated with viral infections such as Epstein–Barr virus (EBV), human papillomavirus (HPV) and human herpesvirus 8 (HHV-8)). Lymphopenia without any obvious cause is common with advancing age.

Leucocytosis (high white cell count)

An increase in the total numbers of circulating white cells is called leucocytosis. This is usually due to an increase in a specific type of cell (see Box 24.9). It is important to realise that an increase in a single type of white cell (e.g. eosinophils or monocytes) may not increase the total white cell count (WCC) above the upper limit of normal and will be apparent only if the 'differential' of the white count is examined.

Neutrophilia

An increase in the number of circulating neutrophils is called a neutrophilia or a neutrophil leucocytosis. It can result from an increased production of cells from the bone marrow or redistribution from the marginated pool. The normal neutrophil count depends on age, race and certain physiological parameters. During pregnancy, not only is there an increase in neutrophils, but also earlier forms, such as metamyelocytes, can be found in the blood. The causes of neutrophilia are shown in Box 24.9.

Eosinophilia

A high eosinophil count of more than 0.5×10^9/L is usually secondary to infection (especially parasites; Ch. 14), allergy (e.g. eczema, asthma, reactions to drugs; Ch. 4), immunological disorders (e.g. polyarteritis, sarcoidosis) or malignancy (e.g. lymphomas) (see Box 24.9). Usually, such eosinophilia is short-lived.

In the rarer primary disorders there is a persistently raised, often clonal, eosinophilia, e.g. in myeloproliferative disorders, subtypes of acute myeloid leukaemia and idiopathic hypereosinophilic syndrome (HES). Specific mutations in receptor tyrosine kinase genes have been found in some primary eosinophilias (e.g. causing rearrangements of platelet-derived growth factor receptors α and β or c-kit), which allow diagnosis and, in some cases, specific therapy with tyrosine kinase inhibitors such as imatinib.

Eosinophil infiltration can damage many organs (e.g. heart, lungs, gastrointestinal tract, skin, musculoskeletal system); evaluation of eosinophilia therefore includes not only the identification of any underlying cause and its appropriate treatment, but also assessment of any related organ damage.

Lymphocytosis

Lymphocytosis is an increase in circulating lymphocytes above that expected for the patient's age. In adults, this is greater than 3.5×10^9/L. Infants and children have higher counts; age-related reference ranges should be consulted. Causes are shown in Box 24.9; the most common is viral infection.

Lymphadenopathy

Enlarged lymph glands may be an important indicator of haematological disease, but they are not uncommon in reaction to infection or inflammation (Box 24.11). The sites of lymph node groups, and symptoms and signs that may help elucidate the underlying cause are shown on page 943. Nodes that enlarge in response to local infection or inflammation ('reactive nodes') usually expand rapidly and are painful, whereas those due to haematological disease are more frequently painless. Localised lymphadenopathy should elicit a search for a source of inflammation or primary malignancy in the appropriate drainage area:

- the scalp, ear, mouth and throat, face, teeth or thyroid for neck nodes
- the breast for axillary nodes
- the perineum or external genitalia for inguinal nodes.

24.9 How to interpret white blood cell results

Neutrophils A

Neutrophilia
- Infection: bacterial, fungal
- Trauma: surgery, burns
- Infarction: myocardial infarct, pulmonary embolus, sickle-cell crisis
- Inflammation: gout, rheumatoid arthritis, ulcerative colitis, Crohn disease
- Malignancy: solid tumours, Hodgkin lymphoma
- Myeloproliferative disease: polycythaemia vera, chronic myeloid leukaemia
- Physiological: exercise, pregnancy

Neutropenia
- Infection: viral, bacterial (e.g. *Salmonella*), protozoal (e.g. malaria)
- Drugs: see Box 24.10
- Autoimmune: connective tissue disease
- Alcohol
- Bone marrow infiltration: leukaemia, myelodysplasia
- Congenital: Kostmann syndrome
- Constitutional: African Caribbean and Middle Eastern descent

Eosinophils B

Eosinophilia
- Allergy: hay fever, asthma, eczema
- Infection: helminth (Box 14.20)
- Drug hypersensitivity: e.g. gold, sulphonamides
- Vasculitis: e.g. eosinophilic granulomatosis with polyangiitis (Churg–Strauss), granulomatosis with polyangiitis (Wegener granulomatosis)
- Connective tissue disease: polyarteritis nodosa
- Malignancy: solid tumours, lymphomas
- Primary bone marrow disorders: myeloproliferative disorders, hypereosinophilic syndrome (HES) and chronic eosinophilic leukaemias, acute myeloid leukaemia

Basophils C

Basophilia
- Myeloproliferative disease: chronic myeloid leukaemia (most typically)
- Inflammation: acute hypersensitivity, ulcerative colitis, Crohn disease

Monocytes D

Monocytosis
- Infection: bacterial (e.g. tuberculosis)
- Inflammation: connective tissue disease, ulcerative colitis, Crohn disease
- Malignancy: solid tumours, chronic myelomonocytic leukaemia

Lymphocytes E

Lymphocytosis
- Infection: viral, bacterial (e.g. *Bordetella pertussis*)
- Lymphoproliferative disease: chronic lymphocytic leukaemia, lymphoma
- Post-splenectomy

Lymphopenia
- Inflammation: connective tissue disease
- Lymphoma
- Renal failure
- Sarcoidosis
- Drugs: glucocorticoids, cytotoxics
- Congenital: severe combined immunodeficiency
- Human immunodeficiency virus (HIV) infection

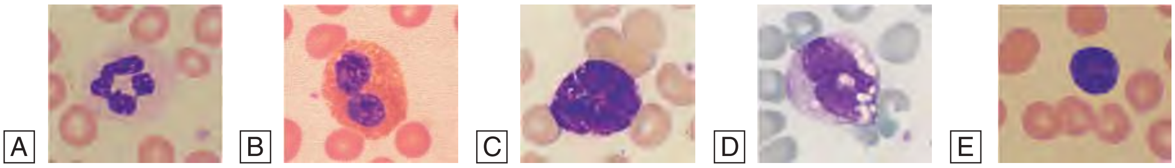

Fig. 24.12 **Appearance of white blood cells.** A Neutrophil. B Eosinophil. C Basophil. D Monocyte. E Lymphocyte.

24.10 Drugs that can induce neutropenia*

Group	Examples
Analgesics/anti-inflammatory agents	Gold, penicillamine, naproxen
Antithyroid drugs	Carbimazole, propylthiouracil
Anti-arrhythmics	Quinidine, procainamide
Antihypertensives	Captopril, enalapril, nifedipine
Antidepressants/psychotropics	Amitriptyline, dosulepin, mianserin
Antimalarials	Pyrimethamine, dapsone, sulfadoxine, chloroquine
Anticonvulsants	Phenytoin, sodium valproate, carbamazepine
Antibiotics	Sulphonamides, penicillins, cephalosporins
Miscellaneous	Cimetidine, ranitidine, chlorpropamide, zidovudine

*Many drugs can induce cytopenias. Many chemotherapy drugs and immunosuppressant drugs predictably cause neutropenia. In suspected cases check summary of product characteristics of the drug.

24.11 Causes of lymphadenopathy

Infective
- Bacterial: streptococcal, tuberculosis, brucellosis
- Viral: Epstein–Barr virus (EBV), human immunodeficiency virus (HIV)
- Protozoal: toxoplasmosis
- Fungal: histoplasmosis, coccidioidomycosis

Neoplastic
- Primary: lymphomas, leukaemias
- Secondary: lung, breast, thyroid, stomach, melanoma

Connective tissue disorders
- Rheumatoid arthritis
- Systemic lupus erythematosus (SLE)

Sarcoidosis

Amyloidosis

Drugs
- Phenytoin

Generalised lymphadenopathy may be secondary to infection, often viral, connective tissue disease or extensive skin disease (dermatopathic lymphadenopathy), but is more likely to signify underlying haematological malignancy. Weight loss and drenching night sweats that may require a change of nightclothes are associated with haematological malignancies, particularly lymphoma.

Initial investigations in lymphadenopathy include an FBC (to detect evidence of infection, inflammation or haematological disease such as leucocytosis, thrombocytosis or lymphopenia), measurement of erythrocyte sedimentation rate (ESR) or more commonly CRP and a chest X-ray (to detect mediastinal lymphadenopathy). If the findings suggest malignancy, a formal cutting needle or excision biopsy of a representative node is indicated to obtain a histological diagnosis. Increasingly, such lymph node biopsies are carried out under image guidance using ultrasound or CT scanning, rather than formal surgical excision biopsy. However, the quality of such specimens is variable and can be difficult to interpret, especially if they are small.

Splenomegaly

The spleen may be enlarged due to involvement by lymphoproliferative disease, the resumption of extramedullary haematopoiesis in myeloproliferative disease, enhanced reticulo-endothelial activity in autoimmune haemolysis, expansion of the lymphoid tissue in response to infections, or vascular congestion because of portal hypertension (Box 24.12).

24.12 Causes of splenomegaly

Congestive

Portal hypertension
- Cirrhosis
- Hepatic vein occlusion
- Portal vein thrombosis
- Stenosis or malformation of portal or splenic vein

Cardiac
- Chronic congestive cardiac failure
- Constrictive pericarditis

Infective

Bacterial
- Endocarditis
- Sepsis
- Tuberculosis
- Brucellosis
- Salmonella

Viral
- Hepatitis
- Epstein–Barr
- Cytomegalovirus

Protozoal
- Malaria*
- Leishmaniasis (kala-azar)*
- Trypanosomiasis

Fungal
- Histoplasmosis

Inflammatory/granulomatous disorders
- Felty syndrome in rheumatoid arthritis
- Systemic lupus erythematosus
- Sarcoidosis

Haematological

Red cell disorders
- Megaloblastic anaemia
- Hereditary spherocytosis
- Haemoglobinopathies

Autoimmune haemolytic anaemias

Myeloproliferative disorders
- Chronic myeloid leukaemia*
- Myelofibrosis*
- Polycythaemia vera
- Essential thrombocythaemia

Neoplastic
- Leukaemias, including chronic myeloid leukaemia*
- Lymphomas

Other malignancies
- Metastatic cancer – rare

Lysosomal storage diseases
- Gaucher disease
- Niemann–Pick disease

Miscellaneous
- Cysts, amyloid, thyrotoxicosis, haemophagocytic syndromes and other histiocytic disorders

*Causes of massive splenomegaly.

Hepatosplenomegaly is suggestive of lympho- or myeloproliferative disease, liver disease or infiltration (e.g. with amyloid). Associated lymphadenopathy is suggestive of lymphoproliferative disease. An enlarged spleen may cause abdominal discomfort, accompanied by back pain and abdominal bloating and early satiety due to stomach compression. Splenic infarction produces severe abdominal pain radiating to the left shoulder tip, associated with a splenic rub on auscultation. Rarely, spontaneous or traumatic rupture and bleeding may occur.

Investigation should focus on the suspected cause. Imaging of the spleen by ultrasound or computed tomography (CT) will detect variations in density in the spleen, which may be a feature of lymphoproliferative disease; it also allows imaging of the liver and abdominal lymph nodes. Biopsy of enlarged abdominal or superficial lymph nodes may provide the diagnosis, as might a bone marrow biopsy in splenic lymphomas. A chest X-ray or CT of the thorax will detect mediastinal lymphadenopathy. An FBC may show pancytopenia secondary to hypersplenism, when the enlarged spleen has become overactive, pooling and destroying blood cells prematurely. If other abnormalities are present, such as abnormal lymphocytes or a leucoerythroblastic blood film, a bone marrow examination is indicated. Screening for infectious or liver disease may be appropriate. If all investigations are unhelpful, especially if there are abnormalities within the spleen, splenic needle core biopsy under image guidance is increasingly undertaken and safe. Splenectomy may be diagnostic but is rarely carried out in these circumstances.

Bleeding

Normal bleeding is seen following surgery and trauma. Pathological bleeding occurs when structurally abnormal vessels rupture or when a vessel is breached in the presence of a defect in haemostasis. This may be due to a deficiency or dysfunction of platelets, the coagulation factors or von Willebrand factor, or occasionally to excessive fibrinolysis, which is most commonly observed following therapeutic thrombolysis (Ch. 16).

Clinical assessment

'Screening' blood tests (see Box 24.3) do not reliably detect all causes of pathological bleeding (e.g. von Willebrand disease, scurvy, certain anticoagulant and antiplatelet drugs and the causes of purpura listed in Box 24.13) and should not be used indiscriminately. A careful clinical evaluation is the key to diagnosis of bleeding disorders (p. 1006). It is important to consider the following:

- *Site of bleeding*. Bleeding into muscle and joints, along with retroperitoneal and intracranial haemorrhage, indicates a likely defect in coagulation factors. Purpura, prolonged bleeding from superficial cuts, epistaxis, gastrointestinal haemorrhage or menorrhagia is more likely to be due to thrombocytopenia, a platelet function disorder or von Willebrand disease. Recurrent bleeds at a single site suggest a local structural abnormality rather than coagulopathic bleeding.
- *Duration of history*. It may be possible to assess whether the disorder is congenital or acquired.
- *Precipitating causes*. Bleeding arising spontaneously indicates a more severe defect than bleeding that occurs only after trauma.
- *Surgery*. Ask about operations. Dental extractions, tonsillectomy and circumcision are stressful tests of the haemostatic system. Immediate post-surgical bleeding suggests defective platelet plug formation and primary haemostasis; delayed haemorrhage is more

24.13 Causes of non-thrombocytopenic purpura

- Senile purpura
- Factitious purpura
- Henoch–Schönlein purpura (Ch. 25)
- Vasculitis (Ch. 25)
- Paraproteinaemias
- Purpura fulminans, e.g. in disseminated intravascular coagulation secondary to sepsis

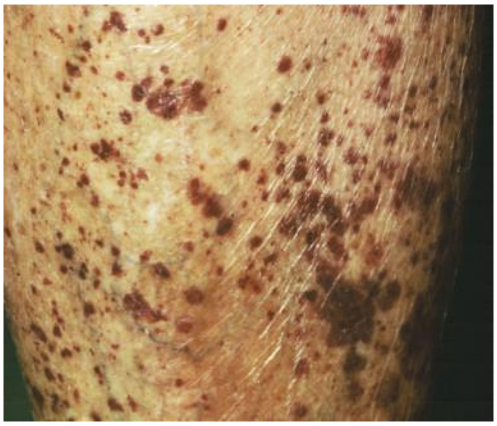

Fig. 24.13 Petechial purpura.

suggestive of a coagulation defect. However, in post-surgical patients, persistent bleeding from a single site is more likely to indicate surgical bleeding than coagulopathic bleeding.

- *Family history*. While a positive family history may be present in patients with inherited disorders, the absence of affected relatives does not exclude a hereditary bleeding diathesis; about one-third of cases of haemophilia arise in individuals without a family history, and deficiencies of factor VII, X and XIII are recessively inherited. Recessive disorders are more common in cultures where there is consanguineous marriage.
- *Drugs*. Use of antithrombotic, anticoagulant and fibrinolytic drugs must be elicited. Drug interactions with warfarin and drug-induced thrombocytopenia should be considered. Some 'herbal' remedies may result in a bleeding diathesis.

Clinical examination may reveal different patterns of skin bleeding. Petechial purpura is minor bleeding into the dermis that is flat and non-blanching (Fig. 24.13). Petechiae are typically found in patients with thrombocytopenia or platelet dysfunction. Palpable purpura occurs in vasculitis. Ecchymosis, or bruising, is more extensive bleeding into deeper layers of the skin. The lesions are initially dark red or purple, but become yellow as haemoglobin is degraded. Retroperitoneal bleeding presents with a flank or peri-umbilical haematoma. Telangiectasia of lips and tongue points to hereditary haemorrhagic telangiectasia (p. 993). Joints should be examined for evidence of haemarthroses. A full examination is important, as it may give clues to an underlying associated systemic illness such as a haematological or other malignancy, liver disease, renal failure, connective tissue disease and possible causes of splenomegaly.

Validated scoring systems are available to help determine if an individual's bleeding history is clinically significant. The International Society of Thrombosis and Haemostasis Bleeding Assessment Tool (ISTH BAT) is one example of such a score. Using this, the cut-offs for abnormal bleeding scores are ≥ 4 in adult males, ≥ 6 in adult females and ≥ 3 in children.

Investigations

Screening investigations and their interpretation are described on page 950. If the patient has a history that is strongly suggestive of a bleeding disorder and all the preliminary screening tests give normal results, further investigations, such as measurement of von Willebrand factor and assessment of platelet function, should be performed.

Thrombocytopenia (low platelet count)

A reduced platelet count may arise by one of two mechanisms:

- decreased or abnormal production (bone marrow failure and hereditary thrombocytopathies)
- increased consumption following release into the circulation (immune-mediated, DIC or sequestration).

24.14 Causes of thrombocytopenia

Decreased production

Marrow hypoplasia

- Childhood bone marrow failure syndromes, e.g. Fanconi anaemia, dyskeratosis congenita, amegakaryocytic thrombocytopenia
- Idiopathic aplastic anaemia
- Drug-induced: cytotoxics, antimetabolites
- Transfusion-associated graft-versus-host disease

Marrow infiltration

- Leukaemia
- Myeloma
- Carcinoma (rare)
- Myelofibrosis
- Osteopetrosis
- Lysosomal storage disorders, e.g. Gaucher disease

Haematinic deficiency

- Vitamin B_{12} and/or folate deficiency

Familial (macro-)thrombocytopathies

- Myosin heavy chain abnormalities, e.g. Alport syndrome, Fechtner syndrome, May–Hegglin anomaly
- Bernard–Soulier syndrome
- Montreal platelet syndrome
- Wiskott–Aldrich syndrome (small platelets)
- Mediterranean macrothrombocytopathy

Increased consumption

Immune mechanisms

- Idiopathic thrombocytopenic purpura*
- Neonatal alloimmune thrombocytopenia
- Post-transfusion purpura
- Drug-associated, especially quinine, vancomycin and heparin

Coagulation activation

- Disseminated intravascular coagulation (DIC) (see Box 24.74)

Mechanical pooling

- Hypersplenism

Thrombotic microangiopathies

- Haemolytic uraemic syndrome (HUS) and atypical HUS
- Liver disease
- Thrombotic thrombocytopenic purpura
- Pre-eclampsia/HELLP

Others

- Gestational thrombocytopenia
- Type 2B von Willebrand disease
- Pseudo von Willebrand disease

*Associated conditions include collagen vascular diseases (particularly systemic lupus erythematosus), B-cell malignancy, HIV infection and antiphospholipid syndrome
(HELLP = haemolysis, elevated liver enzymes and low platelet syndrome)

Spontaneous bleeding does not usually occur until the platelet count falls below 20 × 10^9/L, unless their function is also compromised. Purpura and spontaneous bruising are characteristic, but there may also be oral, nasal, gastrointestinal or genitourinary bleeding. Severe thrombocytopenia (< 10 × 10^9/L) may result in retinal haemorrhage and potentially fatal intracranial bleeding, but this is rare.

Investigations are directed at the possible causes listed in Box 24.14. Blood films are the single most useful initial investigation. Examination of the bone marrow may reveal increased megakaryocytes in consumptive causes of thrombocytopenia, or the underlying cause of bone marrow failure in leukaemia, hypoplastic anaemia or myelodysplasia.

Treatment (if required) depends on the underlying cause. Platelet transfusion is rarely required and is usually confined to patients with bone marrow failure and platelet counts below 10 × 10^9/L, or to clinical situations with actual or predicted serious haemorrhage.

Thrombocytosis (high platelet count)

The most common reason for a raised platelet count is that it is reactive to another process, such as infection, inflammation, connective tissue disease, malignancy, iron deficiency, acute haemolysis or gastrointestinal bleeding (Box 24.15). The presenting clinical features are usually those

24.15 Causes of a raised platelet count

Reactive thrombocytosis

- Acute and chronic inflammatory disorders
- Infection
- Malignant disease
- Tissue damage
- Haemolytic anaemias
- Post-splenectomy
- Post-haemorrhage

Clonal thrombocytosis

- Primary thrombocythaemia
- Polycythaemia vera
- Chronic myeloid leukaemia
- Myelofibrosis
- MDS
- MDS/MPN with *SF3B1* mutation/ring sideroblasts and thrombocytosis
- MDS with isolated deletion of 5q

(MDS = myelodysplastic syndromes; MPN = myeloproliferative neoplasm)

24.16 Causes of pancytopenia

Bone marrow failure

- Hypoplastic/aplastic anaemia (p. 1004): inherited, idiopathic, viral, drugs

Bone marrow infiltration

- Acute leukaemia
- Myeloma
- Lymphoma
- Carcinoma
- Haemophagocytic syndrome
- Myelodysplastic syndromes

Ineffective haematopoiesis

- Megaloblastic anaemia
- Acquired immunodeficiency syndrome (AIDS)

Peripheral pooling/destruction

- Hypersplenism: portal hypertension, Felty syndrome, malaria, myelofibrosis
- Systemic lupus erythematosus

of the underlying disorder, and haemostasis is rarely affected. Reactive thrombocytosis is distinguished from the myeloproliferative disorders by the presence of uniform small platelets, lack of splenomegaly and the presence of an associated underlying disorder. The key to diagnosis is the clinical history and examination, combined with observation of the platelet count over time (reactive thrombocytosis gets better with resolution of the underlying cause).

The platelets are a product of an abnormally expanding clone of cells in the myeloproliferative disorders, chronic myeloid leukaemia and some forms of myelodysplasia. As with PV, patients with essential thrombocythaemia may present with thrombosis or, rarely, bleeding. Stroke, transient ischaemic attacks, amaurosis fugax, digital ischaemia or gangrene, aquagenic pruritus, splenomegaly and systemic upset are also features. Patients with myeloproliferative disorders may also present with features such as aquagenic pruritus, splenomegaly and systemic upset.

Pancytopenia

Pancytopenia refers to the combination of anaemia, leucopenia and thrombocytopenia. It may be due to reduced production of blood cells because of bone marrow suppression or infiltration, or there may be peripheral destruction or splenic pooling of mature cells. Causes are shown in Box 24.16. A bone marrow aspirate and trephine are usually required to establish the diagnosis.

Infection

Infection is a major complication of haematological disorders. It relates to the immunological deficit caused by the disease itself, or its treatment with chemotherapy and/or immunotherapy (pp. 317 and 178).

Principles of management of haematological disease

Blood components and transfusion

Blood transfusion from an unrelated donor inevitably carries risk, including adverse immunological interactions between the host and infused blood (see below), and transmission of infectious agents. Although there are many compelling clinical indications for blood component transfusion, there are also many clinical circumstances where transfusion is standard practice but the evidence for its effectiveness is limited. In these settings, allogeneic transfusion may be avoided by following protocols that recommend the use of low haemoglobin thresholds for red cell transfusion, perioperative blood salvage and antifibrinolytic drugs.

Blood components

Blood components are prepared from whole blood or specific blood constituents collected from individual donors and include red cells, platelets, plasma and cryoprecipitate (Box 24.17).

Plasma derivatives are licensed pharmaceutical products produced on a factory scale from large volumes of human plasma obtained from many people and treated to reduce the risk of transmissible infection. Examples include:

- *Coagulation factors*. Concentrates of factors VIII, IX and von Willebrand factor are used for the treatment of conditions such as haemophilia A, haemophilia B and von Willebrand disease, respectively. Coagulation factors made by recombinant DNA technology are now preferred due to reduced infection risk, but plasma-derived products are still used in many countries.
- *Immunoglobulins*. Intravenous or subcutaneous immunoglobulin G (IVIgG, SCIgG) is administered as regular replacement therapy to reduce infective complications in patients with primary and secondary immunodeficiency. A short, high-dose course of IVIgG may also be effective in some immunological disorders, including immune thrombocytopenia (p. 1006) and Guillain–Barré syndrome (Ch. 27). IVIgG can cause acute reactions and must be infused strictly according to the manufacturer's product information. There is a risk of renal dysfunction in susceptible patients and in these circumstances immunoglobulin products containing low or no sucrose are preferred. Anti-zoster immunoglobulin has a role in the prophylaxis of varicella zoster (Ch. 14). Anti-Rhesus D immunoglobulin is used in pregnancy to prevent haemolytic disease of the newborn (see Box 24.19).
- *Human albumin*. This is available in two strengths. The 5% solution can be used as a colloid resuscitation fluid, but it is no more effective and is more expensive than crystalloid solutions. Human albumin 20% solution may be used in the management of hypoproteinaemic oedema in nephrotic syndrome (Ch. 18) and refractory ascites in chronic liver disease (Ch. 23). It is hyperoncotic and expands plasma volume by more than the amount infused.

Blood components and their uses are summarised in Box 24.17.

Blood donation

A safe supply of blood components depends on a well-organised system with regular donation by healthy individuals who have no apparent excess risk of infections transmissible in blood (Fig. 24.14). Blood donations are obtained by either venesection of a unit of whole blood or collection of a specific component, such as platelets, by apheresis. During apheresis, the donor's blood is drawn via a closed system into a machine that separates it into its component parts by centrifugation and collects the desired component into a bag, returning the rest of the blood to the donor. Each donation must be tested for hepatitis B virus (HBV), hepatitis C virus (HCV), HIV and human T-cell lymphotropic virus (HTLV) nucleic acid and/or antibodies. Platelet concentrates may be tested for bacterial

i 24.17 Blood components and their use

Component	Major haemorrhage	Other indications
Red cell concentrate[1]		
Most of the plasma is removed and replaced with a solution of glucose and adenine in saline to maintain viability of red cells ABO compatibility with recipient essential	Replace acute blood loss: increase circulating red cell mass to relieve clinical features caused by insufficient oxygen delivery. Order 4–6 U initially to allow high red cell to FFP transfusion ratios of (at least) 2:1	*Severe anaemia* If no cardiovascular disease, transfuse to maintain Hb at 70 g/L If known or likely to have cardiovascular disease, maintain Hb at 90 g/L
Platelet concentrate		
One adult dose is made from four donations of whole blood, or from a single platelet apheresis donation ABO compatibility with recipient preferable	Maintain platelet count $> 50 \times 10^9$/L, or in multiple or central nervous system trauma $> 100 \times 10^9$/L If ongoing bleeding, order when platelets $< 100 \times 10^9$/L to allow for delivery time Each adult dose has a minimum of 2.4×10^{11} platelets, which raises platelet count by 40×10^9/L unless there is consumptive coagulopathy, e.g. disseminated intravascular coagulation	*Thrombocytopenia*, e.g. in acute leukaemia Maintain platelet count $> 10 \times 10^9$/L if not bleeding Maintain platelet count $> 20 \times 10^9$/L if minor bleeding or at risk (sepsis, concurrent use of antibiotics, abnormal coagulation) Increase platelet count $> 50 \times 10^9$/L for minor invasive procedure (e.g. lumbar puncture, gastroscopy and biopsy, insertion of indwelling lines, liver biopsy, laparotomy) or in acute, major blood loss Increase platelet count $> 100 \times 10^9$/L for operations in critical sites such as brain or eyes
Fresh frozen plasma[2]		
150–300 mL plasma from one donation of whole blood ABO compatibility with recipient recommended	Dilutional coagulopathy with a PT prolonged > 50% is likely after replacement of 1–1.5 blood volumes with red cell concentrate Give initially in (at least) a ratio of 1 FFP:2 red cell concentrate; order 15–20 mL/kg and allow for thawing time. Further doses only if bleeding continues and guided by PT and APTT	*Replacement of coagulation factor deficiency* If no virally inactivated or recombinant product is available *Thrombotic thrombocytopenic purpura* Plasma exchange is frequently effective
Cryoprecipitate[2]		
Fibrinogen and coagulation factor concentrated from plasma by controlled thawing 10–20 mL pack contains: Fibrinogen 150–300 mg Factor VIII 80–120 U von Willebrand factor 80–120 U In UK supplied as pools of 5 U	Aim to keep fibrinogen > 1.5 g/L. 2 pooled units (of 10 donations) will raise fibrinogen by 1 g/L	*von Willebrand disease and haemophilia* If virus-inactivated or recombinant products are not available

[1] Whole blood is an alternative to red cell concentrate. ABO compatibility with recipient essential.

[2] Pooled plasma can be treated with solvent and detergent or single units treated with methylene blue as an additional viral inactivation step. Virus-inactivated plasma may be considered for large-volume exposure, as in treatment of thrombotic thrombocytopenic purpura, in critically ill patients to reduce the risk of allergic reactions.

(APTT = activated partial thromboplastin time; FFP = fresh frozen plasma; Hb = haemoglobin; PT = prothrombin time)

contamination. The need for other microbiological tests depends on local epidemiology. For example, testing for *Trypanosoma cruzi* (Chagas disease; Ch. 14) is necessary in areas of South America and the United States where infection is prevalent. Tests for West Nile virus have been required in the United States and UK since this agent became more prevalent, and components for use in specific patient groups are prepared from hepatitis E virus-negative donors in the UK.

Adverse effects of transfusion

In the UK, death attributable to transfusion is rare, at 2.7 per 100 000 transfusions; this includes avoidable deaths caused by circulatory overload or where a delay in timely supply of components was contributory. Moderate or severe febrile, allergic and hypotensive reactions occur in around 16 per 100 000 transfusions and are usually seen in patients who have had repeated transfusions. Any symptoms or signs that arise during a transfusion must be taken seriously, as they may be the first warnings of a serious reaction. Figure 24.16 outlines the symptoms and signs, management and investigation of acute reactions to blood components.

Red cell incompatibility

Red blood cell membranes contain numerous cell surface molecules that are potentially antigenic (see Fig. 24.4). The ABO and Rhesus D antigens are the most important in routine transfusion and antenatal practice.

ABO blood groups

The frequency of the ABO antigens varies among different populations. The ABO blood group antigens are oligosaccharide chains that project from the red cell surface. These chains are attached to proteins and lipids that lie in the red cell membrane. The *ABO* gene encodes a glycosyltransferase that catalyses the final step in the synthesis of the chain, which has three common alleles: A, B and O. The O allele encodes an inactive enzyme, leaving the ABO antigen precursor (called the H antigen) unmodified. The A and B alleles encode enzymes that differ by four amino acids and hence attach different sugars to the end of the chain. Individuals are tolerant to their own ABO antigens, but do not suppress B-cell clones producing antibodies against ABO antigens that they do not carry themselves (Box 24.18). They are, therefore, capable of mounting a humoral immune response to these ‘foreign’ antigens.

ABO-incompatible red cell transfusion

If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the *recipient*’s IgM anti-A, anti-B or anti-AB binds to the *transfused* red cells. This activates the full complement pathway (Ch. 4), creating pores in the red cell membrane and destroying the transfused red cells in the circulation (intravascular haemolysis). The anaphylatoxins C3a and C5a, released by complement activation, liberate cytokines such as tumour necrosis factor (TNF), interleukin (IL)-1 and IL-8, and stimulate degranulation of mast

Fig. 24.14 Blood donation, processing and storage. [1]Platelet apheresis involves circulating the donor's blood through a cell separator to remove platelets before returning other blood components to the donor. [2]In the UK, plasma for fractionation was imported as a precautionary measure against variant Creutzfeldt–Jakob disease (vCJD) but since 2022, UK plasma has been considered safe for manufacture of immunoglobulin for use in the UK and for the manufacture of albumin medicinal products. (HIV = human immunodeficiency virus; HTLV = human T-cell lymphotropic virus)

i 24.18 ABO blood group antigens and antibodies

ABO blood group	Red cell A or B antigens	Antibodies in plasma	UK frequency (%)
O	None	Anti-A and anti-B	46
A	A	Anti-B	42
B	B	Anti-A	9
AB	A and B	None	3

cells with release of vasoactive mediators. All these substances may lead to inflammation, increased vascular permeability and hypotension which may, in turn, cause shock and renal failure. Inflammatory mediators can also cause platelet aggregation, lung peribronchial oedema and smooth muscle contraction. About 20%–30% of ABO-incompatible transfusions cause some degree of morbidity, and 5%–10% cause or contribute to a patient's death. The main reason for this relatively low morbidity is the lack of potency of ABO antibodies in group A or B subjects; even if the recipient is group O, those who are very young or very old usually have weaker antibodies that do not lead to the activation of large amounts of complement.

The Rhesus D blood group and haemolytic disease of the newborn

About 15% of populations of predominantly European descent are Rhesus negative: that is, they lack the Rhesus D (RhD) red cell surface antigen (see Fig. 24.4). In other populations (e.g. in Chinese and Bengalis), only 1%–5% are Rhesus negative. RhD negative individuals do not normally produce substantial amounts of anti-RhD antibodies. However, if RhD positive red cells enter the circulation of an RhD negative individual, IgG antibodies are produced. This can occur during pregnancy if the mother is exposed to fetal cells via fetomaternal haemorrhage, or following transfusion. If a woman is sensitised, during a subsequent pregnancy, anti-RhD antibodies can cross the placenta; if the fetus is RhD positive, haemolysis with severe fetal anaemia and hyperbilirubinaemia can result. This can cause severe neurological damage or death due to haemolytic disease of the newborn (HDN). Therefore, an RhD negative female who may subsequently become pregnant should never be transfused with RhD positive blood.

In RhD negative women, administration of anti-RhD immunoglobulin (anti-D) perinatally can block the immune response to RhD antigen on fetal cells and is the only effective product for preventing the development of Rhesus antibodies (Box 24.19).

HDN can also be caused by other alloantibodies against red cell antigens, usually after previous pregnancies or transfusions. These antigens include Rhc, RhC, RhE, Rhe, and the Kell, Kidd and Duffy antigen systems. HDN can also occur if there is fetomaternal ABO incompatibility, most commonly seen in a group O mother with a group A fetus. The fetus is generally less severely affected by ABO incompatibility than by RhD, Rhc or Kell antigen mismatch and the incompatibility is often picked up coincidentally after birth.

Other immunological complications of transfusion

Rare but serious complications include transfusion-associated lung injury (TRALI) and transfusion-associated graft-versus-host disease (TA GVHD). The latter occurs when transfused viable lymphocytes are not rejected by the recipient because the donor and recipient share a common HLA haplotype, or because the recipient is immunocompromised. The donor lymphocytes attack the recipient's tissues resulting in acute GVHD (p. 966). Prevention is by gamma- or X-ray irradiation of blood components before their administration to prevent lymphocyte proliferation. Those at risk of TA GVHD who must receive irradiated blood components include patients with congenital T-cell immunodeficiencies or Hodgkin lymphoma, patients with aplastic anaemia receiving immunosuppressive therapy with antithymocyte globulin (ATG), recipients of haematopoietic stem cell transplants or of blood from a family member, neonates who have received an intrauterine transfusion, and patients taking T-lymphocyte-suppressing drugs, such as fludarabine and other purine analogues.

24.19 Rhesus D blood groups in pregnancy

- **Haemolytic disease of the newborn (HDN)**: occurs when the mother has anti-red cell immunoglobulin G (IgG) antibodies that cross the placenta and haemolyse fetal red cells.
- **Screening for HDN in pregnancy**: at the time of booking (12–16 weeks) and again at 28–34 weeks' gestation, every pregnant woman should have a blood sample sent for determination of ABO and Rhesus D (RhD) group and testing for red cell alloantibodies that may be directed against paternal blood group antigens present on fetal red cells.
- **Anti-D immunoglobulin prophylaxis in a pregnant woman who is RhD negative**: antenatal anti-D prophylaxis is offered at 28–34 weeks to RhD negative pregnant women who have no evidence of immune anti-D. This prevents the formation of antibodies that could cause HDN. Following delivery of an RhD positive baby, the mother is given further anti-D within 72 hours; a maternal sample is checked for remaining fetal red cells and additional anti-D is given if indicated. Additional anti-D is also given after potential sensitising events antenatally (e.g. early bleeding). Doses vary according to national recommendations.

Transfusion-transmitted infection

Over the past 30 years, HBV, HIV-1 and HCV have been identified and effective tests introduced to detect and exclude infected donations. Where blood is from 'safe' donors and correctly tested, the current risk of a donated unit being infectious is very small. In the UK, the estimated chance that a unit of blood from a 'safe' donor might be infected with one of the viruses for which blood is tested is approximately 1 in 34 million units for HIV-1, less than 1 in 100 million for HCV and 1 in 1.8 million for HBV. However, some patients who received transfusions before these tests were available suffered serious consequences from infection; this serves as a reminder to avoid non-essential transfusion since it is impossible to exclude the emergence of new or currently unrecognised transfusion-transmissible infection. Licensed plasma derivatives that have been virus-inactivated do not transmit HIV, HTLV, HBV, HCV, cytomegalovirus or other lipid-enveloped viruses.

Variant CJD is a human prion disease linked to bovine spongiform encephalitis (BSE; Ch. 27). The risk of a recipient acquiring the agent of vCJD from a transfusion is uncertain, but of 16 recipients of blood from donors who later developed the disease, 3 have died with clinical vCJD and 2 others had postmortem immunohistological features of infection.

Bacterial contamination of a blood component – usually platelets – is extremely rare (there have been no proven cases in the UK in recent years) but can result in severe bacteraemia/sepsis in the recipient.

Safe transfusion procedures – consent to receive transfusion

The proposed transfusion and any alternatives should be discussed with the patient or, if that is not possible, with a relative. Their consent to proceed with transfusion should be obtained and the discussion documented. Some patients may refuse transfusion because of religious or cultural beliefs (e.g. Jehovah Witnesses) and require specialised management to survive profound anaemia following blood loss.

Pre-transfusion testing

To ensure that red cells supplied for transfusion are compatible with the intended recipient, the transfusion laboratory will perform either a 'group and screen' procedure or a 'cross-match'. In the group and screen procedure, the red cells from the patient's blood sample are tested to determine the ABO and RhD type, and the patient's serum is also tested against an array of red cells expressing the most important antigens to detect any red cell antibodies. Any antibody detected can be identified by further testing, so that red cell units that lack the corresponding antigen can be selected. The patient's sample can be held in the laboratory for up to a week, so that the hospital blood bank can quickly prepare compatible blood without the need for a further patient sample. Conventional cross-matching consists of the group and antibody screen, followed by direct confirmation of the compatibility of individual units of red cells with the patient's serum. Full cross-matching takes about 45 minutes if no red cell antibodies are present but may require hours if a patient has multiple antibodies.

Blood can be supplied by 'electronic issue', without the need for compatibility cross-matching, if the laboratory's computer system shows that the patient's ABO and RhD groups have been identified and confirmed on two separate occasions and their antibody screen is negative. This allows group-specific units to be issued quickly and safely for elective and emergency transfusion.

Bedside procedures for safe transfusion

Errors leading to patients receiving the wrong blood are an important avoidable cause of mortality and morbidity. Many incompatible transfusions result from failure to adhere to standard procedures for taking correctly labelled blood samples from the patient and ensuring that the correct pack of blood component is transfused into the intended patient. In the UK in 2024, the annual incidence of transfusion of an incorrect blood component was approximately 16 per 100 000 units transfused.

Every hospital where blood is transfused should have a written transfusion policy used by all staff who order, check or administer blood products (Fig. 24.15). Management of suspected transfusion reactions is shown in Figure 24.16.

Transfusion in major haemorrhage

The successful management of a patient with major haemorrhage requires frontline clinical staff to be trained to recognise significant blood loss early and to intervene before shock is established. Hospitals should have local major haemorrhage protocols, and all clinical staff must be familiar with their content. Good teamwork and communication are essential to prevent poor clinical outcomes, suboptimal or inappropriate transfusion practice and component wastage. Fresh frozen plasma (FFP) should be given as part of initial resuscitation in (at least) a 1:2 ratio with red cell concentrate (RCC) until coagulation results are available. If the patient is bleeding, a ratio of FFP to RCC of 1:1 should be given until laboratory results are available, and use of cryoprecipitate should be considered. Once the bleeding is under control, further FFP transfusion should be guided by laboratory results with transfusion triggers of PT and/or APTT above 1.5 times normal for a standard dose of FFP (15–20 mL/kg). Cryoprecipitate should be given if the fibrinogen level falls below 1.5 g/L. Platelets should be kept above 50 × 10^9/L; to allow for delivery time, platelets should be requested if there is ongoing bleeding and the platelet count has fallen below 100 × 10^9/L. Blood component use in major haemorrhage is summarised in Box 24.17 and key points in transfusion medicine in Box 24.20.

Anti-cancer drugs

Cytotoxic chemotherapy

Many haematological malignancies are sensitive to the effects of cytotoxic chemotherapy drugs and, as such, they remain the mainstay of treatment for most haematological cancers (Box 24.21; see also Fig. 8.11). There is a wide range of drugs available that work by damaging DNA or disrupting cellular metabolism in such a way that natural apoptosis mechanisms, such as *TP53*, are activated and the cell dies. Despite cancer cells being more sensitive, chemotherapy is largely non-specific and kills some normal cells as well as cancer cells. This leads to common side-effects of treatment, such as transient bone marrow failure, hair loss, mucositis and infertility. The supportive care of patients undergoing chemotherapy is critical in overcoming these side-effects. It is this supportive care, including blood product support, antibiotics, antifungal drugs, growth factors and antiemetics, that has allowed specialist haematology units to achieve the best possible results from intensive chemotherapy: for example, when treating acute leukaemia.

The basic principles of chemotherapy include combining several non-cross-reacting drugs in a regimen that kills a fixed proportion of cancer cells with a given dose. Several cycles of the combination are given to achieve gradual reduction of the tumour burden, to induce remission and, in some instances, to produce a cure (Ch. 8).

Monoclonal antibodies

In recent years, chemotherapy has been improved by the addition of treatments that are more targeted to the cancer cell, particularly monoclonal antibodies; for example, rituximab (anti-CD20) has been added to CHOP (cyclophosphamide, doxorubicin, vincristine, prednisolone) and other regimens. This has significantly improved the outcome in a range of CD20-positive B-cell lymphomas, including diffuse large B-cell lymphoma (DLBCL), follicular lymphoma and mantle cell lymphoma. As well as 'naked' monoclonal antibodies that kill malignant cells by engaging antibody-dependent cytotoxic T cells or complement, chemotherapy drugs can also be linked to a monoclonal antibody to allow targeting of the chemotherapy drug to the specific cancer cell. Examples of such antibody–drug conjugates (ADCs) or 'payload' antibodies include the linking of the intercalating antibiotic calicheamicin to anti-CD33 (gemtuzumab ozogamicin) in the treatment of acute myeloid leukaemia (see Fig. 24.29) and to anti-CD22 (inotuzumab ozogamicin) in the treatment of acute lymphoblastic leukaemia (see Fig. 24.30).

Taking blood for pre-transfusion testing

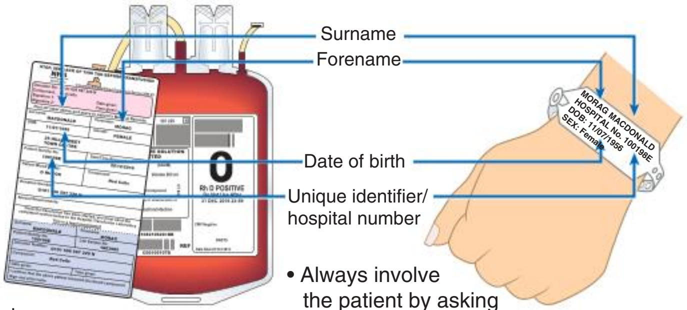
- Positively identify the patient at the bedside
- Label the sample tube and complete the request form clearly and accurately after identifying the patient
- Do not write forms and labels in advance

Administering blood

- Positively identify the patient at the bedside
- Ensure that the identification of each blood pack matches the patient's identification
- Check that the ABO and RhD groups of each pack are compatible with the patient's
- Check each pack for evidence of damage
- If in doubt, do not use and return to the blood bank
- Complete the forms that document the transfusion of each pack

- Check the compatibility label on the pack against the patient's wristband

Blood pack **Patient's wristband**



- Always involve the patient by asking them to state their name and date of birth, where possible

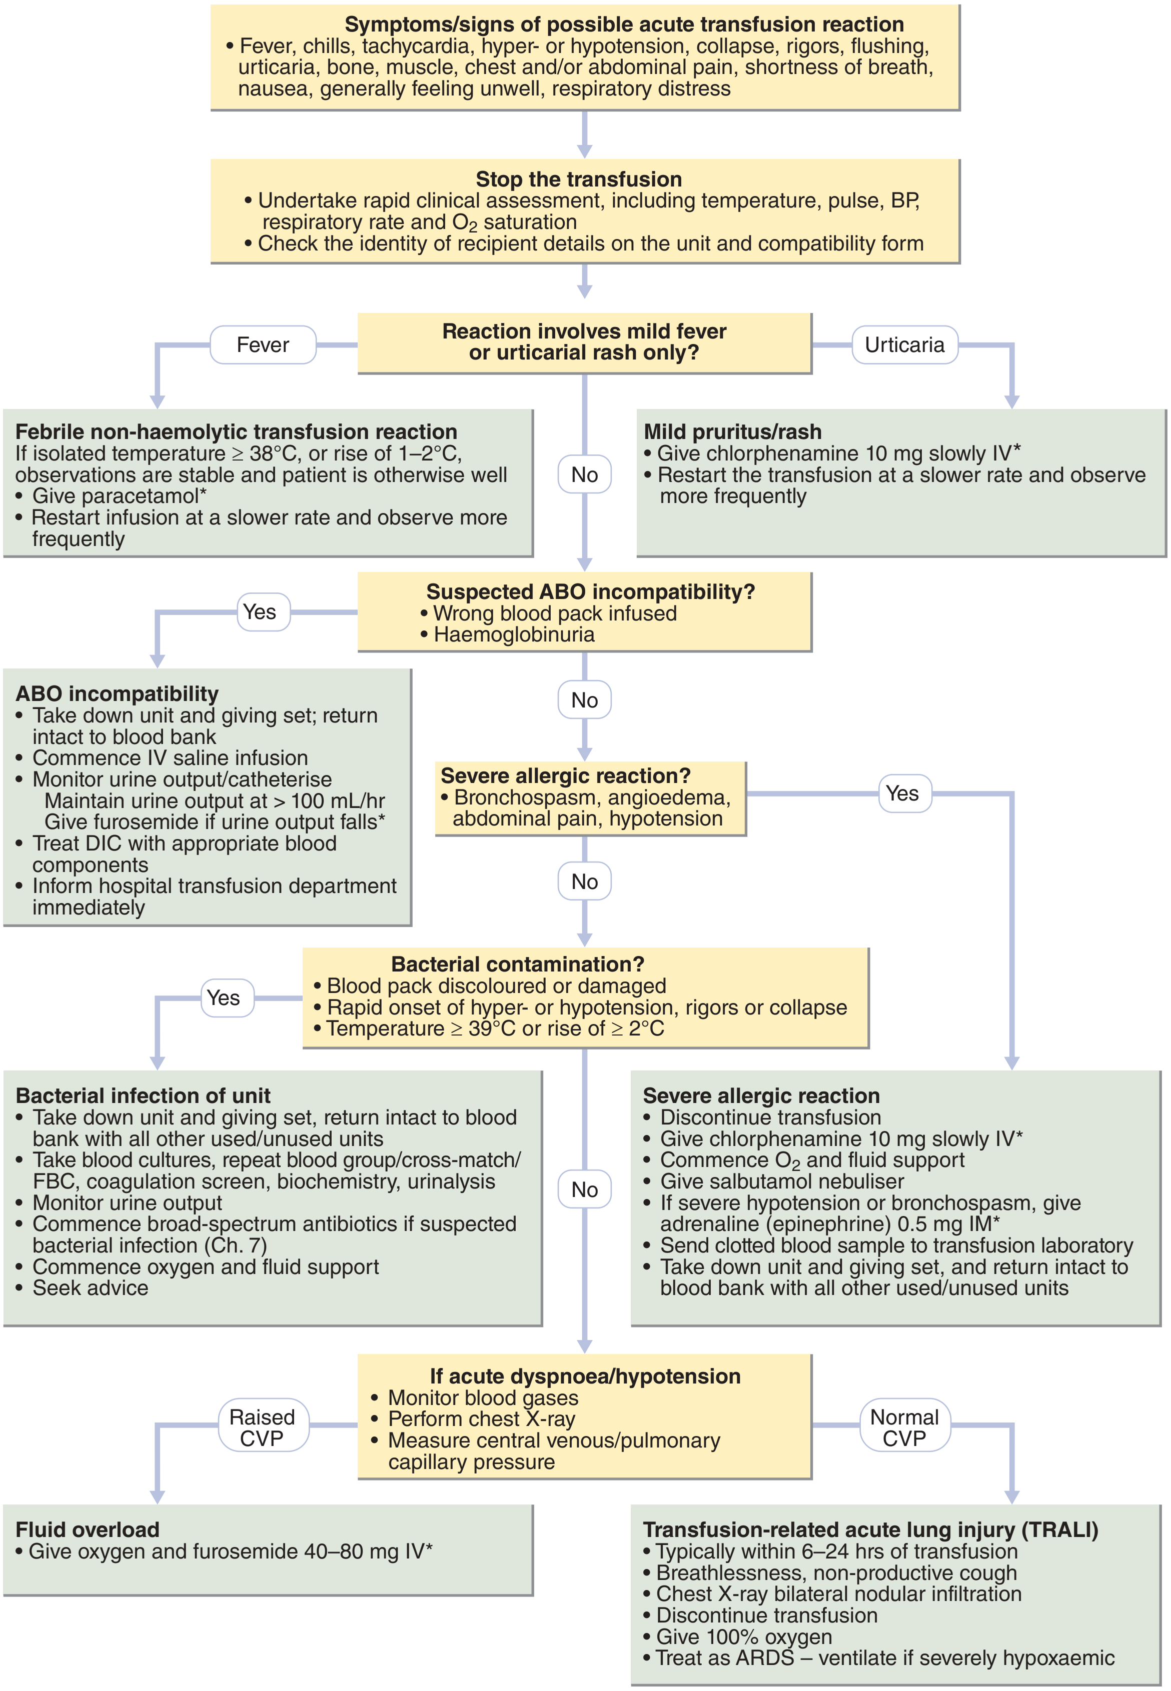
Record-keeping

- Record in the patient's notes the reason for transfusion, the component given, dose, any adverse effects and the clinical response

Observations

- Transfusions should only be given when the patient can be observed
- Blood pressure, pulse and temperature should be monitored before and 15 minutes after starting each pack
- In conscious patients, further observations are only needed if the patient has symptoms or signs of a reaction
- In unconscious patients, check pulse and temperature at intervals during transfusion
- Signs of abnormal bleeding during the transfusion could be due to disseminated intravascular coagulation resulting from an acute haemolytic reaction

Fig. 24.15 Bedside procedures for safe blood transfusion. The patient's safety depends on adherence to standard procedures for taking samples for compatibility testing, administering blood, record-keeping and observations.



Symptoms/signs of possible acute transfusion reaction
- Fever, chills, tachycardia, hyper- or hypotension, collapse, rigors, flushing, urticaria, bone, muscle, chest and/or abdominal pain, shortness of breath, nausea, generally feeling unwell, respiratory distress

Stop the transfusion
- Undertake rapid clinical assessment, including temperature, pulse, BP, respiratory rate and O_2 saturation
- Check the identity of recipient details on the unit and compatibility form

Reaction involves mild fever or urticarial rash only?

Febrile non-haemolytic transfusion reaction
If isolated temperature ≥ 38°C, or rise of 1–2°C, observations are stable and patient is otherwise well
- Give paracetamol*
- Restart infusion at a slower rate and observe more frequently

Mild pruritus/rash
- Give chlorphenamine 10 mg slowly IV*
- Restart the transfusion at a slower rate and observe more frequently

Suspected ABO incompatibility?
- Wrong blood pack infused
- Haemoglobinuria

ABO incompatibility
- Take down unit and giving set; return intact to blood bank
- Commence IV saline infusion
- Monitor urine output/catheterise
  Maintain urine output at > 100 mL/hr
  Give furosemide if urine output falls*
- Treat DIC with appropriate blood components
- Inform hospital transfusion department immediately

Severe allergic reaction?
- Bronchospasm, angioedema, abdominal pain, hypotension

Bacterial contamination?
- Blood pack discoloured or damaged
- Rapid onset of hyper- or hypotension, rigors or collapse
- Temperature ≥ 39°C or rise of ≥ 2°C

Bacterial infection of unit
- Take down unit and giving set, return intact to blood bank with all other used/unused units
- Take blood cultures, repeat blood group/cross-match/FBC, coagulation screen, biochemistry, urinalysis
- Monitor urine output
- Commence broad-spectrum antibiotics if suspected bacterial infection (Ch. 7)
- Commence oxygen and fluid support
- Seek advice

Severe allergic reaction
- Discontinue transfusion
- Give chlorphenamine 10 mg slowly IV*
- Commence O_2 and fluid support
- Give salbutamol nebuliser
- If severe hypotension or bronchospasm, give adrenaline (epinephrine) 0.5 mg IM*
- Send clotted blood sample to transfusion laboratory
- Take down unit and giving set, and return intact to blood bank with all other used/unused units

If acute dyspnoea/hypotension
- Monitor blood gases
- Perform chest X-ray
- Measure central venous/pulmonary capillary pressure

Fluid overload
- Give oxygen and furosemide 40–80 mg IV*

Transfusion-related acute lung injury (TRALI)
- Typically within 6–24 hrs of transfusion
- Breathlessness, non-productive cough
- Chest X-ray bilateral nodular infiltration
- Discontinue transfusion
- Give 100% oxygen
- Treat as ARDS – ventilate if severely hypoxaemic

Fig. 24.16 Investigation and management of acute transfusion reactions. *Use size-appropriate dose in children. (ARDS = acute respiratory distress syndrome; BP = blood pressure; CVP = central venous pressure; DIC = disseminated intravascular coagulation; FBC = full blood count; IV = intravenous)

24.20 Key points in transfusion medicine

- A restrictive strategy for red cell transfusion (Hb < 70 g/L) is at least as effective as a liberal strategy (< 100 g/L).
- The majority of reports in haemovigilance schemes, such as SHOT, relate to errors in the process of transfusion.
- Although transfusion-transmitted infection is a major concern for patients receiving transfusion, it is rare.
- In patients with trauma or burns or those who have had surgery, there is no evidence that resuscitation with albumin or other colloid solutions reduces the risk of death compared to resuscitation with crystalloid solutions.
- It is recommended that transfusion should be carried out overnight only in unavoidable circumstances.

(SHOT = Serious Hazards of Transfusion)

24.21 Examples of commonly used cytotoxic chemotherapy drugs in haematology*

Alkylating agents (cross-link double-stranded DNA by adding an alkyl group)

- Cyclophosphamide
- Melphalan
- Chlorambucil

Anthracyclines (intercalate between base pairs in the DNA molecule)

- Daunorubicin
- Doxorubicin
- Idarubicin

Antimetabolites (inhibit DNA and RNA synthesis)

- Cytosine arabinoside
- Fludarabine
- Methotrexate

Vinca alkaloids (cause disruption of tubulin)

- Vincristine
- Vinblastine

Topoisomerase II inhibitors (prevent DNA repair)

- Etoposide
- Daunorubicin
- Mitoxantrone

Monoclonal antibodies

Naked antibodies engaging antibody-dependent cytotoxic T cell or complement

Anti-CD20

- Rituximab
- Obinutuzumab

Anti-CD19

- Blinatumomab – bispecific T-cell engager (BiTE)

Antibody-delivered cytotoxicity (ADC or 'payload antibodies')

Anti-CD33 linked to calicheamicin

- Gemtuzumab ozogamicin

Anti-CD22 linked to calicheamicin

- Inotuzumab ozogamicin

Anti-CD30 linked to monomethyl auristatin E

- Brentuximab vedotin

Targeted small molecules

Inhibitors of tyrosine kinases (TKIs)

- Imatinib, dasatinib, nilotinib, ponatinib, bosutinib and asciminib in CML
- Midostaurin, gilteritinib and quizartinib in *FLT3*-positive AML

Inhibitors of B-cell signalling in lymphoid malignancies

- Inhibitors of Bruton tyrosine kinase in CLL: ibrutinib, acalabrutinib and zanubrutinib
- Inhibitors of PI3 kinase in CLL and follicular lymphoma, idelalisib

*For sites of action of these agents in the cell cycle, see Figure 8.2.
(AML = acute myeloid leukaemia; CD = cluster of differentiation; CLL = chronic lymphocytic leukaemia; CML = chronic myeloid leukaemia; FLT3 = FMS-like tyrosine kinase 3; PI3 = phosphatidylinositol-3)

Small molecule targeted therapies

Small molecules targeted at the mechanisms causing cancer are replacing cytotoxic chemotherapy in some disease situations. The most successful of these to date in haematological practice are tyrosine kinase inhibitors targeting BCR::ABL1 in chronic myeloid leukaemia, which have transformed the treatment of this disease over the last 25 years (see Fig. 24.31). This is a rapidly growing area of medicine and now includes inhibitors of B-cell signalling in chronic lymphocytic leukaemia and lymphomas (see Fig. 24.33) and drugs that target mutated gene products, such as FMS-like tyrosine kinase 3–internal tandem duplication (*FLT3-ITD*) and isocitrate dehydrogenases (*IDH1* & *2*) in acute myeloid leukaemia. More details of specific therapies are given later in the chapter.

Growth factor therapy

Growth factors are molecules that regulate blood cell production and were first identified in the 1980s. Recombinant pharmacological forms of some growth factors are in regular clinical use.

Erythropoietin regulates the early stages of erythrocyte maturation in the bone marrow. Erythropoietin-alpha is licensed for the treatment of anaemia in patients with low-risk myelodysplastic syndromes (MDS) (p. 993). Related alternative erythropoiesis stimulating agents (ESAs), such as darbepoetin and erythropoietin-beta are also used in MDS. Low baseline red cell transfusion requirement and serum EPO level (< 200 IU/L) predict for a better response to ESA therapy in MDS. Responders have improved haemoglobin levels, delayed red cell transfusion requirement, better quality of life and a probable survival advantage. ESAs are used in other anaemic states such as in myelofibrosis and post stem cell transplantation, though the evidence base for such use is less clear. ESA replacement therapy has been used for over 30 years in chronic renal failure (p. 633). Non-licensed use of EPO includes illicit performance-enhancement in athletics, which can lead to polycythaemia.

Granulocyte colony-stimulating factor (G–CSF) regulates neutrophil proliferation, maturation, margination and release. G–CSF has several uses in haematology.

- To reduce the length of the neutropenic period following intensive chemotherapy, such as that used to treat acute leukaemia during consolidation (not during remission induction), relapsed lymphoma and following stem cell transplantation (see also p. 163). On average, the neutropenic phase is reduced by 2–3 days allowing shorter courses of antibiotics for neutropenic sepsis and earlier discharge from hospital.
- To support the neutrophil count following outpatient-based chemotherapy, to reduce the risk of neutropenic sepsis and to enable cycles of chemotherapy to be delivered on time, which is important for efficacy. As an example, patients commonly receive primary G–CSF prophylaxis following each cycle of R-CHOP (cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin), prednisolone) for high-grade lymphoma, although some younger patients receive secondary prophylaxis for each subsequent cycle after a single episode of neutropenic sepsis.
- To mobilise haematopoietic stem cells from the bone marrow into the circulation so that they can be collected by leukapheresis for use in stem cell transplantation. G–CSF given alone, or shortly after chemotherapy, can increase stem cell circulation up to 1000-fold. An additional stem cell mobilising agent, plerixafor, is sometimes added to G–CSF to improve mobilisation efficiency.
- G–CSF is used to increase the neutrophil count in some patients with autoimmune neutropenia who suffer frequent infections, or in some congenital neutropenias with neutrophil elastase gene (*ELANE*) mutations (cyclical neutropenia). However, long-term use of G–CSF in severe congenital neutropenia (SCN/Kostmann syndrome) is contraindicated because of the risk of leukaemia. Such patients frequently have an acquired somatic mutation in the G–CSF receptor (*CSF3R*) and are susceptible to developing MDS and acute myeloid leukaemia (AML).

Immunotherapy

This includes cellular immunotherapy (see below) and non-cellular immunotherapy such as antibody and antibody conjugate–mediated cytotoxicity as outlined above, bispecific antibodies and checkpoint inhibitor therapy as described in Chapter 8. Checkpoint inhibitor therapy has, to date, proved less useful in haematological malignancies than in solid tumours. This might be because haematological malignancies tend to have fewer acquired mutations to stimulate T-cell attack than solid tumours, or that the host immune system is damaged by the haematological malignancy or prior intensive chemotherapy.

Haematopoietic stem cell transplantation

Transplantation of haematopoietic stem cells (HSCT) has offered the only hope of 'cure' in a variety of haematological and non-haematological disorders (Box 24.22). As standard treatment improves, the indications for HSCT are being refined and extended, although its use remains most common in haematological malignancies. The type of HSCT is defined according to the donor and source of stem cells:

- In *allogeneic* HSCT, the stem cells come from a *donor* – either a related donor (usually an HLA-identical sibling) or a closely HLA-matched volunteer unrelated donor (VUD).
- In an *autologous* transplant, the stem cells are harvested from the *patient* and stored in the vapour phase of liquid nitrogen until required. Stem cells can be harvested from bone marrow or, most commonly nowadays, from the blood.

Allogeneic HSCT

Healthy bone marrow or blood stem cells from a donor are infused intravenously into the recipient, who has been suitably 'conditioned'. The conditioning treatment (chemotherapy with or without radiotherapy) is 'myeloablative' or, increasingly, 'non-myeloablative'. Myeloablative conditioning destroys malignant cells and immunosuppresses the recipient, as well as ablating the recipient's haematopoietic tissues. Reduced intensity conditioning (non-myeloablative) relies on intense immunosuppression to provide 'immunological space' for transplanted stem cells. The infused donor cells 'home' to the marrow, engraft and produce enough erythrocytes, granulocytes and platelets for the patient's needs after about 2–4 weeks. During this period of aplasia, patients are at risk of infection and bleeding and require intensive supportive care as described on page 988. It may take several years to regain normal immunological function and patients remain at risk from opportunistic infections, particularly in the first year.

An advantage of receiving allogeneic donor stem cells is that the donor's immune system can recognise residual recipient malignant cells and destroy them. This immunological 'graft-versus-leukaemia/disease' (GVL) effect is a powerful tool against many haematological tumours and can be boosted post-transplantation by the infusion of T cells taken from the donor: so-called donor lymphocyte infusion (DLI).

Considerable morbidity and mortality are associated with HSCT. The best results are obtained in younger patients (<40 years) with minimal residual disease, who have an HLA-identical sibling donor. However, reduced-intensity conditioning (RIC) has enabled treatment of older or less fit patients, in whom many haematological malignancies occur. In this form of transplantation, rather than using very intensive myeloablative conditioning, which causes morbidity from organ damage, relatively low doses of chemotherapy drugs, such as fludarabine and cyclophosphamide or busulfan, are used in combination with antibodies such as alemtuzumab (which targets CD52 on mature lymphoid cells) or anti-thymocyte globulin (ATG) to immunosuppress the recipient and allow donor stem cells to engraft. The emerging donor immune system then eliminates malignant cells via the 'graft-versus-disease' effect, which may be boosted by the elective use of donor T-cell infusions post-transplant. Such transplants have produced long-term remissions in some patients with acute leukaemia and myelodysplastic syndromes aged 40–70 years, who would not previously have been considered for a myeloablative allograft.

24.22 Indications for allogeneic haematopoietic stem cell transplantation

- Neoplastic disorders affecting stem cell compartments (e.g. leukaemias, MDSs)
- Failure of haematopoiesis (e.g. aplastic anaemia)
- Major inherited defects in blood cell production/function (e.g. thalassaemia, immunodeficiency diseases, sickle cell disorder)
- Inherited metabolic disorders with missing enzymes or cell lines

(MDSs = myelodysplastic syndromes)

Complications

These are outlined in Boxes 24.23 and 24.24. The risks and outcomes of transplantation depend upon several patient- and disease-related factors. In general, 25% die from procedure-related complications, such as infection and GVHD, and there remains a significant risk of the haematological malignancy relapsing. The long-term survival for patients undergoing allogeneic HSCT in acute leukaemia is around 50%.

Graft-versus-host disease

GVHD is caused by the cytotoxic activity of donor T lymphocytes that become sensitised to their new host, regarding it as foreign. This may cause either an acute or a chronic form of GVHD.

24.23 Complications of allogeneic haematopoietic stem cell transplantation

Early

- Anaemia
- Infections
- Bleeding
- Acute GVHD
- Mucositis – pain, nausea, diarrhoea
- Liver veno-occlusive disease

Late

- Chronic GVHD
- Infertility
- Cataracts
- Second malignancy

(GVHD = graft-versus-host disease)

24.24 Infections during recovery from haematopoietic stem cell transplantation (HSCT)

Infection (see Ch. 14)	Time after HSCT	Management
Herpes simplex	0–4 weeks (aplastic phase)	Aciclovir prophylaxis and therapy
Bacterial, fungal	0–4 weeks (aplastic phase)	As for acute leukaemia – antibiotic and antifungal prophylaxis and therapy
Cytomegalovirus	5–21 weeks (cell-mediated immune deficiency)	Anti-CMV prophylaxis e.g. letermovir, valganciclovir. Antigen screening in blood (PCR) and pre-emptive therapy (e.g. ganciclovir, valganciclovir)
Varicella zoster	After 13 weeks	Aciclovir prophylaxis and therapy
Pneumocystis jirovecii	8–26 weeks	Co-trimoxazole
Encapsulated bacteria	8 weeks to years (immunoglobulin deficiency, prolonged with GVHD)	Prophylaxis and revaccination

(GVHD = graft-versus-host disease; PCR = polymerase chain reaction)

Acute GVHD occurs in the first 100 days after transplant in about one-third of patients. It can affect the skin, causing rashes, the liver, causing jaundice, and the gut, causing diarrhoea, and may vary from mild to lethal. Prevention includes HLA-matching of the donor, immunosuppressant drugs, including methotrexate, ciclosporin, alemtuzumab, ATG or increasingly post-transplant cyclophosphamide (PTC). PTC has in particular improved the outcomes of haploidentical transplants (half HLA matched, e.g. a sibling or parent). Severe presentations are very difficult to control and, despite high-dose glucocorticoids, may result in death.

Chronic GVHD may follow acute GVHD or arise independently; it occurs later than acute GVHD. It often resembles a connective tissue disorder, although in mild cases a rash may be the only manifestation. Chronic GVHD is usually treated with glucocorticoids and prolonged immunosuppression with, for example, ciclosporin. Newer drugs are available to treat acute and chronic GVHD where steroids have failed, including ruxolitinib (JAK-2 inhibitor), ibrutinib (BTK-inhibitor), axatilimab (CSF-1 receptor blocker) and belumosudil, an inhibitor of Rho-associated coiled-coil kinase 2 (ROCK2). All modulate the immune response in one way or another.

Chronic GVHD results in an increased infection risk. However, associated with chronic GVHD is the GVL effect and a lower relapse rate of the underlying malignancy. Suppressing GVHD whilst maintaining GVL remains one of the major goals of allogeneic HSCT research.

Autologous HSCT

This procedure is also used in certain haematological malignancies. The patient's stem cells from blood or marrow are first harvested and frozen when their disease is in remission. After conditioning myeloablative therapy, the autologous stem cells are reinfused into the blood stream in order to rescue the patient from the marrow damage and aplasia caused by chemotherapy. This is an effective way of safely delivering high-dose chemotherapy to chemosensitive cancers. Autologous HSCT may be used as consolidation chemotherapy for disorders that do not primarily involve the haematopoietic tissues, or for patients in whom very good remissions have been achieved. The most common indications nowadays are lymphomas and myeloma. The preferred source of stem cells for autologous transplants is peripheral blood (PBSCT). These stem cells engraft more quickly, with marrow recovery occurring within 2–3 weeks. There is no risk of GVHD and no immunosuppression is required. Therefore, autologous HSCT carries a lower procedure-related mortality rate than allogeneic HSCT at around 1%–5%, but there is a higher rate of recurrence of malignancy because the anti-malignancy effect is solely dependent on the conditioning chemotherapy with no 'graft-versus-disease' effect. There is ongoing interest in using autologous HSCT to treat severe autoimmune diseases. The theory is that the patient's immune system is 'reset' to not attack host tissues. Early success in multiple sclerosis has led to ongoing randomised controlled trials in this area.

Alternative cellular therapies

Whilst HSCT remains a major cellular therapy for a range of malignant and some non-malignant haematological conditions, newer cell-based treatments have recently been introduced into practice and are collectively described as immune effector cell therapy (IECT). These include donor T cells primed to respond to specific viruses, particularly Epstein–Barr virus (EBV). Immunocompromised patients, such as those post–solid organ or haematopoietic transplantation, can suffer from reactivation of latent CMV or EBV infection and develop life-threatening complications, e.g. pneumonitis (CMV) and post-transplant lymphoproliferative disease (PTLD; EBV). Primed donor T cells can treat these conditions, especially when alternative approaches such as reduction in immunosuppression or antiviral drugs have failed. CMV IECT is largely superseded by effective antiviral drugs, but EBV IECT remains an option for patients with PTLD not responding to alternative therapies such as rituximab or chemotherapy.

Chimeric antigen receptor T-cell therapy

Another exciting cellular treatment, chimeric antigen receptor T-cell (CAR-T) therapy, has been developed for patients with some B-cell malignancies where alternative treatments have failed. This technology is based on genetic engineering where a patient's own T cells are harvested and a new chimeric receptor gene is introduced into the cell (see Fig 4.15). This produces a cell surface receptor that uses the antigen-binding domain of an antibody molecule to recognise a target on the malignant B cell (CD19) or plasma cell (B-cell maturation antigen, BCMA) coupled to a T-cell receptor-activating domain (Fig. 24.17). This

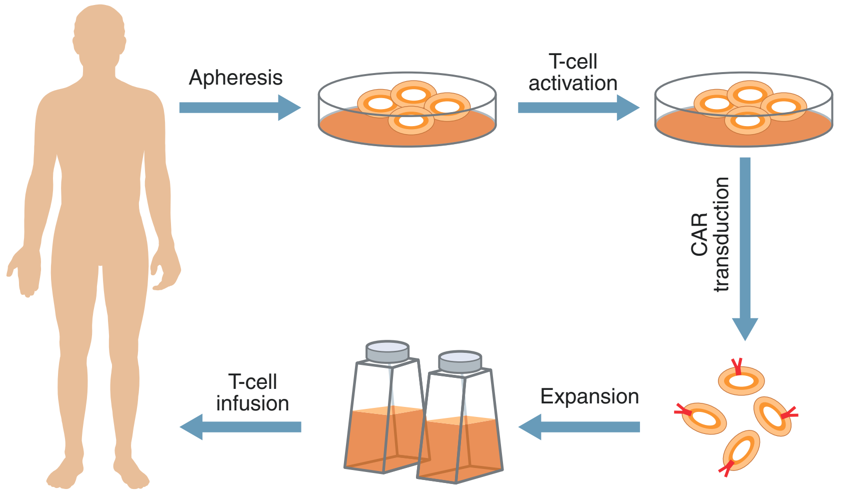


Fig. 24.17 The manufacturing process for CAR-T cells. The chimeric antigen receptor (CAR) is genetically engineered by combining the extracellular antigen receptor binding domain from a monoclonal antibody with the intracellular activation domain from a T-cell receptor (see Fig. 4.15). The new CAR uses the monoclonal antibody binding domain, e.g. anti-CD19, to bind to the target on the cancer cell surface, and this can now activate the T-cell effector killing. The CAR-T cells are manufactured by transducing the new gene for CAR into the patient's T cells. T cells are harvested from the patient by apheresis and then genetically altered in a laboratory process that takes about 4 weeks. The manufactured CAR-T cells are expanded in numbers during this time in tissue culture before being reinfused into the patient. *Modified from Fesnak A, O'Doherty U. Clinical development and manufacture of chimeric antigen receptor T cells and the role of leukapheresis. Eur Oncol Haematol 2017;13(1):28–34 and Majzner RG, Mackall CL. Clinical lessons learned from the first leg of the CAR T cell journey. Nat Med 2019;25:1341–1355 with permission.*

chimeric B/T receptor can effectively bind to the malignant B cell and activate the T cell to kill it. There are three licensed CAR-T products available in the UK and the current licensed indications are shown in Box 24.25. This novel therapy has cured some patients who were in a desperate situation, with data in diffuse large B-cell lymphoma (the commonest indication) showing approximately 40% long-term survival. Acute complications of CAR-T therapy relate to the inflammatory response induced by CAR-T cells binding to the target malignant B cells and include cytokine release syndrome (CRS) and immune cell–associated neurological syndrome (ICANS). Chronic complications include cytopenias and B-cell aplasia leading to hypogammaglobulinaemia and infections, and relapse of the underlying malignancy.

Bispecific antibody therapy

Whilst not a direct cellular therapy, bispecific antibody T-cell engagers (BiTE) encourage endogenous, autologous T cells to kill malignant cells. Bispecific antibodies consist of two antigen-binding sites, one to antigen on the target cancer cell and one to CD3 on the T-cell surface. Binding to these antigens brings the T cell into immediate proximity with the target cancer cell (engagement) and promotes cell killing (Fig. 24.18). Currently available bispecific antibodies target CD19 in patients with relapsed ALL (blinatumomab) and relapsed DLBCL (epcoritamab and glofitamab) and BCMA in relapsed myeloma (teclistamab and elranatamab).

i 24.25 Current licensed indications for CAR-T products in the UK

CAR-T cell product	Clinical indication
Tisagenlecleucel (Kymriah)	Used to treat relapsed B-cell acute lymphoblastic leukaemia (B-cell ALL) in children and young people up to 25 years old Used to treat some adults with diffuse large B-cell lymphoma (DLBCL), primary mediastinal B cell lymphoma, and transformed follicular lymphoma
Axicabtagene ciloleucel (Yescarta)	Used to treat some adults with diffuse large B-cell lymphoma (DLBCL), primary mediastinal B-cell lymphoma and transformed follicular lymphoma
Brexucabtagene autoleucel (Tecartus)	Used to treat people 26 years of age and over with relapsed B-cell ALL Used to treat some people with relapsed mantle cell lymphoma

There are no head-to-head comparisons of CAR-T cell therapy with BiTE therapy to advise on sequencing of these treatments in relapsed disease. However, some patients have benefitted from the alternative therapy when one has failed.

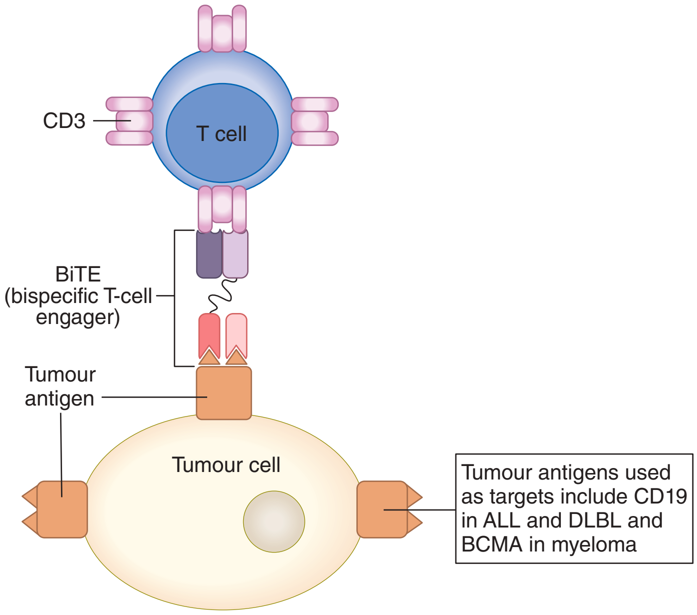
Gene therapy

Gene therapies are complex, lengthy and expensive to develop and introduce into clinical practice (p. 55). The first gene editing therapy for sickle-cell disorder and beta-thalassaemia has recently been approved and may offer a cure. Exagamglogene autotemcel is a non-viral therapy that uses CRISPR/Cas 9 gene editing technology (Ch. 3) to edit the *BCL11A* gene in the patient's collected haematopoietic stem cells. *BCL11A* is a transcription factor that inhibits fetal haemoglobin production in erythroid cells following birth. After editing at the erythroid enhancer region, the gene is switched off. The edited cells are then reinfused into the patient after conditioning chemotherapy, and following stem cell engraftment and differentiation, increased HbF production occurs. This has been shown to be effective in eliminating vasoactive crises in sickle cell disorder and transfusion requirements in beta-thalassaemia.

Gene therapy approaches in haemophilia have focused on a clotting factor transgene being delivered directly to the patient via intravenous infusion using a liver-directed viral vector. Recombinant adeno-associated viral vectors have most commonly been used. Valoctocogene (factor VIII) and etranacogene (factor IX) have shown efficacy in haemophilia A and B, respectively.

Anticoagulant and antithrombotic therapy

There are numerous indications for anticoagulant and antithrombotic medications (Box 24.26). The guiding principles are outlined here, but management in specific indications is discussed elsewhere in the book. Broadly speaking, antiplatelet medications are of greater efficacy in the prevention of arterial thrombosis and of less value in the prevention of venous thromboembolism (VTE). Thus, antiplatelet agents, such as aspirin, clopidogrel and, increasingly, ticagrelor, are the drugs of choice in acute coronary events (Ch. 16) and in ischaemic cerebrovascular disease, while warfarin and other anticoagulants are favoured in VTE (p. 1010) and management of atrial fibrillation (Ch. 16). In some extremely prothrombotic situations, such as coronary artery stenting, a combination of anticoagulant and antiplatelet drugs is used.



CD3
T cell
BiTE (bispecific T-cell engager)
Tumour antigen
Tumour cell
Tumour antigens used as targets include CD19 in ALL and DLBL and BCMA in myeloma

Fig. 24.18 A bispecific antibody (BiTE) engaging a cytotoxic T cell to kill a tumour cell. (ALL = acute lymphoblastic leukaemia; BCMA = B-cell maturation antigen; CD = cluster of differentiation; DLBCL = diffuse large B-cell lymphoma)

24.26 Indications for anticoagulation

Heparin/LMWH/fondaparinux

- Prevention and treatment of VTE
- Percutaneous coronary intervention
- Post-thrombolysis for MI
- Unstable angina pectoris
- Non-Q wave MI
- Acute peripheral arterial occlusion
- Cardiopulmonary bypass
- Haemodialysis and haemofiltration

Coumarins (warfarin etc.)

• Prevention and treatment of VTE • Arterial embolism • Atrial fibrillation with specific risk factors for stroke (p. 451) • Mobile mural thrombus post-MI • Extensive anterior MI • Dilated cardiomyopathy • Cardioversion • Ischaemic stroke in antiphospholipid syndrome • Mitral stenosis and mitral regurgitation with atrial fibrillation	Therapeutic INR 2.5
• Recurrent venous thrombosis while on warfarin • Mechanical prosthetic cardiac valves	INR 3.5

Rivaroxaban

- Prevention and treatment of VTE
- Atrial fibrillation with risk factors for stroke
- Post-acute coronary syndrome
- Symptomatic coronary artery disease and peripheral vascular disease

Dabigatran etexilate

- Prevention and treatment of VTE
- Atrial fibrillation with risk factors for stroke

Apixaban

- Prevention and treatment of VTE
- Atrial fibrillation with risk factors for stroke

Edoxaban

- Treatment of VTE
- Atrial fibrillation with risk factors for stroke

(INR = International Normalised Ratio; LMWH = low-molecular-weight heparin; MI = myocardial infarction; VTE = venous thromboembolism)

A wide range of anticoagulant and antithrombotic drugs is used in clinical practice. These drugs and their modes of action are given in Box 24.27 and Figure 24.19. Newer agents allow predictable anticoagulation without the need for frequent monitoring and dose titration. Although warfarin remains an option for oral anticoagulation, newer oral anticoagulants (dabigatran, rivaroxaban, edoxaban and apixaban), which can be given at fixed doses with predictable effects and no need for monitoring, have now been approved for the prevention of perioperative VTE, the treatment of established VTE, prevention of recurrent VTE and stroke prevention in patients with non-valvular atrial fibrillation.

24.27 Modes of action of anticoagulant and antithrombotic drugs

Mode of action	Drug
Antiplatelet drugs	
Cyclo-oxygenase (COX) inhibition	Aspirin
Adenosine diphosphate (ADP) receptor inhibition	Clopidogrel Prasugrel Ticagrelor
Glycoprotein IIb/IIIa inhibition	Abciximab Tirofiban Eptifibatide
Phosphodiesterase inhibition	Dipyridamole
Oral anticoagulants	
Vitamin K antagonism	Warfarin/coumarins
Direct thrombin inhibition	Dabigatran
Direct Xa inhibition	Rivaroxaban Apixaban Edoxaban
Injectable anticoagulants	
Antithrombin-dependent inhibition of thrombin and Xa	Heparin LMWH
Antithrombin-dependent inhibition of Xa	Fondaparinux Danaparoid
Direct thrombin inhibition	Argatroban Bivalirudin

(LMWH = low-molecular-weight heparin)

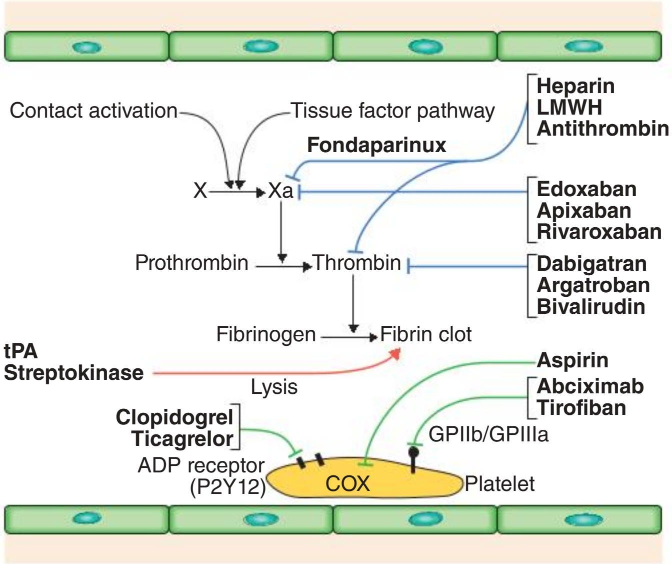


Fig. 24.19 Sites of action of antithrombotic and fibrinolytic medicines. Heparin and low-molecular-weight heparin (LMWH) enhance the avidity of antithrombin for factor Xa and thrombin (factor IIa). Fondaparinux also binds antithrombin but only inhibits factor Xa. The direct oral anticoagulants (DOACs) rivaroxaban, apixaban, edoxaban and dabigatran directly inhibit specific proteases in the common pathway. Glycoprotein (GP) IIb/IIIa is a receptor for fibrinogen and von Willebrand factor and aids platelet activation and aggregation. P2Y12 is the receptor for adenosine diphosphate (ADP) and its activation also triggers platelet aggregation. Aspirin is an inhibitor of cyclo-oxygenase (COX) in platelets. (tPA = tissue plasminogen activator)

Heparins

Unfractionated heparin (UFH) and low-molecular-weight heparins (LMWHs) act as anticoagulants by binding a specific pentasaccharide sequence to antithrombin. This enhances the avidity of antithrombin for its substrates, which are the activated proteases of the coagulation pathway such as Xa and thrombin (see Figs. 24.6E and 24.19). Fondaparinux is a synthetic pentasaccharide, which also binds antithrombin and has similar properties to LMWH. LMWHs preferentially augment antithrombin activity against factor Xa. For the licensed indications, LMWHs are at least as efficacious as UFH, but have several advantages:

- LMWHs are nearly 100% bioavailable and so produce reliable dose-dependent anticoagulation.

24.28 Treatments for emergencies in haematological practice

- Reversal of life- and limb-threatening haemorrhage in anticoagulated patients:
  Warfarin: prothrombin complex concentrate and IV vitamin K_1
  Unfractionated heparin: protamine sulphate
  Dabigatran: idarucizumab
  Rivaroxaban and apixaban: andexanet alfa
- Recognition of thrombotic thrombocytopenic purpura and treatment with plasma exchange
- Recognition of coagulopathy associated with acute promyelocytic leukaemia and treatment with all-trans-retinoic acid and fibrinogen replacement
- Recognition of chest syndrome and stroke in patients with sickle-cell disorder and red cell transfusion or exchange transfusion
- Recognition of neutropenic sepsis in patients receiving chemotherapy and early treatment with empirical broad-spectrum antibiotics

(IV = intravenous)

- LMWHs do not require monitoring of their anticoagulant effect (except possibly in patients at extremes of body weight or those with a glomerular filtration rate below 30 mL/min).
- LMWHs have a half-life of around 4 hours when given subcutaneously, compared with 1 hour for UFH. This permits once-daily dosing by the subcutaneous route, rather than the therapeutic continuous intravenous infusion or twice-daily subcutaneous administration required for UFH.
- While rates of bleeding are similar between products, the risk of osteoporosis and heparin-induced thrombocytopenia is much lower for LMWH.

UFH is, however, more completely reversed by protamine sulphate in the event of bleeding and at the end of cardiopulmonary bypass, for which UFH remains the drug of choice (Box 24.28).

LMWHs are widely used for the prevention and treatment of VTE, the management of acute coronary syndromes and for most other scenarios listed in Box 24.26. In some situations, UFH is still favoured by some clinicians, though there is little evidence that it is advantageous, except when rapid reversibility is required. UFH is useful in patients with a high risk of bleeding, e.g. those who have peptic ulceration or who may require urgent surgery. It is also favoured in the treatment of life-threatening thromboembolism, e.g. major pulmonary embolism with significant hypoxaemia, hypotension and right-sided heart strain. In this situation, UFH is started with a loading intravenous bolus followed by a continuous infusion. The level of anticoagulation should be assessed by the APTT at regular intervals. It is usual to aim for a patient APTT that is 1.5–2.5 times the control time of the test. Monitoring of UFH treatment by APTT is not without difficulties and other assays, such as the specific anti-Xa assay calibrated for measurement of UFH, provides more accurate guidance.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a rare complication of heparin therapy, caused by induction of anti-heparin/PF4 antibodies that bind to and activate platelets via an Fc receptor. This results in platelet activation and a prothrombotic state, with paradoxical thrombocytopenia. HIT is more common in surgical than medical patients (especially cardiac and orthopaedic patients), with use of UFH rather than LMWH, and with higher doses of heparin. Some adenovirus vector-based SARS-CoV-2 RNA vaccines have been associated with a similar condition characterised by venous thrombosis (often cerebral) and paradoxical thrombocytopenia.

Clinical features

Patients present, typically 5–14 days after starting heparin treatment, with a fall in platelet count of more than 30% from baseline. The count may still be in the reference range. The patient may be asymptomatic, or develop venous or arterial thrombosis and skin lesions, including overt skin necrosis. Affected patients may complain of pain or itch at injection sites and of systemic symptoms, such as shivering, following heparin injections. Patients who have received heparin in the preceding 100 days and who have pre-formed antibodies may develop acute systemic symptoms and an abrupt fall in platelet count in the first 24 hours after re-exposure.

Investigations

The pre-test probability of the diagnosis is assessed using the 4Ts scoring system. This assigns a score based on:

- the *T*hrombocytopenia
- the *T*iming of the fall in platelet count
- the presence of new *T*hrombosis
- the likelihood of ano*T*her cause for thrombocytopenia.

Individuals at low risk need no further testing. Those with intermediate and high likelihood scores should have the diagnosis confirmed or refuted using a validated laboratory test. Examples include rapid screening tests (lateral flow/particle gel/latex immunoassays) and anti-PF4 enzyme-linked immunosorbent assay (ELISA).

Management

Heparin should be discontinued as soon as HIT is diagnosed and an alternative anticoagulant that does not cross-react with the antibody should be substituted. Argatroban (a direct thrombin inhibitor) and danaparoid (a heparin analogue) are licensed for use in the UK. Fondaparinux is not licensed for this indication but can also be used. In asymptomatic patients with HIT who do not receive an alternative anticoagulant, around 50% will sustain a thrombosis in the subsequent 30 days. Patients with established thrombosis have a poorer prognosis.

Coumarins

Although several coumarin anticoagulants are used around the world, warfarin is the most common.

Coumarins inhibit the vitamin K–dependent post-translational carboxylation of factors II (prothrombin), VII, IX and X in the liver (see Fig. 24.6D). This results in anticoagulation due to an effective deficiency of these factors. This is monitored by the INR, a standardised test based on measurement of the prothrombin time (see Box 24.3). Recommended target INR values for specific indications are given in Box 24.26.

Warfarin anticoagulation typically takes more than 3–5 days to become established, even using loading doses. Patients who require rapid initiation of therapy may receive higher initiation doses of warfarin. A typical regimen in this situation is to give 10 mg warfarin on the first and second days, with 5 mg on the third day; subsequent doses are titrated against the INR. Patients without an urgent need for anticoagulation (e.g. atrial fibrillation) can have warfarin introduced slowly using lower doses. Low-dose regimens are associated with a lower risk of the patient developing a supratherapeutic INR, and hence a lower bleeding risk. The duration of warfarin therapy depends on the clinical indication, and while treatment of deep vein thrombosis (DVT) or preparation for cardioversion may require a finite duration, anticoagulation to prevent cardioembolic stroke in atrial fibrillation or from heart valve disease is long-term.

The major problems with warfarin are:

- a narrow therapeutic window
- metabolism that is affected by many factors
- numerous drug interactions.

Drug interactions are common through protein binding and metabolism by the cytochrome P450 system. Inter-individual differences in warfarin doses required to achieve a therapeutic INR are mostly accounted for by naturally occurring polymorphisms in the *CYP2C9* and the *VKORC1* genes (which predict the metabolism and function of warfarin, respectively) and dietary intake of vitamin K.

24.29 How to assess risks of anticoagulation

Contraindications

- Recent surgery, especially to eye or central nervous system
- Pre-existing haemorrhagic state, e.g. advanced liver disease, haemophilia, thrombocytopenia
- Pre-existing structural lesions, e.g. peptic ulcer
- Recent cerebral or gastrointestinal haemorrhage
- Uncontrolled hypertension
- Cognitive impairment
- Frequent falls

Bleeding risk score

- Several bleeding risk scores exist for different indications for anticoagulation
- The validation of most bleeding risk scores has been poor
- Many risk factors for thrombosis are also risk factors for bleeding
- HAS BLED is the best validated score for patients with atrial fibrillation. Following anticoagulant-related bleeding, reassessment of bleeding and thrombosis risk is indicated
- In many cases, patients benefit from recommencing anticoagulants after bleeding

Major bleeding is the most common serious side-effect of warfarin and occurs in 1%–2% of patients each year. Fatal haemorrhage, which is most commonly intracranial, occurs in about 0.25% per annum. There are scoring systems that predict the annual bleeding risk and these can be used to help compare the risks and benefits of warfarin for an individual patient (Box 24.29). There are also some specific contraindications to anticoagulation (see Box 24.29). Management of warfarin includes strategies for over-anticoagulation and for bleeding:

- If the INR is above the therapeutic level, warfarin should be withheld or the dose reduced. If the patient is not bleeding, it may be appropriate to give a small dose of vitamin K either orally or intravenously (1–2.5 mg), especially if the INR is greater than 8.
- In the event of bleeding, withhold further warfarin. Minor bleeding can be treated with 1–2.5 mg of vitamin K intravenously (IV). Major haemorrhage should be treated as an emergency with vitamin K 5–10 mg slowly IV, combined with coagulation factor replacement (see Box 24.28). This should optimally be a prothrombin complex concentrate (30–50 U/kg) that contains factors II, VII, IX and X; if that is not available, fresh frozen plasma (15–30 mL/kg) should be given.

Direct oral anticoagulants

Direct oral anticoagulants (DOACs) are specific inhibitors of key proteases in the common pathway and offer an alternative to coumarins in the management of VTE and the prevention of stroke and systemic embolism in patients with atrial fibrillation. Dabigatran inhibits thrombin while rivaroxaban, apixaban and edoxaban inhibit Xa (see Fig. 24.19). The key features of these drugs include the fact that they are efficacious in fixed oral doses, have a short half-life of around 10 hours, achieve peak plasma levels 2–4 hours after oral intake, have very few drug interactions and are all moderately dependent on renal function for their excretion. An initial perceived drawback was the lack of specific reversal agents for these drugs, but the monoclonal antibody idarucizumab is now available for the reversal of dabigatran and andexanet alfa, a site-inactivated Xa molecule, has recently been licensed for the reversal of apixaban and rivaroxaban (see Box 24.28).

DOACs are now licensed for the prevention of VTE following high-risk orthopaedic surgery (except edoxaban), the acute management and prevention of recurrence of VTE and the prevention of stroke and systemic embolism in patients with non-valvular atrial fibrillation with risk factors. Dosing is standard across a range of conditions but is affected by extremes (low and high) of body weight and impaired renal function. The general perception is that in these indications they are at least as efficacious as dose-adjusted coumarin and probably associated with less clinically significant bleeding.

Anaemias

Around 30% of the total world population is anaemic and half of these, some 600 million people, have iron deficiency. The classification of anaemia by the size of the red cells (MCV) indicates the likely cause (see Figs. 24.10 and 24.11).

Red cells in the bone marrow must acquire a minimum level of haemoglobin before being released into the blood stream (Fig. 24.20). While in the marrow compartment, red cell precursors undergo cell division driven by erythropoietin. If red cells cannot acquire haemoglobin at a normal rate, they will undergo more divisions than normal and will have a low MCV when released into the blood. The MCV is low because component parts of the haemoglobin molecule are not fully available: that is, iron in iron deficiency, globin chains in thalassaemia, haem ring in congenital sideroblastic anaemia and, occasionally, poor iron utilisation in the anaemia of chronic disease/anaemia of inflammation.

In megaloblastic anaemia, the biochemical consequence of vitamin B_{12} or folate deficiency is an inability to synthesise new bases to make DNA. A similar defect of cell division is seen in the presence of cytotoxic drugs or haematological disease in the marrow, such as myelodysplasia. In these states, cells haemoglobinise normally, but undergo fewer cell divisions, resulting in circulating red cells with a raised MCV. The red cell membrane is composed of a lipid bilayer that will freely exchange with the plasma pool of lipid. Conditions such as liver disease, hypothyroidism, hyperlipidaemia and pregnancy are associated with raised lipids and may also cause a raised MCV. Reticulocytes are larger than mature red cells, so when the reticulocyte count is raised – e.g. in haemolysis – this may also increase the MCV.

Some considerations specific to anaemia in old age are listed in Box 24.30.

Iron deficiency anaemia

This occurs when iron losses or physiological requirements exceed absorption.

Blood loss

The most common explanation in men and post-menopausal women is gastrointestinal blood loss (Ch. 22). This may result from occult gastric or colorectal malignancy, gastritis, peptic ulceration, inflammatory bowel disease, diverticulitis, polyps and angiodysplastic lesions. Worldwide, hookworm and schistosomiasis are the most common causes of gut blood loss (Ch. 14). Gastrointestinal blood loss may be exacerbated by the chronic use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which cause intestinal erosions and impair platelet function. In women of child-bearing age, menstrual blood loss, pregnancy and breastfeeding contribute to iron deficiency by depleting iron stores; in developed countries, one-third of pre-menopausal women have low iron stores, but only 3% display iron-deficient haematopoiesis. Very rarely, chronic haemoptysis or haematuria may cause iron deficiency.

Malabsorption

A dietary assessment should be made in all patients to ascertain their iron intake (Ch. 5). Gastric acid is required to release iron from food and helps to keep iron in the soluble ferrous state (Fig. 24.21). Achlorhydria in older people or that due to drugs such as proton pump inhibitors may contribute to the lack of iron availability from the diet, as may previous gastric surgery. Iron is absorbed actively in the upper small intestine and hence can be affected by coeliac disease (p. 837).

Physiological demands

At times of rapid growth, such as infancy and puberty, iron requirements increase and may outstrip absorption. In pregnancy, iron is diverted to

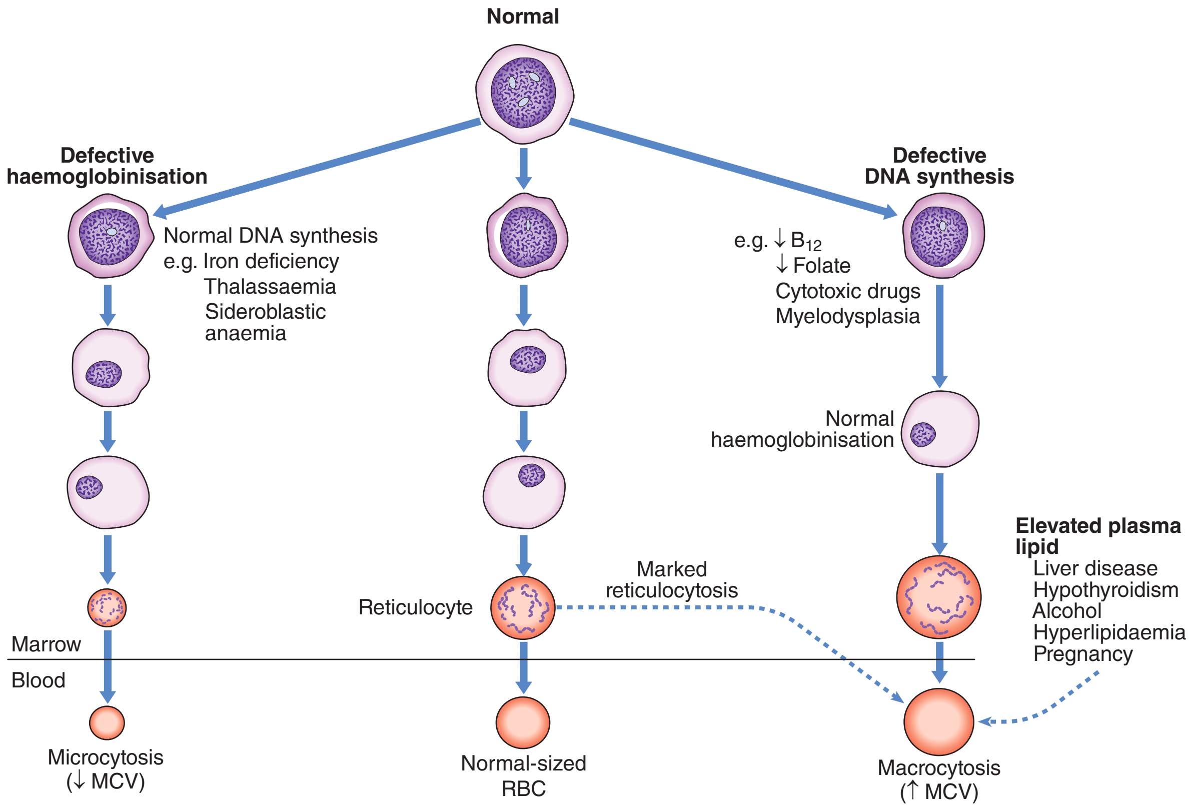

Fig. 24.20 Factors that influence the size of red cells in anaemia. In microcytosis, the MCV is <76 fL. In macrocytosis, the MCV is >100 fL. (MCV = mean cell volume; RBC = red blood cell)

24.30 Anaemia in old age

- **Mean haemoglobin**: falls with age in both sexes but remains well within the reference range. When a low haemoglobin does occur, it is generally due to disease.
- **Anaemia can never be considered 'normal' in old age**.
- **Symptoms**: may be subtle and insidious. Cardiovascular features such as dyspnoea and oedema, and cerebral features such as dizziness and apathy, tend to predominate.
- **Ferritin**: if lower than 45 µg/L in older people, is highly predictive of iron deficiency. Conversely, ferritin may be raised by chronic disease and so a normal ferritin does not exclude iron deficiency.
- **Serum iron and transferrin**: fall with age because of the prevalence of other disorders, and are not reliable indicators of deficiency.
- **Most common cause of iron deficiency**: gastrointestinal blood loss.
- **Most common cause of vitamin B_{12} deficiency**: pernicious anaemia, as the prevalence of chronic atrophic gastritis rises in old age.
- **Neuropsychiatric symptoms associated with vitamin B_{12} deficiency**: well-established association but a causal relationship has not been clearly shown. Dementia associated with vitamin B_{12} deficiency in the absence of haematological abnormalities is rare.
- **Anaemia of chronic disease**: frequent in old age because of the rising prevalence of diseases that inhibit iron transport.

the fetus, the placenta and the increased maternal red cell mass, and is lost with bleeding at parturition (Box 24.31).

Investigations

Confirmation of iron deficiency

Serum ferritin is a measure of iron stores in tissues and is the best single test to confirm iron deficiency (Box 24.32). A subnormal level is most often due to iron deficiency or, very rarely, hypothyroidism or vitamin C deficiency. Ferritin levels can be raised in liver disease and in the acute phase response; in these conditions, a ferritin level of up to 100 µg/L may still be compatible with low bone marrow iron stores.

Plasma iron and total iron binding capacity (TIBC) are measures of iron availability; hence, they are affected by many factors besides iron stores. Plasma iron has a marked diurnal and day-to-day variation and becomes very low during an acute phase response, but is raised in liver disease and haemolysis. Levels of transferrin, the binding protein for iron, are lowered by malnutrition, liver disease, the acute phase response and nephrotic syndrome, but raised by pregnancy and the oral contraceptive pill. A transferrin saturation ([iron/TIBC]×100) of less than 16% is consistent with iron deficiency but is less specific than a low ferritin measurement.

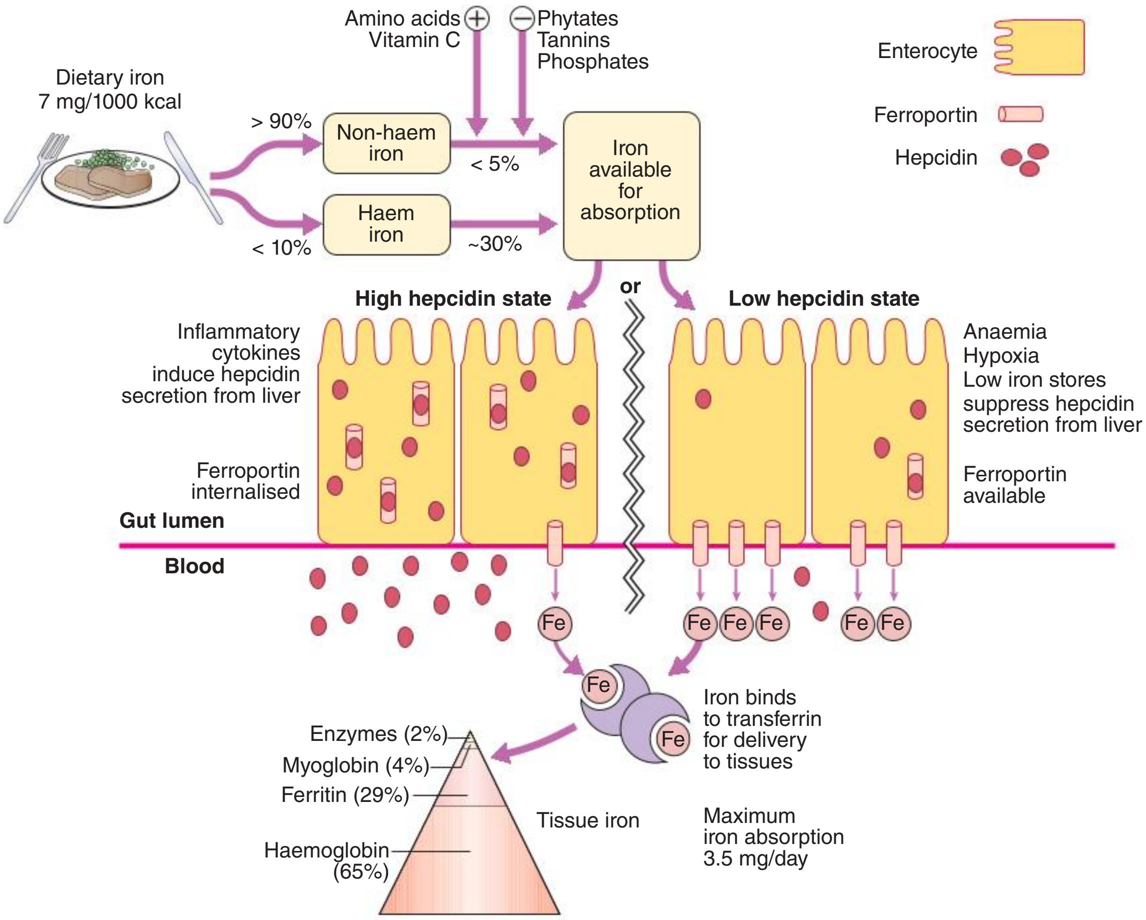
All proliferating cells express membrane transferrin receptors to acquire iron; a small amount of this receptor is shed into blood, where it can be detected in a free soluble form. When iron stores are low, cells up-regulate transferrin receptor expression and the levels of soluble plasma transferrin receptor increase. This can be measured by immunoassay and used to distinguish storage iron depletion in the presence of an acute phase response or liver disease, when a raised level indicates iron deficiency. In difficult cases, it may still be necessary to examine a bone marrow aspirate for iron stores.

Investigation of the cause

This will depend on the age and sex of the patient, as well as the history and clinical findings. In men and in post-menopausal women with a normal diet, the upper and lower gastrointestinal tract should be investigated by endoscopy or radiological studies. Current guidelines suggest exclusion of coeliac disease by antibody testing at an early stage of investigation of iron deficiency. In the tropics, stool and urine should be examined for parasites (Box 14.19).

Management

Unless the patient has angina, heart failure or evidence of cerebral hypoxia, transfusion is not indicated, and oral iron replacement is



Dietary iron

appropriate. Ferrous sulphate 200 mg 3 times daily (195 mg of elemental iron per day) is adequate and should be continued for 3–6 months to replete iron stores. Many patients suffer gastrointestinal side-effects with ferrous sulphate, including dyspepsia and altered bowel habit. When this occurs, reduction in dose or another alternative oral preparation should be tried. Delayed-release preparations are not useful, since they release iron beyond the upper small intestine, where it cannot be absorbed.

The haemoglobin should rise by around 10 g/L every 7–10 days and a reticulocyte response will be evident within a week. A failure to respond adequately may be due to non-adherence, continued blood loss, malabsorption or an incorrect diagnosis. Patients with malabsorption, chronic gut disease or inability to tolerate any oral preparation may need parenteral iron therapy. Previously, iron dextran or iron sucrose was used, but new preparations of ferric isomaltose and ferric carboxymaltose have fewer allergic effects and are preferred. Doses required can be calculated based on the patient's starting haemoglobin and body weight. Observation for anaphylaxis following an initial test dose is recommended.

Anaemia of chronic disease

Anaemia of chronic disease (ACD), also known as anaemia of inflammation (AI), is a common type of anaemia, particularly in hospital populations. It occurs in the setting of chronic infection, chronic inflammation or neoplasia. The anaemia is not related to bleeding, haemolysis or marrow infiltration, is mild, with haemoglobin in the range of 85–115 g/L, and is usually associated with a normal MCV (normocytic, normochromic), though this may be reduced in long-standing inflammation. The serum iron is low, but iron stores are normal or increased, as indicated by the ferritin or stainable marrow iron.

24.31 Haematological physiology in pregnancy

- **Full blood count**: increased plasma volume (40%) lowers normal haemoglobin (reference range reduced to > 105 g/L at 28 weeks). The mean cell volume (MCV) may increase by 5 fL. A progressive neutrophilia occurs. Gestational thrombocytopenia (rarely < 60 × 10^9/L) is a benign phenomenon.
- **Depletion of iron stores**: iron deficiency is a common cause of anaemia in pregnancy and, if present, should be treated with oral iron supplement.
- **Vitamin B$_{12}$**: serum levels are physiologically low in pregnancy but deficiency is uncommon.
- **Folate**: tissue stores may become depleted, and folate supplementation is recommended in all pregnancies (see Box 5.32).
- **Coagulation factors**: from the second trimester, procoagulant factors increase approximately threefold, particularly fibrinogen, von Willebrand factor and factor VIII. This causes activated protein C resistance and a shortened activated partial thromboplastin time (APTT), and contributes to a prothrombotic state.
- **Anticoagulants**: levels of protein C increase from the second trimester, while levels of free protein S fall as C4b binding protein increases.

24.32 Investigations to differentiate anaemia of chronic disease from iron deficiency anaemia

	Ferritin	Iron	TIBC	Transferrin saturation	Soluble transferrin receptor
Iron deficiency anaemia	↓	↓	↑	↓	↑
Anaemia of chronic disease	↑/Normal	↓	↓	↓	↓/Normal

(TIBC = total iron binding capacity)

Pathogenesis

It has become clear that the key regulatory protein that accounts for the findings characteristic of ACD/AI is hepcidin, which is produced by the liver (see Fig. 24.21). Hepcidin production is induced by pro-inflammatory cytokines, especially IL-6. Hepcidin binds ferroportin on the membrane of iron-exporting cells, such as small intestinal enterocytes and macrophages, internalising the ferroportin and thereby inhibiting the export of iron from these cells into the blood. The iron remains trapped inside the cells in the form of ferritin, levels of which are therefore normal or high in the face of low serum iron and anaemia. Inhibition or blockade of hepcidin is a potential target for treatment of this form of anaemia.

Diagnosis and management

It is often difficult to distinguish ACD associated with a low MCV from iron deficiency. Box 24.32 summarises the investigations and results. Examination of the marrow may ultimately be required to assess iron stores directly. A trial of oral iron can be given in difficult situations. A positive response occurs in true iron deficiency, but not in ACD. Measures that reduce the severity of the underlying disorder generally help to improve ACD. Trials of higher-dose intravenous iron are under way to try to bypass the hepcidin-induced blockade. Pilot studies have been successful, for example in treating anaemia in post–intensive therapy unit patients.

Megaloblastic anaemia

This results from a deficiency of vitamin B_{12} or folic acid, or from disturbances in folic acid metabolism. Folate is an important substrate of, and vitamin B_{12} a co-factor for, the generation of the essential amino acid methionine from homocysteine. This reaction produces tetrahydrofolate, which is converted to thymidine monophosphate for incorporation into DNA. Deficiency of either vitamin B_{12} or folate will therefore produce high plasma levels of homocysteine and impaired DNA synthesis.

The result is cells with arrested nuclear maturation but normal cytoplasmic development: so-called nucleocytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence, changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. The high proliferation rate of bone marrow results in striking changes in the haematopoietic system in megaloblastic anaemia. Cells become arrested in development and die within the marrow; this ineffective erythropoiesis results in an expanded hypercellular marrow. The megaloblastic changes are most evident in the early nucleated red cell precursors and haemolysis within the marrow results in a raised bilirubin and lactate dehydrogenase (LDH), but without the reticulocytosis characteristic of other forms of haemolysis (see Box 24.33). Iron stores are usually raised. The mature red cells are large and oval, and sometimes contain nuclear remnants. Nuclear changes are seen in the immature granulocyte precursors and a characteristic appearance is that of ‘giant’ metamyelocytes with a large ‘sausage-shaped’ nucleus. The mature neutrophils show hypersegmentation of their nuclei, with cells having six or more nuclear lobes. If severe, pancytopenia may be present in the peripheral blood.

Vitamin B_{12} deficiency, but not folate deficiency, is associated with neurological disease in up to 40% of cases, although advanced neurological disease due to B_{12} deficiency is now uncommon in the developed world. The main pathological finding is focal demyelination affecting the spinal cord, peripheral nerves, optic nerves and cerebrum. The most common manifestations are sensory, with peripheral paraesthesiae and ataxia of gait. The clinical, diagnostic features of megaloblastic anaemia are summarised in Boxes 24.33 and 24.34, and the neurological features of B_{12} deficiency in Box 24.35.

24.33 Clinical features of megaloblastic anaemia

Symptoms

- Malaise (90%)
- Breathlessness (50%)
- Paraesthesiae (80%)
- Sore mouth (20%)
- Weight loss
- Impotence
- Poor memory
- Depression
- Personality change
- Hallucinations
- Visual disturbance

Signs

- Smooth tongue
- Angular cheilosis
- Vitiligo
- Skin pigmentation
- Heart failure
- Pyrexia

24.34 Investigations in megaloblastic anaemia

Investigation	Result
Haemoglobin	Often reduced, may be very low
Mean cell volume	Usually raised, commonly > 120 fL
Erythrocyte count	Low for degree of anaemia
Blood film	Oval macrocytosis, poikilocytosis, red cell fragmentation, neutrophil hypersegmentation
Reticulocyte count	Low for degree of anaemia
Leucocyte count	Low or normal
Platelet count	Low or normal
Bone marrow	Increased cellularity, megaloblastic changes in erythroid series, giant metamyelocytes, dysplastic megakaryocytes, increased iron in stores, pathological non-ring sideroblasts
Serum ferritin	Elevated
Plasma lactate dehydrogenase	Elevated, often markedly

24.35 Neurological findings in B_{12} deficiency

Peripheral nerves

- Glove and stocking paraesthesiae
- Loss of ankle reflexes

Spinal cord

- Subacute combined degeneration of the cord
  Posterior columns – diminished vibration sensation and proprioception
  Corticospinal tracts – upper motor neuron signs

Cerebrum

- Dementia
- Optic atrophy
- Autonomic neuropathy

Vitamin B_{12}

Vitamin B_{12} absorption

The average daily diet contains 5–30 µg of vitamin B_{12}, mainly in meat, fish, eggs and milk – well in excess of the 1 µg daily requirement. In the stomach, gastric enzymes release vitamin B_{12} from food and at gastric pH it binds to a carrier protein termed haptocorrin (transcobalamin-1 or R-protein) produced in saliva. This protects vitamin B_{12} from gastric acid. The gastric parietal cells produce intrinsic factor, a vitamin B_{12}-binding protein that optimally binds vitamin B_{12} at pH 8. As gastric emptying occurs, pancreatic secretion raises the pH and vitamin B_{12} released from the diet switches from the haptocorrin to intrinsic factor. Bile also contains vitamin B_{12}, which is available for reabsorption in the intestine. The vitamin B_{12}–intrinsic factor complex binds to specific receptors in the terminal ileum, and vitamin B_{12} is actively transported by the enterocytes to plasma, where it binds to haptocorrin and transcobalamin-II, a transport protein produced by the liver, which carries it to the tissues for utilisation. The haptocorrin-bound vitamin B_{12} represents the majority in the circulation and is inactive, perhaps acting as an additional store. The liver stores enough vitamin B$_{12}$ to last for approximately 3 years and this, together with the enterohepatic circulation, means that vitamin B$_{12}$ deficiency takes years to become manifest, even if all dietary intake is stopped or severe B$_{12}$ malabsorption supervenes.

Blood levels of vitamin B$_{12}$ (cobalamin) provide a reasonable indication of tissue stores and are usually diagnostic of deficiency. The first-line tests for most laboratories are total B$_{12}$ (serum cobalamin) or active B$_{12}$ (serum holotranscobalamin); the latter is used as the initial test for suspected vitamin B$_{12}$ deficiency in pregnancy.

Additional tests, including measurement of methylmalonic acid and plasma homocysteine levels are available. If the person has suspected vitamin B$_{12}$ deficiency caused by recreational use of nitrous oxide, plasma homocysteine or serum methylmalonic acid (MMA) should be used as the initial test. Levels of cobalamins fall in normal pregnancy. Pregnancy reference ranges vary between laboratories, but levels below 150 ng/L are common and, in the last trimester, 5%–10% of women have levels below 100 ng/L. Spuriously low B$_{12}$ values occur in women using the oral contraceptive pill and in patients with myeloma, in whom paraproteins can interfere with vitamin B$_{12}$ assays.

Causes of vitamin B$_{12}$ deficiency

The main causes of B$_{12}$ deficiency are shown in Box 24.36.

Dietary deficiency

This occurs only in strict vegans, but the onset of clinical features can occur at any age between 10 and 80 years. Less strict vegetarians often have slightly low vitamin B$_{12}$ levels, but are not tissue vitamin B$_{12}$-deficient.

24.36 Causes of B$_{12}$ deficiency

- Diet low in vitamin B$_{12}$ (without the regular use of over-the-counter preparations), for example, in people who:
  - follow a diet that excludes, or is low in, animal-source foods (such as a vegan diet, or diets excluding meat for religious beliefs)
  - do not consume food or drinks fortified with vitamin B$_{12}$
  - have an allergy to some foods such as eggs, milk or fish
  - find it difficult to buy or prepare food (for example, people who have dementia or frailty, or those with mental health conditions)
  - find it difficult to obtain or afford foods rich in vitamin B$_{12}$ (for example, people on low income)
  - have a restricted diet (for example, because of an eating disorder)
- Family history of vitamin B$_{12}$ deficiency or an autoimmune condition
- Health conditions:
  - atrophic gastritis affecting the gastric body
  - coeliac disease or another autoimmune condition (such as thyroid disease, Sjögren syndrome or type 1 diabetes)
- Medicines:
  - colchicine
  - H$_2$-receptor antagonists
  - metformin (see the MHRA safety advice on metformin and reduced vitamin B$_{12}$)
  - phenobarbital
  - pregabalin
  - primidone
  - proton pump inhibitors
  - topiramate
- Previous abdominal or pelvic radiotherapy
- Previous gastrointestinal surgery:
  - many bariatric operations (for example, Roux-en-Y gastric bypass or sleeve gastrectomy)
  - gastrectomy or terminal ileal resection
- Recreational nitrous oxide use

Adapted from Vitamin B12 deficiency in over 16s: diagnosis and management. NICE guideline [NG239]. Published: 06 March 2024. With permission.
(MHRA = Medicines & Healthcare products Regulatory Agency)

Gastric pathology

Release of vitamin B$_{12}$ from food requires normal gastric acid and enzyme secretion, and this is impaired by hypochlorhydria in older patients or following gastric surgery. Total gastrectomy invariably results in vitamin B$_{12}$ deficiency within 5 years, often combined with iron deficiency; these patients need life-long 3-monthly vitamin B$_{12}$ injections. After partial gastrectomy, vitamin B$_{12}$ deficiency develops in only 10%–20% of patients by 5 years; an annual injection of vitamin B$_{12}$ should prevent deficiency in this group. Patients may develop B$_{12}$ deficiency after certain types of bariatric surgery (see Ch. 5).

Pernicious anaemia

This is an organ-specific autoimmune disorder in which the gastric mucosa is atrophic, with loss of parietal cells causing intrinsic factor deficiency. In the absence of intrinsic factor, less than 1% of dietary vitamin B$_{12}$ is absorbed. Pernicious anaemia has an incidence of 25/100 000 population over the age of 40 years in developed countries, but an average age of onset of 60 years. It is more common in individuals with other autoimmune disease (Hashimoto thyroiditis, Graves disease, vitiligo or Addison disease; Ch. 20) or a family history of these or pernicious anaemia. The finding of anti-intrinsic factor antibodies in the context of B$_{12}$ deficiency is diagnostic of pernicious anaemia without further investigation. Antiparietal cell antibodies are present in over 90% of cases, but are also present in 20% of normal females over the age of 60 years; a negative result makes pernicious anaemia less likely, but a positive result is not diagnostic.

Small bowel pathology

One-third of patients with pancreatic exocrine insufficiency fail to transfer dietary vitamin B$_{12}$ from R protein to intrinsic factor. This usually results in slightly low vitamin B$_{12}$ values, but no tissue evidence of vitamin B$_{12}$ deficiency. Inflammatory disease of the terminal ileum, such as Crohn disease, may impair the absorption of vitamin B$_{12}$–intrinsic factor complex, as may surgery on that part of the bowel. Motility disorders or hypogammaglobulinaemia can result in bacterial overgrowth, and the ensuing competition for free vitamin B$_{12}$ can lead to deficiency. A small number of people heavily infected with the fish tapeworm (Ch. 14) develop vitamin B$_{12}$ deficiency.

Recreational nitrous oxide use

Recreational nitrous oxide causes vitamin B$_{12}$ deficiency by inactivating the vitamin in the body, probably via oxidation. Neurological symptoms relating to B$_{12}$ inactivation can develop over a few weeks to months of prolonged use.

Folate

Folate absorption

Folates are produced by plants and bacteria; hence, dietary leafy vegetables (spinach, broccoli, lettuce), fruits (bananas, melons) and animal protein (liver, kidney) are a rich source. An average Western diet contains more than the minimum daily intake of 50 μg, but excess cooking destroys folates. Most dietary folate is present as polyglutamates; these are converted to monoglutamate in the upper small bowel and actively transported into plasma. Plasma folate is loosely bound to plasma proteins such as albumin and there is enterohepatic circulation. Total body stores of folate are small, and deficiency can occur in a matter of weeks.

Folate deficiency

The causes and diagnostic features of folate deficiency are shown in Boxes 24.37 and 24.38. Edentulous older people or psychiatric patients are particularly susceptible to dietary deficiency, and this is exacerbated in the presence of gut disease or malignancy. Pregnancy-induced folate deficiency is the most common cause of megaloblastosis worldwide and is more likely in the context of twin pregnancies, multiparity and hyperemesis gravidarum. Serum folate measurement is very sensitive to dietary intake; a single folate-rich meal can normalise serum folate in a patient with true folate deficiency, whereas anorexia, alcohol and anticonvulsant

24.37 Causes of folate deficiency

Diet

- Poor intake of vegetables

Malabsorption

- e.g. Coeliac disease, small bowel surgery including some forms of bariatric surgery

Increased demand

- Cell proliferation, e.g. haemolysis
- Pregnancy

Drugs*

- Certain anticonvulsants (e.g. phenytoin)
- Contraceptive pill
- Certain cytotoxic drugs (e.g. methotrexate)

*Usually only a problem in patients deficient in folate from another cause

24.38 Investigation of folic acid deficiency

Diagnostic findings

- Serum folate levels may be low but are difficult to interpret
- Low red cell folate levels indicate prolonged folate deficiency and are probably the most relevant measure

Corroborative findings

- Macrocytic dysplastic blood picture
- Megaloblastic marrow

therapy can reduce it in the absence of megaloblastosis. For this reason, red cell folate levels are a more accurate indicator of folate stores and tissue folate deficiency.

Management of megaloblastic anaemia

If a patient with severe megaloblastic anaemia is very ill and treatment must be started before vitamin B_{12} and red cell folate results are available, that treatment should always include both folic acid and vitamin B_{12}. The use of folic acid alone in the presence of vitamin B_{12} deficiency may result in worsening of neurological features.

Rarely, if severe angina or heart failure is present, transfusion can be used. The cardiovascular system is adapted to the chronic anaemia present in megaloblastosis and the volume load imposed by transfusion may result in decompensation and severe cardiac failure. In such circumstances, exchange transfusion or slow administration of 1 U of red cells with diuretic cover may be considered.

Vitamin B_{12} deficiency

Vitamin B_{12} deficiency is treated with hydroxycobalamin. In cases of malabsorption caused by autoimmune gastritis (pernicious anaemia), 1000 µg IM for 6 doses, 2 or 3 days apart, followed by maintenance therapy of 1000 µg every 3 months for life, is recommended. In the presence of neurological involvement, a dose of 1000 µg on alternate days until there is no further improvement, followed by maintenance as above, is recommended. In dietary deficiency and malabsorption from other causes, oral B_{12} replacement may suffice and is increasingly used in primary care. Where malabsorption is the suspected cause, a dose of at least 1 mg per day should be prescribed. For drug-induced causes, including nitrous oxide, oral or IM B_{12} replacement can be considered. Clearly, stopping the offending drug is important. The reticulocyte count will peak by the 5th–10th day after starting replacement therapy. The haemoglobin will rise by 10 g/L every week until normalised. The response of the marrow is associated with a fall in plasma potassium levels and rapid depletion of iron stores. If an initial response is not maintained and the blood film is dimorphic (i.e. shows a mixture of microcytic and macrocytic cells), the patient may need additional iron therapy. Sensory neuropathy may take 6–12 months to correct; long-standing neurological damage may not improve.

Folate deficiency

Oral folic acid (5 mg daily for 3 weeks) will treat acute deficiency, and 5 mg once weekly is adequate maintenance therapy. Prophylactic folic acid in pregnancy prevents megaloblastosis in women at risk and reduces the risk of fetal neural tube defects (see Box 5.32). Prophylactic supplementation is also given in chronic haematological disease associated with reduced red cell lifespan (e.g. haemolytic anaemias).

Haemolytic anaemia

Haemolysis indicates that there is shortening of the normal red cell lifespan of 120 days. There are many causes, as shown in Figure 24.22. To compensate, bone marrow may increase its output of red cells six- to eightfold by increasing the proportion of red cells produced, expanding the volume of active marrow, and releasing reticulocytes prematurely. Anaemia occurs only if the rate of destruction exceeds this increased production rate.

There are some general features of haemolysis and other specific features that help to identify the reason for haemolysis. Results of investigations that establish the presence of haemolysis are shown in Box 24.39. Red cell destruction overloads pathways for haemoglobin breakdown in the liver (p. 882), causing a modest rise in unconjugated bilirubin in the blood and mild jaundice. Increased reabsorption of urobilinogen from the gut results in an increase in urinary urobilinogen (pp. 887 and 946). Red cell destruction releases LDH into the serum. Bone marrow compensation results in reticulocytosis and sometimes nucleated red cell precursors appear in the blood. Increased proliferation of the bone marrow can result in thrombocytosis, neutrophilia and, if marked, immature granulocytes in the blood, producing a leucoerythroblastic blood film. The appearances of the red cells may give an indication of the likely cause of the haemolysis:

- spherocytes are small, dark red cells that suggest autoimmune haemolysis or hereditary spherocytosis
- sickle cells suggest sickle-cell disorder
- red cell fragments indicate microangiopathic haemolysis
- bite cells (normal-sized red cells that look as if they have been partially eaten) suggest oxidative haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, with megaloblastic blood features.

The differential diagnosis of haemolysis is determined by the clinical scenario in combination with the results of blood film examination and Coombs testing for antibodies directed against red cells (see below and Fig. 24.22).

Extravascular haemolysis

Physiological red cell destruction occurs in the reticulo-endothelial cells in the liver or spleen, so avoiding free haemoglobin in the plasma. In most haemolytic states, haemolysis is predominantly extravascular.

Intravascular haemolysis

Less commonly, red cell lysis occurs within the blood stream due to membrane damage by complement (ABO transfusion reactions, paroxysmal nocturnal haemoglobinuria), infections (malaria, *Clostridium perfringens*), mechanical trauma (heart valves, DIC) or oxidative damage (e.g. enzymopathies such as glucose-6-phosphate dehydrogenase deficiency, which may be triggered by drugs such as dapsone and maloprim). When intravascular red cell destruction occurs, free haemoglobin is released into the plasma. Free haemoglobin is toxic to cells and binding proteins have evolved to minimise this risk. Haptoglobin is an α_2-globulin produced by the liver which binds free haemoglobin, resulting in a fall in its levels during active haemolysis. Once haptoglobins are saturated, free haemoglobin is oxidised to form methaemoglobin, which binds to albumin in turn forming methaemalbumin, which can be detected spectrophotometrically in the Schumm test. Methaemoglobin is degraded and

Additional features of intravascular haemolysis

- ↓ Haptoglobin
- ↑ Methaemalbumin
- Positive urinary haemosiderin
- Haemoglobinuria

any free haem is bound to a second binding protein called haemopexin. If all the protective mechanisms are saturated, free haemoglobin may appear in the urine (haemoglobinuria). When fulminant, this gives rise to black urine, as in severe *falciparum* malaria infection (Ch. 14). In smaller amounts, renal tubular cells absorb the haemoglobin, degrade it and store the iron as haemosiderin. When the tubular cells are subsequently sloughed into the urine, they give rise to haemosiderinuria, which is always indicative of intravascular haemolysis (see Box 24.39).

Causes of haemolytic anaemia

These can be classified as inherited or acquired (see Fig. 24.22).

- *Inherited* red cell abnormalities resulting in chronic haemolytic anaemia may arise from pathologies of the red cell membrane (hereditary spherocytosis or elliptocytosis), haemoglobin (haemoglobinopathies), or protective enzymes that prevent cellular oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD).
- *Acquired* causes include auto- and alloantibody-mediated destruction of red blood cells and other mechanical, toxic and infective causes.

Red cell membrane defects

The structure of the red cell membrane is shown in Figure 24.4. The basic structure is a cytoskeleton ‘stapled’ on to the lipid bilayer by special protein complexes. This structure ensures great deformability and elasticity; the red cell diameter is 8 μm, but the narrowest capillaries in the circulation are in the spleen, measuring just 2 µm in diameter. When the normal red cell structure is disturbed, usually by a quantitative or functional deficiency of one or more proteins in the cytoskeleton, cells lose their elasticity. Each time such cells pass through the spleen, they lose membrane relative to their cell volume. This results in an increase in mean cell haemoglobin concentration (MCHC), abnormal cell shape (see Box 24.2) and reduced red cell survival due to extravascular haemolysis.

Hereditary spherocytosis

This is usually inherited as an autosomal dominant condition, although 25% of cases have no family history and represent new mutations. The incidence is approximately 1:5000 in high-income countries, but this may be an under-estimate since the disease may present de novo in patients aged over 65 years and is often discovered as a chance finding on a blood count. The most common abnormalities are deficiencies of beta spectrin or ankyrin (see Fig. 24.4). The severity of spontaneous haemolysis varies. Most cases are associated with an asymptomatic compensated chronic haemolytic state with spherocytes present on the blood film, reticulocytosis and mild hyperbilirubinaemia. Pigment gallstones are present in up to 50% of patients and may cause symptomatic cholecystitis. Occasional cases are associated with more severe haemolysis; these may be due to coincidental polymorphisms in alpha spectrin or co-inheritance of a second defect involving a different protein. These cases tend to present earlier in life with symptomatic, sometimes transfusion-dependent anaemia.

The clinical course may be complicated by crises:

- *Haemolytic crisis* occurs when the severity of haemolysis increases; this is rare and usually is associated with infection.
- *Megaloblastic crisis* follows the development of folate deficiency; this may occur as a first presentation of the disease in pregnancy.
- *Aplastic crisis* occurs in association with parvovirus (erythrovirus) infection (p. 336). Parvovirus causes a common exanthem in children, but if individuals with chronic haemolysis become infected, the virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count.

Investigations

The patient and other family members should be screened for features of compensated haemolysis (see Box 24.39). This may be all that is required to confirm the diagnosis. Haemoglobin levels are variable, depending on the degree of compensation. The blood film will show spherocytes, but the direct Coombs test (Fig. 24.23) is negative, excluding immune haemolysis. An osmotic fragility test may show increased sensitivity to lysis in hypotonic saline solutions, but is limited by lack of sensitivity and specificity. More specific flow cytometric tests detecting binding of eosin-5-maleimide to red cells can be considered in borderline cases, as can a red cell gene panel.

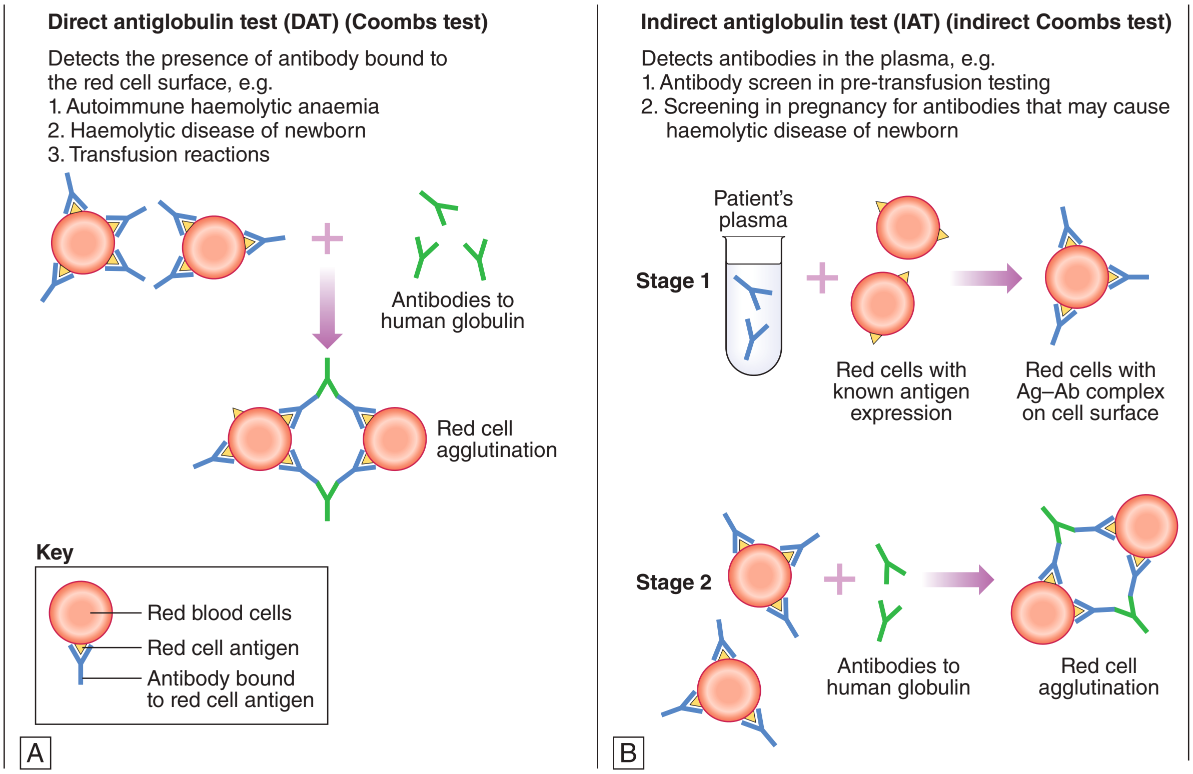
Management

Folic acid prophylaxis (5 mg daily) should be given for life. In severe cases, consideration may be given to splenectomy, which improves but does not normalise red cell survival. Potential indications for splenectomy include moderate to severe haemolysis with complications (anaemia and gallstones), although splenectomy should be delayed where possible until after 6 years of age in view of the subsequent risk of sepsis. Guidelines for the management of patients after splenectomy are presented in Box 24.40.

Acute, severe haemolytic crises require transfusion support, but cross-matched blood must be transfused slowly as haemolytic transfusion reactions may occur (see Fig. 24.16).

Hereditary elliptocytosis

This term refers to a heterogeneous group of disorders that produce an increase in elliptocytic red cells on the blood film and a variable degree of haemolysis. This is due to a functional abnormality of one or more anchor proteins in the red cell membrane, e.g. alpha spectrin or protein 4.1 (see Fig. 24.4). Inheritance may be autosomal dominant or recessive. Hereditary elliptocytosis is less common than hereditary spherocytosis in



Direct antiglobulin test (DAT) (Coombs test)
Detects the presence of antibody bound to the red cell surface, e.g.

24.40 Management of the splenectomised patient

- Vaccinate with pneumococcal, *Haemophilus influenzae* type B, meningococcal group C and influenza vaccines at least 2–3 weeks before elective splenectomy. Vaccination should be given after emergency surgery but may be less effective. COVID-19 and annual influenza vaccinations are recommended
- Pneumococcal re-immunisation should be given at least 5-yearly and influenza annually. Vaccination status must be documented
- Life-long prophylactic penicillin V (500 mg twice daily) is recommended. In penicillin-allergic patients, consider a macrolide
- Patients should be educated regarding the risks of infection and methods of prophylaxis
- A card or bracelet should be carried to alert health professionals to the risk of overwhelming sepsis
- In sepsis, patients should be resuscitated and given intravenous antibiotics to cover pneumococcus, *Haemophilus* and meningococcus, according to local resistance patterns
- The risk of cerebral malaria is increased in the event of infection
- Animal bites should be promptly treated with local disinfection and antibiotics to prevent serious soft tissue infection and sepsis

Western countries, with an incidence of 1/10 000, but is more common in equatorial Africa and parts of South-east Asia. The clinical course is variable and depends on the degree of membrane dysfunction caused by the inherited molecular defect(s); most cases present as an asymptomatic blood film abnormality, but occasional cases result in neonatal haemolysis or a chronic compensated haemolytic state. Management of the latter is the same as for hereditary spherocytosis.

A characteristic variant of hereditary elliptocytosis occurs in South-east Asia, particularly Malaysia and Papua New Guinea, with stomatocytes and ovalocytes in the blood. This has a prevalence of up to 30% in some communities because it offers relative protection from malaria and thus has sustained a high gene frequency. The blood film is often very abnormal and immediate differential diagnosis is broad.

Red cell enzymopathies

The mature red cell must produce energy via ATP to maintain a normal internal environment and cell volume while protecting itself from the oxidative stress presented by oxygen carriage. ATP is generated by glycolysis, while the hexose monophosphate shunt produces nicotinamide adenine dinucleotide phosphate (NADPH) and glutathione to protect against oxidative stress. The impact of functional or quantitative defects in the enzymes in these pathways depends on the importance of the steps affected and the presence of alternative pathways. In general, defects in the hexose monophosphate shunt pathway result in periodic haemolysis precipitated by episodic oxidative stress, while those in the glycolysis pathway result in shortened red cell survival and chronic haemolysis.

Glucose-6-phosphate dehydrogenase deficiency

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is pivotal in the hexose monophosphate shunt pathway. Deficiencies result in the most common human enzymopathy, affecting 10% of the world's population, with a geographical distribution that parallels the malaria belt because heterozygotes are protected from malarial parasitisation. The enzyme is a heteromeric structure made of catalytic subunits that are encoded by a gene on the X chromosome. The deficiency, therefore, affects males and rare homozygous females, but it is carried by females. Carrier heterozygous females are usually only affected in the neonatal period or in the presence of skewed X-inactivation.

Over 400 subtypes of G6PD are described. The most common types associated with normal activity are the B+ enzyme present in most populations of European descent and 70% of those of African Caribbean origin, and the A+ variant present in 20% of African Caribbeans. The two common variants associated with reduced activity are the A− variety in approximately 10% of African Caribbeans, and the Mediterranean or B− variety in those of European origin. In East and West Africa, up to 20% of males and 4% of females (homozygotes) are affected and have enzyme levels of about 15% of normal. The deficiency in European and East Asian populations is more severe, with enzyme levels as low as 1%.

24.41 Glucose-6-phosphate dehydrogenase deficiency

Clinical features

- Acute drug-induced haemolysis to (e.g.):
  - Analgesics: aspirin, phenacetin
  - Antimalarials: primaquine, quinine, chloroquine, pyrimethamine
  - Antibiotics: sulphonamides, nitrofurantoin, ciprofloxacin
  - Miscellaneous: quinidine, probenecid, vitamin K, dapsone
- Chronic compensated haemolysis
- Infection or acute illness
- Neonatal jaundice: may be a feature of the B− enzyme
- Favism, i.e. acute haemolysis after ingestion of broad beans (*Vicia fava*)

Laboratory features

Non-spherocytic intravascular haemolysis during an attack

The blood film will show:

- Bite cells (red cells with a 'bite' of membrane missing)
- Blister cells (red cells with surface blistering of the membrane)
- Irregularly shaped small cells
- Polychromasia reflecting the reticulocytosis
- Denatured haemoglobin visible as Heinz bodies within the red cell cytoplasm with a supravital stain such as methyl violet

G6PD level

- Can be indirectly assessed by screening methods that usually depend on the decreased ability to reduce dyes
- Direct assessment of G6PD is made in those with low screening values
- Care must be taken close to an acute haemolytic episode because reticulocytes may have higher enzyme levels and give rise to a false normal result

Clinical features and investigation findings are shown in Box 24.41.

Management aims to stop the intake of any precipitant drugs or foods and treat any underlying infection. Favism, due to the consumption of fava beans, is the classically described precipitant of haemolysis in patients with G6PD deficiency. Acute transfusion support may be life-saving.

Pyruvate kinase deficiency

This is the second most common red cell enzyme defect. It results in deficiency of ATP production and chronic haemolytic anaemia. It is inherited as an autosomal recessive trait. The extent of anaemia is variable; the blood film shows characteristic 'prickle cells' that resemble holly leaves. Enzyme activity is only 5%–20% of normal. Transfusion support may be necessary during periods of haemolysis. Mitapivat is the first FDA-approved oral, allosteric, pyrovate kinase activator, which reduces haemolysis and improves haemoglobin levels.

Pyrimidine 5′ -nucleotidase deficiency

The pyrimidine 5′-nucleotidase enzyme catalyses the dephosphorylation of nucleoside monophosphates and is important during the degradation of RNA in reticulocytes. It is inherited as an autosomal recessive trait and is as common as pyruvate kinase deficiency in Mediterranean, African and Jewish populations. The accumulation of excess ribonucleoprotein results in coarse basophilic stippling (see Box 24.2), associated with a chronic haemolytic state. The enzyme is very sensitive to inhibition by lead and this is the reason why basophilic stippling is a feature of lead poisoning.

Autoimmune haemolytic anaemia

This results from increased red cell destruction due to red cell autoantibodies. The antibodies may be IgG or IgM, or more rarely IgE or IgA. If an antibody avidly fixes complement, it will cause intravascular haemolysis, but if complement activation is weak, the haemolysis will be extravascular (in the reticulo-endothelial system). Antibody-coated red cells lose membrane to macrophages in the spleen and hence spherocytes are present in the blood. The optimum temperature at which the antibody is active (thermal specificity) is used to classify immune haemolysis:

- *Warm antibodies* bind best at 37°C and account for 80% of cases. The majority are IgG and often react against Rhesus antigens.
- *Cold antibodies* bind best at 4°C but can bind up to 37°C in some cases. They are usually IgM and bind complement. To be clinically relevant, they must act within the range of normal body temperatures. They account for the other 20% of cases.

Warm autoimmune haemolysis

The incidence of warm autoimmune haemolysis is approximately 1/100 000 population per annum; it occurs at all ages but is more common in middle age and in females. No underlying cause is identified in up to 50% of cases. The remainder are secondary to a wide variety of other conditions (see Fig. 24.22B).

Investigations

There is evidence of haemolysis, spherocytes and polychromasia on the blood film. The diagnosis is confirmed by the direct Coombs or antiglobulin test (see Fig. 24.23). The patient's red cells are mixed with Coombs reagent, which contains antibodies against human IgG/IgM/complement. If the red cells have been coated by antibody in vivo, the Coombs reagent will induce their agglutination, and this can be detected visually. The relevant antibody can be eluted from the red cell surface and tested against a panel of typed red cells to determine against which red cell antigen it is directed. The most common specificity is for Rhesus antigens and most often anti-e; this is helpful when choosing blood to cross-match. The direct Coombs test can be negative in the presence of brisk haemolysis. A positive test requires about 200 antibody molecules to attach to each red cell; with a very avid complement-fixing antibody, haemolysis may occur at lower levels of antibody-binding. The standard Coombs reagent will miss IgA or IgE antibodies. Around 10% of all warm autoimmune haemolytic anaemias are Coombs test negative.

Management

If the haemolysis is secondary to an underlying cause, this must be treated and any implicated drugs stopped.

It is usual to treat patients initially with prednisolone (1 mg/kg orally). A response is seen in 70%–80% of cases but may take up to 3 weeks; a rise in haemoglobin will be matched by a fall in bilirubin, LDH and reticulocyte levels. Once the haemoglobin has normalised and the reticulocytosis resolved, the glucocorticoid dose can be reduced slowly over several weeks. Glucocorticoids probably work by decreasing macrophage destruction of antibody-coated red cells and reducing antibody production.

Transfusion support may be required for life-threatening problems, such as the development of heart failure or rapid unabated falls in haemoglobin. The least incompatible blood should be used, but this may still give rise to transfusion reactions or the development of alloantibodies.

If the haemolysis fails to respond to glucocorticoids or can only be stabilised by large doses, then second-line therapy with the anti-CD20 monoclonal antibody rituximab should be considered. Failure to respond to rituximab can be followed by consideration of treatment with a range of immunomodulatory/immunosuppressive agents or splenectomy. Pharmacological agents include azathioprine, ciclosporin, danazol and mycophenolate mofetil. Splenectomy is associated with a good response in 50%–60% of cases. The operation can be performed laparoscopically with reduced morbidity. There are concerns about all modes of third-line therapy as long-term immunosuppression carries a risk of malignancy, while splenectomy is associated with an excess of severe infection due to the capsulate organisms pneumococcus and meningococcus (see Box 24.40).

Supportive measures in the management of autoimmune haemolytic anaemia include folic acid, bone protection with bisphosphonate given the prolonged use of high-dose glucocorticoids, and pharmacological thromboprophylaxis due to an increased risk of venous thromboembolism.

Cold agglutinin disease

This is mediated by antibodies, usually IgM, which bind to the red cells at low temperatures and cause them to agglutinate. It may cause intravascular haemolysis if complement fixation occurs. This can be chronic when the antibody is monoclonal, or acute or transient when the antibody is polyclonal.

Chronic cold agglutinin disease

This typically affects older adult patients and may be associated with an underlying low-grade B-cell lymphoma. It causes low-grade intravascular haemolysis with cold, painful and often blue fingers, toes, ears or nose (acrocyanosis). The latter is due to red cell agglutination in the small vessels in these colder, exposed areas. The blood film shows red cell agglutination and the MCV may be spuriously high because the automated analysers detect red cell aggregates as single cells. Monoclonal IgM usually has anti-I or, less often, anti-i specificity. Treatment is primarily by transfusion support but may also be directed at any underlying lymphoma. Patients must keep extremities warm, especially in winter. Some patients respond to rituximab and, nowadays, bendamustine or similar chemotherapy for low-grade lymphomas is considered if a clonal abnormality is detected. Recently inhibitors of complement have shown promise and trials of sutimlimab, an inhibitor of C1, has produced sustained improvements in haemolysis, anaemia and quality of life, providing therapy is continued. For patients requiring blood transfusion, the cross-match sample must be placed in a transport flask at a temperature of 37°C and blood must be administered via a blood warmer. All patients should receive folic acid supplementation.

Other causes of cold agglutination

Cold agglutination can occur in association with *Mycoplasma pneumoniae* or with infectious mononucleosis. Paroxysmal cold haemoglobinuria is a very rare cause seen in children, in association with viral or bacterial infection. An IgG antibody binds to red cells in the peripheral circulation, but lysis occurs in the central circulation when complement fixation takes place. This antibody is termed the Donath–Landsteiner antibody and has specificity against the P antigen on the red cells.

Alloimmune haemolytic anaemia

Alloimmune haemolytic anaemia is caused by antibodies against non-self red cells. It has two main causes, occurring after:

- unmatched blood transfusion (see Fig. 24.16)
- maternal sensitisation to paternal antigens on fetal cells (haemolytic disease of the newborn, see Box 24.19).

Non-immune haemolytic anaemia

Endothelial damage

Disruption of red cell membrane may occur in a number of conditions and is characterised by the presence of red cell fragments on the blood film and markers of intravascular haemolysis:

- *Mechanical heart valves*. High flow through incompetent valves or periprosthetic leaks through the suture ring holding a valve in place result in shear stress damage.
- *March haemoglobinuria*. Vigorous exercise, such as prolonged marching or marathon running, can cause red cell damage in the capillaries in the feet.
- *Thermal injury*. Severe burns cause thermal damage to red cells, characterised by fragmentation and the presence of microspherocytes in the blood.
- *Microangiopathic haemolytic anaemia*. Fibrin deposition in capillaries can cause severe red cell disruption. It may occur in a wide variety

of conditions: disseminated carcinomatosis, malignant or pregnancy-induced hypertension, haemolytic uraemic syndrome (Ch. 18), thrombotic thrombocytopenic purpura and disseminated intravascular coagulation (p. 1013).

Infection

Plasmodium falciparum malaria (p. 374) may be associated with intravascular haemolysis; when severe, this is termed blackwater fever because of the associated haemoglobinuria. *Clostridium perfringens* sepsis (p. 306), usually in the context of ascending cholangitis or necrotising fasciitis, may cause severe intravascular haemolysis with marked spherocytosis due to bacterial production of a lecithinase that destroys the red cell membrane.

Chemicals or drugs

Dapsone and sulfasalazine cause haemolysis by oxidative denaturation of haemoglobin. Denatured haemoglobin forms Heinz bodies in the red cells, visible on supravital staining with brilliant cresyl blue. Arsenic gas, copper, chlorates, nitrites and nitrobenzene derivatives may all cause haemolysis.

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired, non-malignant clonal expansion of haematopoietic stem cells deficient in glycosylphosphatidylinositol (GPI) anchor protein. GPI anchors several key molecules to cells and its absence results in clinical outcomes that reflect this, causing intravascular haemolysis and anaemia because of increased sensitivity of red cells to lysis by complement. This happens because key defence mechanisms that protect cells from complement-mediated lysis (CD55 and CD59) are GPI-anchored to red cells under normal circumstances. Episodes of intravascular haemolysis result in haemoglobinuria, most noticeable in early morning urine, which has a characteristic red–brown colour. The disease is associated with an increased risk of venous and arterial thrombosis in unusual sites, such as the liver or abdomen. PNH clones are also associated with hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome (see later). Management is supportive with transfusion and folate supplements and prophylaxis or treatment of thrombosis. Standard care now includes the anti-complement C5 monoclonal antibodies eculizumab and ravulizumab. This has been shown to be effective in reducing haemolysis, transfusion requirements and thrombotic risk. Inhibition of C3 is also now available through the antibody, pegcetacoplan. This has the added benefit of inhibiting both intravascular and extravascular haemolysis. The C5 and C3 inhibitory antibodies both carry a risk of infection, particularly for *Neisseria meningitidis*, and all treated patients must be vaccinated against this organism.

Haemoglobinopathies

These disorders are caused by mutations affecting the genes encoding the globin chains of haemoglobin. Normal haemoglobin is composed of two alpha and two non-alpha globin chains. Alpha globin chains are produced throughout life, including in the fetus, so severe mutations in these may cause intrauterine death. Production of non-alpha chains varies with age; fetal haemoglobin (HbF-αα/γγ) has two gamma chains, while the predominant adult haemoglobin (HbA-αα/ββ) has two beta chains. Thus, disorders affecting the beta chains do not present until after 6 months of age. A constant small amount of haemoglobin A_2 (HbA_2-αα/δδ, usually less than 2%) is made from birth.

The geographical distribution of the common haemoglobinopathies is shown in Figure 24.24. Haemoglobinopathies can be classified into qualitative or quantitative abnormalities.

Qualitative abnormalities – abnormal haemoglobins

In qualitative abnormalities (called the abnormal haemoglobins), there is a functionally important alteration in the amino acid structure of the polypeptide chains of the globin chains. Several hundred such variants are known; they were originally designated by letters of the alphabet, e.g. S, C, D or E, but the more recently described variants are known by names that are usually taken from the town or district in which they were first described. The best-known example is haemoglobin S, found in sickle-cell disorder. Mutations around the haem-binding pocket cause the haem ring to fall out of the structure and produce an unstable haemoglobin. These substitutions often change the charge of the globin chains, producing different electrophoretic mobility, and this forms the basis for the diagnostic use of haemoglobin electrophoresis to identify haemoglobinopathies.

Quantitative abnormalities – thalassaemias

In quantitative abnormalities (the thalassaemias), there are mutations causing a reduced rate of production of one or other of the globin chains, altering the ratio of alpha to non-alpha chains. In alpha-thalassaemia excess beta chains are present, while in beta-thalassaemia excess alpha chains are present. The excess chains precipitate, causing red cell membrane damage and reduced red cell survival due to haemolysis.

Sickle-cell disorder

Sickle-cell disorder results from a single glutamic acid to valine substitution at position 6 of the beta globin polypeptide chain. It is inherited as an autosomal recessive trait. Homozygotes only produce abnormal beta

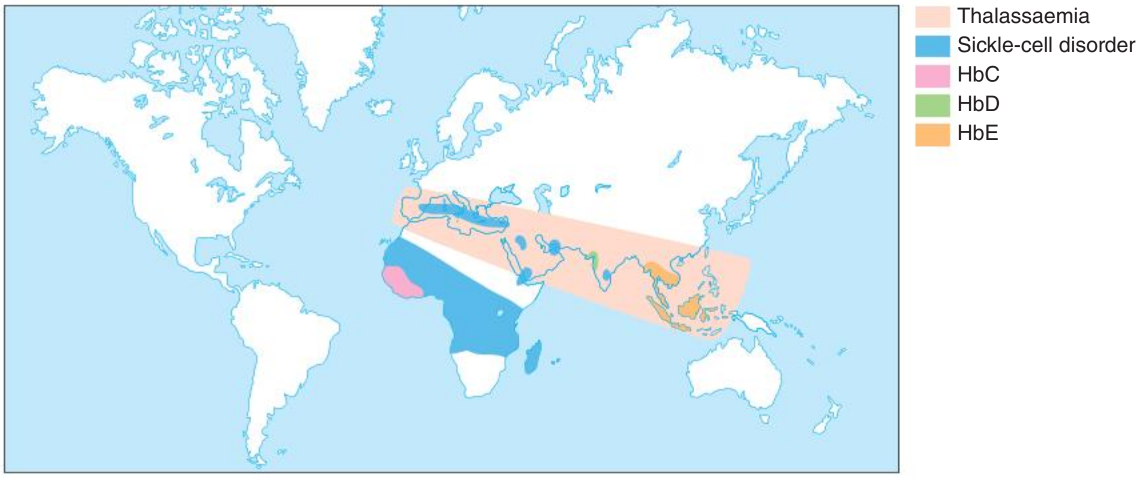

Fig. 24.24 The geographical distribution of the haemoglobinopathies. Map lines delineate study areas and do not necessarily depict accepted national boundaries. *From Hoffbrand AV, Pettit JE. Essential haematology. 3rd ed. Edinburgh: Blackwell Science; 1992.*

chains that make haemoglobin S (HbS, termed SS), and this results in the clinical syndrome of sickle-cell disorder. Heterozygotes produce a mixture of normal and abnormal beta chains that make normal HbA and HbS (termed AS), and this results in sickle-cell trait. Although this was previously thought of as asymptomatic, it may be associated with an increased risk of kidney, spleen and eye conditions; previous concerns around an increased incidence of sudden and cardiovascular death in young adults remains unproven.

Epidemiology

The heterozygote frequency is over 20% in tropical Africa (see Fig. 24.24) whereas in African American populations, sickle-cell trait has a frequency of 8%. Individuals with sickle-cell trait are relatively resistant to the effects of *falciparum* malaria in early childhood; the high prevalence in equatorial Africa can thus be explained by the survival advantage it confers in areas where *falciparum* malaria is endemic. However, homozygous patients with sickle-cell disorder do not have correspondingly greater resistance to *falciparum* malaria. In some parts of Africa, up to 3% of all births are affected; it is estimated that 50%–90% die before their fifth birthday.

Pathogenesis

When haemoglobin S is deoxygenated, the molecules of haemoglobin polymerise to form pseudocrystalline structures known as 'tactoids'. These distort the red cell membrane and produce characteristic sickle-shaped cells (Fig. 24.25). The polymerisation is reversible when re-oxygenation occurs. The distortion of the red cell membrane may become permanent and the red cell 'irreversibly sickled'. The greater the concentration of sickle-cell haemoglobin in the individual cell, the more easily tactoids are formed, but this process may be enhanced or retarded by the presence of other haemoglobins. Thus, the abnormal haemoglobin C variant participates in polymerisation more readily than haemoglobin A, whereas haemoglobin F strongly inhibits polymerisation.

Clinical features

Sickling is precipitated by hypoxia, acidosis, cold temperatures particularly relating to wind chill, dehydration and infection. Irreversibly sickled cells have a shortened survival and plug vessels in the microcirculation. This results in several acute syndromes, termed 'crises', and chronic organ damage (see Fig. 24.25):

- *Painful vaso-occlusive crisis*. Plugging of small vessels in the bones produces acute severe bone pain. This affects areas of active marrow: the hands and feet in children (so-called dactylitis) or the femora, humeri, ribs, pelvis and vertebrae in adults. Patients usually have a systemic response with tachycardia and fever. This is the most common form of crisis.
- *Stroke*. The single most devastating consequence of sickle-cell disorder is stroke. Stroke or silent stroke occurs in 10%–15% of children and adolescents with sickle-cell disorder and approximately a quarter of patients with SS by age 45 years. Sickle-cell patients are also at risk of transient ischaemic attack (TIA) and haemorrhagic stroke. Children at risk of stroke are identified by screening with transcranial Doppler ultrasound, with increased velocity (> 200 cm/s)

associated with increased stroke risk. These children are offered strategies such as chronic transfusion programmes, which reduce stroke risk by 90%, or treatment with hydroxycarbamide to reduce the risk of stroke.

- *Sickle chest syndrome*. This may follow a vaso-occlusive crisis and is the most common cause of death in adult sickle-cell disorder. Bone marrow infarction results in fat emboli to the lungs, which cause further sickling and infarction, leading to ventilatory failure if not treated.
- *Sequestration crisis*. Thrombosis of the venous outflow from an organ causes loss of function and acute painful enlargement. In children, the spleen is the most common site. Massive splenic enlargement may result in severe anaemia, circulatory collapse and death. Recurrent sickling in the spleen in childhood results in infarction, and adults may have no functional spleen. In adults, the liver may undergo sequestration with severe pain due to capsular stretching. Priapism may occur in affected individuals.
- *Aplastic crisis*. Infection of adult sickle-cell patients with human parvovirus B19 (erythrovirus) may result in a severe but self-limiting red cell aplasia. This results in profound anaemia, which may cause heart failure. Folate deficiency, precipitated by haemolysis and increased demand for folate, can lead to a similar clinical scenario. Unlike in all other sickle crises, the reticulocyte count is low.
- *Pregnancy*. Pregnancy in sickle-cell disorder requires planning and multidisciplinary management. Women with sickle-cell disorder have increased pregnancy-related morbidity, which includes painful crisis, placental failure and thrombosis (Box 24.42).

Investigations

Patients with sickle-cell disorder have compensated anaemia, usually around 60–80 g/L. A reticulocytosis is present. The blood film shows sickle cells, target cells, polychromasia and features of hyposplenism from a young age. The presence of HbS can be demonstrated by exposing red cells to a reducing agent such as sodium dithionite; HbA gives a clear solution, whereas HbS polymerises to produce a turbid solution. This forms the basis of emergency screening tests before surgery in appropriate ethnic groups but cannot distinguish between sickle-cell trait and disorder. The definitive diagnosis requires haemoglobin electrophoresis to demonstrate the absence of HbA, 2%–20% HbF and the predominance of HbS. Both parents of the affected individual will have sickle-cell trait.

Management

All patients with sickle-cell disorder should receive prophylaxis with daily folic acid, and appropriate management of the hyposplenic state that is uniformly found in these patients from an early age (see Box 24.40). Seasonal vaccination against influenza and COVID-19 is also advised.

24.42 Sickle-cell disorder in pregnancy

- **Pre-conceptual counselling**: advice on the effect of sickle-cell disorder on pregnancy, and vice versa, should be offered.
- **Vaccination status**: should be updated before conception.
- **Testing of partner**: testing for haemoglobinopathy status is advised.
- **Folic acid**: should be taken in high dose (5 mg daily) prior to and throughout pregnancy.
- **Hydroxycarbamide**: should be discontinued 3 months prior to conception.
- **Angiotensin-converting enzyme (ACE) inhibitors**: should be discontinued prior to conception.
- **Pulmonary hypertension**: should be excluded prior to conception.
- **Placental failure**: women with sickle-cell disorder have increased rates, resulting in pre-eclampsia and intrauterine growth retardation.
- **Aspirin 75 mg**: should be given throughout pregnancy.
- **Thromboprophylaxis after delivery**: all women with sickle-cell disorder should receive thromboprophylaxis with low-molecular-weight heparin for at least 10 days post vaginal delivery and for 6 weeks post caesarean section. Antenatal thromboprophylaxis should be considered for women with additional risk factors for venous thromboembolism (see Box 24.71).
- **Transfusion**: ABO-compatible, extended Rhesus and Kell-matched units at a minimum should be provided. Blood should be cytomegalovirus-negative.

Vaso-occlusive crises are managed by aggressive rehydration, oxygen therapy, adequate analgesia (which often requires opiates) and antibiotics. Transfusion should be with ABO-compatible extended Rhesus and Kell-matched units at a minimum; the selected red cells should be negative for the corresponding antigens if there are clinically significant red cell antibodies (current or historical). Simple top-up transfusion may be used in a sequestration or aplastic crisis. A regular transfusion programme to suppress HbS production and maintain the HbS level below 30% may be indicated in patients with recurrent severe complications, such as cerebrovascular accidents in children or chest syndromes in adults. Exchange transfusion, in which a patient is simultaneously venesected and transfused to replace HbS with HbA, may be used in life-threatening crises or to prepare patients for surgery.

A high HbF level inhibits polymerisation of HbS and reduces sickling. Patients with sickle-cell disorder and high HbF levels have a mild clinical course with few crises. Some agents are able to increase synthesis of HbF, and this has been used to reduce the frequency of severe crises. The oral cytotoxic agent hydroxycarbamide has been shown to have clinical benefit with acceptable side-effects in children and adults who have recurrent severe crises and is prescribed as part of standard of care. Lower doses have been shown to be cost effective in low-income health services. The P-selectin inhibitor crizanlizumab was licensed for use to reduce vaso-occlusive crises, but was recently withdrawn from use in Europe because post-marketing surveillance showed no greater effect than placebo.

Potentially functional curative therapies are allogeneic stem cell transplantation and gene therapy. Allogeneic stem cell transplants from HLA-matched siblings have been performed and are potentially curative and safe with ~5% transplant-related mortality in recent cohorts, though GVHD is a serious potential side effect (p. 966). Ten-year follow-up data suggests improved cognitive function and quality of life in children receiving allogeneic stem cell transplantation compared with standard of care. Gene editing of autologous $CD34^+$ haematopoietic stem and progenitor cells with exagamglogene autotemcel (see p. 1009), following myeloablation, has been shown to eliminate vaso-occlusive crises in 97% of recipients for at least 12 consecutive months.

Prognosis

In Africa, few children with sickle-cell disorder survive to adult life without medical attention. Even with standard medical care, approximately 15% die by the age of 20 years and 50% by the age of 40 years.

Other abnormal haemoglobins

Haemoglobin C (HbC) disorder, another beta-chain haemoglobinopathy, is clinically silent but associated with microcytosis and target cells on the blood film. Compound heterozygotes inheriting one *HbS* gene and one *HbC* gene from their parents have haemoglobin SC disorder, which behaves like a mild form of sickle-cell disorder. SC disorder is associated with a reduced frequency of crises but is not uncommonly associated with complications in pregnancy and retinopathy.

Thalassaemias

Thalassaemia is an inherited impairment of haemoglobin production, in which there is partial or complete failure to synthesise a specific type of globin chain. In alpha-thalassaemia, disruption of one or both alleles on chromosome 16 may occur, with production of some or no alpha globin chains. In beta-thalassaemia, defective production usually results from disabling point mutations causing no (β^0) or reduced (β^-) beta chain production.

Beta-thalassaemia

Failure to synthesise beta chains (beta-thalassaemia) is the most common type of thalassaemia, most prevalent in the Mediterranean area. Heterozygotes have thalassaemia minor, a condition in which there is usually mild microcytic anaemia and little or no clinical disability, and may be detected only when iron therapy for a mild microcytic anaemia fails. Homozygotes (thalassaemia major) either are unable to synthesise haemoglobin A or, at best, produce very little; after the first 4–6 months of life, they develop profound transfusion-dependent hypochromic anaemia. The diagnostic features are summarised in Box 24.43. Intermediate grades of severity occur.

Management and prevention

Treatment is summarised in Box 24.44. Functional cure is now a possibility for selected children with allogeneic HSCT (p. 966) or gene editing therapy (p. 1009). In a recent trial, gene editing of $CD34^+$ haematopoietic stem and progenitor cells with exagamglogene autotemcel, with prior myeloablation, resulted in transfusion independence in 91% of treated patients with transfusion-dependent beta-thalassaemia, because increased levels of HbF compensate for the lack of HbA. It is possible to identify a fetus with homozygous beta-thalassaemia by obtaining chorionic villous material for DNA analysis sufficiently early in pregnancy to allow termination. This examination is appropriate only if both parents are known to be carriers (beta-thalassaemia minor) and will accept a termination.

Alpha-thalassaemia

Reduced or absent alpha-chain synthesis is common in South-east Asia. There are two alpha gene loci on chromosome 16 and therefore each individual carries four alpha gene alleles.

- If one is deleted, there is no clinical effect.
- If two are deleted, there may be a mild hypochromic anaemia.
- If three are deleted, the patient has haemoglobin H disease.
- If all four are deleted, the baby is stillborn (hydrops fetalis).

Haemoglobin H is a beta-chain tetramer, formed from the excess of beta chains, which is functionally useless, so that patients rely on their low levels of HbA for oxygen transport. Treatment of haemoglobin H disease is similar to that of beta-thalassaemia of intermediate severity, involving folic acid supplementation, transfusion if required and avoidance of iron therapy.

24.43 Diagnostic features of beta-thalassaemia

Beta-thalassaemia major (homozygotes)

- Profound hypochromic anaemia
- Evidence of severe red cell dysplasia
- Erythroblastosis
- Absence or gross reduction of the amount of haemoglobin A
- Raised levels of haemoglobin F
- Evidence that both parents have thalassaemia minor

Beta-thalassaemia minor (heterozygotes)

- Mild anaemia
- Microcytic hypochromic erythrocytes (not iron-deficient)
- Some target cells
- Punctate basophilia
- Raised haemoglobin A_2 fraction

24.44 Treatment of beta-thalassaemia major

Problem	Management
Erythropoietic failure	Allogeneic HSCT from HLA-compatible sibling Gene editing therapy Transfusion to maintain Hb > 100 g/L Folic acid 5 mg daily
Iron overload	Iron therapy contraindicated Iron chelation therapy
Splenomegaly causing mechanical problems, excessive transfusion needs	Splenectomy; see Box 24.40

(Hb = haemoglobin; HLA = human leucocyte antigen; HSCT = haematopoietic stem cell transplantation)

Haematological malignancies

Haematological malignancies arise when the processes controlling proliferation, differentiation or apoptosis are corrupted in blood cells because of acquired mutations in key regulatory genes. If mature differentiated cells are involved, the cells tend to have a low growth fraction and produce indolent neoplasms, such as the low-grade lymphomas or chronic leukaemias, when patients have an expected survival of many years. In contrast, if primitive stem or progenitor cells are involved the cells can have the highest growth fractions of all human neoplasms, producing rapidly progressive life-threatening illnesses such as acute leukaemias. In general, haematological neoplasms are diseases of older patients, the exceptions being acute lymphoblastic leukaemia, which predominantly affects children, and Hodgkin lymphoma which predominantly affects people aged 20–40 years. Management of young patients with haematological malignancy is particularly challenging (Box 24.45) and the issues associated with haematological malignancy in older age are described in Box 24.46.

Leukaemias

Leukaemias are malignant disorders of the white cell compartment, characteristically associated with increased numbers of white cells in the bone marrow and/or peripheral blood. The course of leukaemia may vary from a few days or weeks to many years, depending on the type.

24.45 Consequences of haematological malignancy in adolescence

- **Tailored management protocols**: the most effective treatment schedules for leukaemia and lymphoma differ between children and adults. Adolescent patients may be most appropriately managed in specialist centres.
- **Psychosocial effects**: adolescents undergoing treatment for haematological malignancy may suffer significant consequences for their schooling and social development, and require support from a multidisciplinary team.
- **'Late effects'**: adolescents who have been treated with chemotherapy and/or radiotherapy in childhood may be at risk of a wide range of complications, depending on the region irradiated, radiation dose and the drugs used. Particularly relevant complications in this age group include short stature, growth hormone deficiency, delayed puberty and cognitive dysfunction affecting schooling (after cranial irradiation). Life-long follow-up is often undertaken to detect and manage these late effects and to deal with consequences such as infertility and second malignancy.

24.46 Haematological malignancy in old age

- **Median age**: approximately 70 years for most haematological malignancies.
- **Poor-risk biological features**: adverse cytogenetics or the presence of a multidrug resistance phenotype are more frequent.
- **Prognosis**: increasing age is an independent adverse variable in acute leukaemia and aggressive lymphoma.
- **Chemotherapy**: may be less well tolerated. Older people are more likely to have antecedent cardiac, pulmonary or metabolic problems, tolerate systemic infection less well and metabolise cytotoxic drugs differently.
- **Cure rates**: similar to those in younger patients, in those who do tolerate treatment.
- **Decision to treat**: should be based on the individual's biological status, the level of social support available, and the patient's wishes and those of the immediate family, but not on chronological age alone.

Terminology and classification

Leukaemias are traditionally classified into four main groups:

- acute lymphoblastic leukaemia (ALL)
- acute myeloid leukaemia (AML)
- chronic lymphocytic leukaemia (CLL)
- chronic myeloid leukaemia (CML).

In acute leukaemias, there is proliferation of mutated haematopoietic stem and progenitor cells with limited accompanying differentiation, leading to an accumulation of blasts predominantly in the bone marrow causing bone marrow failure. In chronic leukaemias, the malignant clone can differentiate resulting in an accumulation of more mature cells. Lymphocytic and lymphoblastic cells are those derived from the lymphoid progenitor cells (B cells and T cells). Myeloid refers to the other lineages: that is, precursors of red cells, granulocytes, monocytes and platelets (see Fig. 24.2).

The diagnosis of leukaemia is usually suspected from an abnormal blood count, often including a raised white count, and is confirmed by examination of the bone marrow. This includes the morphology of the abnormal cells, analysis of cell surface markers (immunophenotyping), karyotyping to identify clone-specific chromosome abnormalities and molecular studies to identify changes in a wide range of genes. These results are incorporated in the World Health Organization (WHO 5th edition) and International Consensus Classification (ICC) of tumours of haematopoietic and lymphoid tissues; the subclassification of acute leukaemias as per WHO is shown in Box 24.47. The morphological, immunological and genetic features identified in the bone marrow leukaemia cells not only provide an accurate diagnosis, but also give valuable prognostic information, increasingly allowing therapy to be tailored to the patient's disease.

Epidemiology and aetiology

The incidence of leukaemia of all types in the population is approximately 10/10 000 per annum, of which just under half are cases of acute leukaemia. Males are affected more frequently than females, the ratio being about 3:2 in acute leukaemia, 2:1 in chronic lymphocytic leukaemia and 1.3:1 in chronic myeloid leukaemia. Geographical variation in incidence does occur, the most striking being the rarity of chronic lymphocytic leukaemia in Chinese and related races. Acute leukaemia occurs at all ages. Acute lymphoblastic leukaemia shows a peak incidence in children aged 1–5 years. All forms of acute myeloid leukaemia have their lowest incidence in children and young adult life and there is a striking rise over the age of 50. Chronic leukaemias occur mainly in middle and old age.

The cause of the leukaemia is unknown in most patients. Several risk factors have been identified (Box 24.48).

Acute leukaemia

Genetic mutations in haematopoietic stem cells produce leukaemic stem cells. Proliferation of these cells that do not differentiate (mature) leads to an accumulation of primitive and functionless cells (blasts) that take up more and more marrow space at the expense of the normal haematopoietic cells, leading to bone marrow failure. Eventually, this proliferation spills into the blood. Acute myeloid leukaemia (AML) is about four times more common than acute lymphoblastic leukaemia (ALL) in adults. In children, the proportions are reversed, the lymphoblastic variety being more common. The clinical features are usually those of the triad of bone marrow failure (anaemia, bleeding or infection; pp. 952, 957 and 959).

i 24.47 WHO 5th edition classification of acute leukaemia*

- Acute myeloid leukaemia (AML) with defining genetic abnormalities
- Acute myeloid leukaemia (AML) defined by differentiation
- Acute lymphoblastic leukaemia (ALL)
  - B-lymphoblastic leukaemia/lymphoma
  - T-lymphoblastic leukaemia/lymphoma

*Each category has multiple subtypes available in the 5th edition of the World Health Organization Classification of Haematolymphoid Tumours, 2022.

Investigations

Blood examination usually shows anaemia with a normal or raised MCV. The leucocyte count may vary from as low as 1×10^9/L to as high as 300×10^9/L or more. In most patients, the count is below 100×10^9/L. Despite raised WCCs there is commonly neutropenia with blast cells predominating. Severe thrombocytopenia is usual but not invariable. Frequently, blast cells are seen in the blood film, but sometimes the blast cells may be infrequent or absent. A bone marrow examination will confirm the diagnosis. The bone marrow is usually hypercellular, with replacement of normal elements by leukaemic blast cells to varying degrees. The presence of Auer rods (coalesced granules) in the cytoplasm of blast cells indicates a myeloblastic type of leukaemia.

Most subtypes of acute leukaemias are diagnosed when the blast count is more than 20% of the cells (Fig. 24.26). However, the most recent classification systems (WHO 5th edition and International Consensus Classification; ICC) allow some genetic types of leukaemia to be diagnosed at lower blast counts, i.e. 10% in ICC and even at any blast count e.g. AML with *NPM1* mutation in WHO. Furthermore, the ICC has introduced a new category of MDS/AML for some chromosomal and genetic variants with blast counts between 10% and 19%. These and several other inconsistencies between the WHO 5th edition and ICC

i 24.48 Risk factors for leukaemia

Ionising radiation

- After atomic bombing of Japanese cities (myeloid leukaemia)
- Radiotherapy
- Diagnostic X-rays of the fetus in pregnancy

Cytotoxic drugs

- Especially alkylating agents and topoisomerase II inhibitors (therapy-related myeloid malignancies), usually after a latent period of several years with alkylating agents and a few months to 2 years with topoisomerase II inhibitors
- Industrial exposure to benzene

Retroviruses

- Adult T-cell leukaemia/lymphoma (ATLL) caused by human T-cell lymphotropic virus 1 (HTLV-1), most prevalent in Japan, the Caribbean and some areas of Central and South America and Africa

Genetic

- Identical twin of patients with leukaemia
- Down syndrome and certain other genetic syndromes
- Familial single gene disorders (e.g. *GATA-2* mutation/deficiency, *RUNX1* mutation)

Immunological

- Immune deficiency states (e.g. hypogammaglobulinaemia)

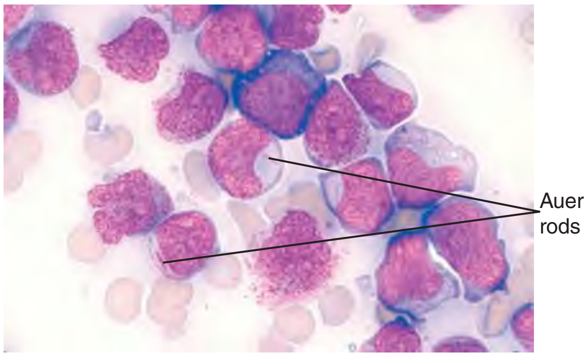

Fig. 24.26 Acute myeloid leukaemia. Bone marrow smear showing large abnormal blast cells, some with Auer rods. *Modified from Rozenberg G. Microscopic haematology. 3rd ed. Sydney: Elsevier Australia; 2011, Fig. B6–18.*

have been problematic for practitioners in day-to-day practice. However, both systems rely on the key principle that classifications and prognoses are determined by immunophenotyping, chromosome and molecular analysis, as shown in Figure 24.27.

Management

Whenever possible, patients with acute leukaemia should be treated within a clinical trial. The subtype of acute leukaemia, patient fitness and comorbidities, and individual patient wishes and expectations are important considerations in therapeutic decision-making. This process can take up to a week while information is gathered (Fig. 24.28). During this hiatus the patient should be prepared as recommended in Box 24.49. It is unwise to attempt intensive management of acute leukaemia unless adequate supportive therapy can be provided. Indeed, better supportive care has been the cornerstone of improved survival over the last 50 years, despite new non-transplant therapeutic benefits only occurring during the last 10 years or so.

The aim of treatment is to eradicate the leukaemic clone of cells without destroying the residual normal stem cell compartment from which repopulation of the haematopoietic tissues will occur. The details of the schedules for treatments are found in specialist texts. The drugs most employed are listed in Box 24.50. Generally, if a patient fails to go into remission with induction treatment, alternative drug combinations may be tried, but the outlook is poor unless remission can be achieved. Disease that relapses during treatment or soon after the end of treatment, including after HSCT, carries a poor prognosis and is difficult to treat. The longer after the end of treatment that relapse occurs, the more likely it is that further treatment will be effective. In some very frail and elderly patients, or in those who have failed multiple lines of therapy, alternative palliative chemotherapy, not designed to achieve remission, may be used to curb excessive leucocyte proliferation, e.g. hydroxycarbamide. The aim is to reduce the blast count without inducing bone marrow failure and maintain quality of life.

Specific therapy

Acute myeloid leukaemia (AML) AML is predominantly a disease of the elderly, and many patients are frail. Treatment has become more complex in recent years and is increasingly tailor-made for AML subgroups defined by genetic abnormalities or persistence of measurable residual disease (MRD). The first decision must be whether to give specific treatment to attempt to achieve remission. The most effective remission induction therapy remains intensive combination chemotherapy. This is

i 24.49 Preparation for specific therapy in acute leukaemia

- Assess comorbidities and performance status
- Assess cardiac function prior to anthracycline use
- Existing infections identified and treated (e.g. urinary tract infection, oral candidiasis, dental, gingival and skin infections)
- Anaemia corrected by red cell concentrate transfusion
- Thrombocytopenic bleeding controlled by platelet transfusions
- If possible, central venous catheter (e.g. PICC/Hickman line) inserted to facilitate access to the circulation for delivery of chemotherapy, fluids, blood products and other supportive drugs
- Tumour lysis risk assessed and prevention started: fluids with allopurinol or rasburicase
- Therapeutic regimen carefully explained to the patient and informed consent obtained
- Consideration of entry into clinical trial

(PICC = peripherally inserted central catheter)

24.50 Drugs commonly used in the treatment of acute leukaemia

Phase	Acute lymphoblastic leukaemia	Acute myeloid leukaemia
Induction	Vincristine (IV) Dexamethasone (oral) L-Asparaginase (IM) Daunorubicin (IV) Methotrexate (intrathecal) Imatinib (oral)* Blinatumomab	Daunorubicin (IV) Cytarabine (IV) Vyxeos liposomal (IV) Etoposide (IV and oral) Gemtuzumab ozogamicin (IV) All-*trans* retinoic acid (ATRA) (oral) Arsenic trioxide (ATO) (IV) Midostaurin (oral) Quizartinib (oral) Azacitidine Venetoclax Ivosidenib
Consolidation	Daunorubicin (IV) Cytarabine (IV) Etoposide (IV) Methotrexate (IV) Imatinib/dasatinib (oral)*	Cytarabine (IV) Amsacrine (IV) Mitoxantrone (IV)
Maintenance	Prednisolone (oral) Vincristine (IV) Mercaptopurine (oral) Methotrexate (oral) Imatinib (oral)*/dasatinib (oral)	Azacitidine (oral) Midostaurin (oral) Quizartinib (oral)
Relapse	Fludarabine (IV) Cytarabine (IV) Idarubicin (IV) Blinatumomab	Fludarabine (IV) Cytarabine (IV) Arsenic trioxide (ATO) (IV) Idarubicin (IV) Gilteritinib

*If Philadelphia chromosome-positive. (IM = intramuscular; IV = intravenous).

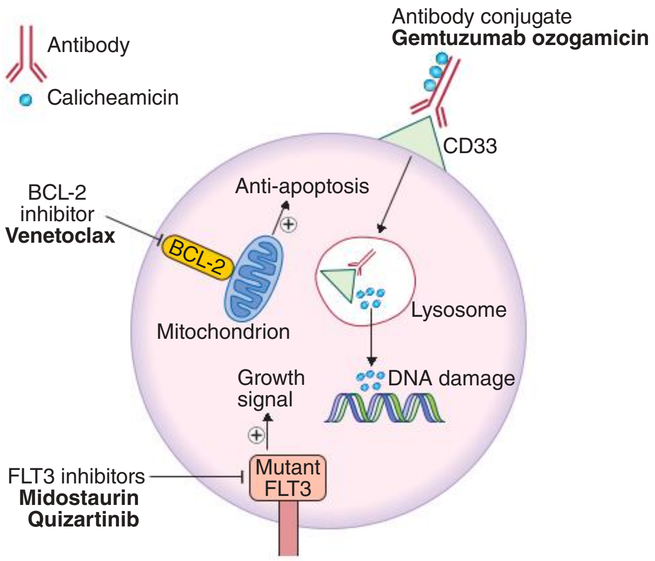

Fig. 24.29 Targeted therapies for acute myeloid leukaemia (AML). Small molecules midostaurin and quizartinib inhibit mutant FLT3 molecules and are used in combination with chemotherapy and as maintenance therapy. Gilteritinib inhibits mutant FLT3 and is used on its own for relapsed patients. Venetoclax inhibits BCL-2 and so induces apoptosis; it is used with the drug azacitidine in older, frailer patients. Gemtuzumab ozogamicin is a conjugate of an antibody and a chemotherapy agent. The antibody binds to CD33 on the cell surface; antibody and CD33 are internalised and the chemotherapy agent calicheamicin causes DNA damage. (BCL-2 = B-cell lymphoma-2; FLT3 = FMS-like tyrosine kinase 3)

a rigorous undertaking for patients, leading to profound bone marrow failure for two to three weeks and associated numerous side-effects. This may not be appropriate for the very old or patients with serious comorbidities. In such patients, supportive treatment can improve well-being, but there remains considerable unmet need as achieving remission positively impacts quality of life. For decades low-intensity chemotherapy, such as single agent low-dose cytosine arabinoside or in recent years single agent azacitidine, have frequently been used in older and frailer patients, but these induce remission in less than 20% of patients. Recently, the addition of the BCL-2 inhibitor venetoclax to azacitidine or cytosine arabinoside has shown significantly improved overall survival, especially the combination with azacitidine (14 months vs 9 months) and this has become the standard of care in patients unfit for intensive chemotherapy (Fig. 24.29).

There are currently three phases of specific treatment for AML:

- *Remission induction*. In this phase, a fraction of the tumour is killed by combinations of chemotherapy drugs. The standard of care for remission induction in AML is daunorubicin with cytosine arabinoside given for 7–10 days in two cycles. Patients with a good or standard risk karyotype, including normal karyotype, benefit from the addition of the antibody–drug conjugate gemtuzumab ozogamicin, which targets CD33 on the AML cell and delivers the DNA damaging drug calicheamicin directly into the cell (see Fig. 24.29), while AML with the *FLT3-ITD* mutation benefits from the addition of the FLT3 inhibitor midostaurin (see Fig. 24.29). Fit, older patients with secondary AML following prior cancer therapy or MDS benefit from a liposomal version of daunorubicin and cytarabine: Vyxeos liposomal. The patient goes through a period of severe bone marrow hypoplasia lasting 2–4 weeks and requires intensive support and inpatient care from a specially trained multidisciplinary team. The aim is to achieve remission, a state in which the blood counts return to normal and the marrow blast count is less than 5%. Quality of life and potential cure is highly dependent on achieving remission; hence, remission induction is the preferred therapy for all patients who are considered fit enough to undergo such treatment.

  For patients unfit for intensive chemotherapy, azacitidine with venetoclax or cytosine arabinoside is given for multiple 21- to 28-day cycles. These combinations are myelosuppressive, especially in the first two cycles before achieving remission, and for this reason the optimal dosing of venetoclax remains uncertain, with several schedules used around the world. Recently patients with *IDH1* pathogenic variants have benefitted from the licensed combination of azacitidine with the IDH1 inhibitor ivosidenib, compared to azacitidine alone. Some genetic subtypes of AML are particularly susceptible to azacitidine and venetoclax combinations, including those with *NPM1* and *IDH1/2* mutations. It remains to be seen whether all patients with such types of AML are better treated with these lower intensive combinations over traditional intensive combination chemotherapy.
- *Remission consolidation*. If remission is achieved, residual disease is reduced further by therapy during the consolidation phase. For those patients following the intensive treatment pathway, this consists of additional courses of chemotherapy, most commonly 1–2 courses of high-dose cytosine arabinoside, again resulting in periods of marrow hypoplasia. In standard and poor-prognosis AML, defined by cytogenetic/molecular genetic abnormalities or persistent MRD, final consolidation includes allogeneic HSCT. For patients following lower intensive treatment pathways, cycles of azacitidine with venetoclax or cytosine arabinoside or ivosidenib are repeated indefinitely until relapse occurs, side-effects are intolerable, or the patient wishes to stop.
- *Remission maintenance*. Maintenance therapy has only recently become an effective tool for some patients with AML compared to its long-established role in ALL. Patients not undergoing allogeneic HSCT with *FLT3* mutated AML receive one year of maintenance with midostaurin. Other non-transplanted patients can benefit from oral azacitidine maintenance.

Relapsed AML carries a poor prognosis. Increasingly, this is pre-empted by monitoring MRD molecularly or by flow cytometry and intervening before haematological relapse occurs. However, whether in a state of MRD relapse or full-blown haematological relapse, the aim is to attempt to achieve further remission and deliver an allogeneic HSCT, if possible.

Acute promyelocytic leukaemia (APML)

A subtype of AML, called acute promyelocytic leukaemia (APML), is characterised by a block in differentiation of malignant promyelocytes. These cells accumulate and lead to bone marrow failure and a tendency to severe bleeding, including into the CNS, because of enhanced fibrinolysis and DIC induced by the procoagulant proteins in the malignant cells, e.g. tPA and uPA. This leukaemia is caused by a translocation of genes on chromosomes 15 (*PML*) and 17 (*RARA*) producing the *PML-RARA* rearrangement, which drives the leukaemia. APML carries the best prognosis of all AML if the patient survives the initial bleeding risk. Furthermore, low-risk cases are effectively treated with a non-chemotherapy regimen of differentiation therapy with all-*trans*-retinoic acid (ATRA) and arsenic trioxide (ATO). Higher-risk patients are treated with ATRA and anthracycline-based chemotherapy or more recently with ATRA and ATO and single agent anthracycline. The prognosis is excellent with 90% cure rate for patients receiving treatment. However, the early death rate from bleeding remains problematic, and intensive supportive care and immediate introduction of ATRA therapy is vital to prevent this.

Acute lymphoblastic leukaemia (ALL) This is predominantly a disease of childhood with a mean age of 2–4 years. However, it also occurs in adulthood, where it is more difficult to treat and carries a poorer prognosis. Once again there are three phases of therapy with treatment tailor-made to risk groups based on genetic abnormalities and levels of MRD. Early MRD response remains the most important prognostic marker in ALL and is a key factor in determining the relapse risk and most appropriate treatment strategy.

- *Remission induction*. As with AML, the aim is to achieve remission using a combination of chemotherapy drugs given over a 4-week period. The drugs commonly used are dexamethasone, vincristine, anthracyclines, methotrexate, mercaptopurine and asparaginase. Induction therapy in ALL is often less damaging and better tolerated than AML; however, the high dosage of glucocorticoids coupled with neutropenia carries a high risk of infections, including fungal infections. Adult patients are more likely to have poor-risk genetic abnormalities. A *BCR::ABL1* rearrangement occurs in about 25% of adult patients; known as Philadelphia positive (Ph+) ALL. Traditionally, TKI therapy, e.g. dasatinib, combined with glucocorticoids and chemotherapy has been the treatment of choice for Ph+ ALL, producing high, but poorly sustained, remission rates (Fig. 24.30). Recently, so-called chemotherapy-free regimens have come to the fore in Ph+ ALL. The TKI ponatinib combined with blinatumomab, a bispecific antibody against CD19 and CD3 to promote T-cell killing (bispecific T-cell engager, BiTE; p. 968), produces very high remission rates > 90%, though relapses remain frequent without consolidation with allogeneic stem cell transplantation. Blinatumomab is likely to have a wider role in ALL in the coming years. A recent large randomised study in children with standard-risk ALL and medium or high risk of relapse demonstrated a significant improvement in disease-free survival with the addition of two cycles of blinatumomab to standard chemotherapy; so much so that the trial was stopped early.

  Old and frail patients with ALL tolerate treatment much less well and require appropriately modified treatment. Adolescent and young adult patients require special support and do better with children's protocols than adult protocols.
- *Remission consolidation*. The consolidation phase builds on the remission by further decreasing the leukaemic burden. The intensity of consolidation depends on the level of MRD at the end of remission induction and includes blocks of chemotherapy drugs. Blinatumomab is increasingly introduced to eradicate persistently positive MRD. Allogeneic HSCT remains a standard of care as consolidation for fit adults with ALL and a suitable donor, but is rarely used in children unless they relapse.

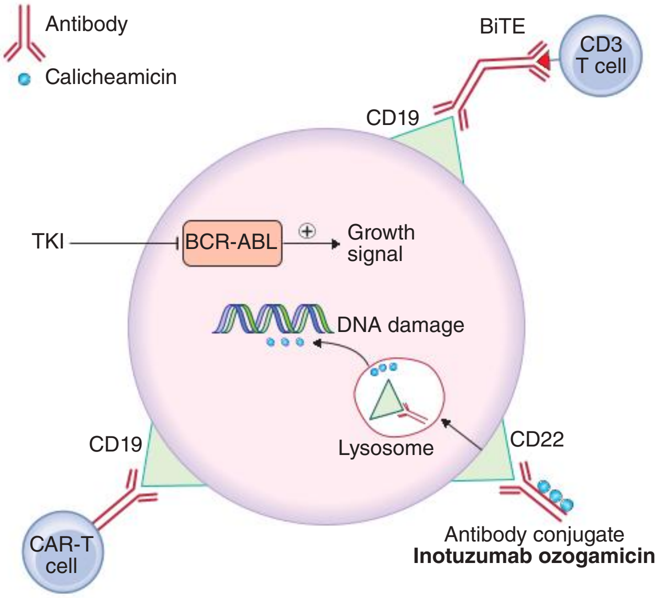

Fig. 24.30 Targeted therapies for acute lymphoblastic leukaemia (ALL). Chimeric antigen receptor T (CAR-T) cells and bispecific T-cell engager (BiTE) (see Fig. 24.18) both promote T-cell killing of the ALL cell. CAR-T as described in Fig. 24.17 and BiTE (blinatumomab) by using an antibody that can simultaneously bind to a leukaemia cell and a T cell to bring them together. TKIs include imatinib, dasatinib and ponatinib. Inotuzumab ozogamicin is a conjugate of an antibody and a chemotherapy agent. The antibody binds to CD22 on the cell surface; antibody and CD22 are internalised and the chemotherapy agent calicheamicin causes DNA damage. (TKI = tyrosine kinase inhibitor)

- *Remission maintenance*. If the patient is still in remission after the consolidation phase for ALL, and is not progressing to allogeneic HSCT, they embark on maintenance therapy with the individual as an outpatient and treatment consisting of a repeating cycle of drug administration. This may extend for up to 3 years if relapse does not occur. In ALL, prophylactic treatment to the central nervous system is required. This is a sanctuary site where standard therapy does not penetrate. This usually consists of a combination of cranial irradiation, intrathecal chemotherapy and high-dose methotrexate, which crosses the blood–brain barrier. Such therapy is integrated into the induction, remission and consolidation phases of therapy.

Relapsed ALL is a complex area and ranges from positive MRD, isolated CNS or testicular relapse to full-blown haematological relapse. The aim is to achieve further remission and frequently to deliver allogeneic HSCT. Newer therapies for relapse again include blinatumomab, which is rapidly becoming a backbone for various stages of ALL therapy. Blinatumomab is shown to be more effective and gives longer survival than further chemotherapy in heavily pre-treated adults with relapsed ALL. Inotuzumab ozogamicin (which targets CD22 and delivers calicheamicin directly into the cell; see Fig. 24.30), nelarabine in T-cell ALL and increasingly CAR-T therapy in selected cases (see Fig. 24.17) are also available for relapsed patients. Some cures occur with these therapies.

Supportive therapy

Aggressive and potentially curative therapy, which involves periods of severe bone marrow failure, would not be possible without appropriate supportive care. The following problems commonly arise.

Anaemia Anaemia is treated with red cell concentrate transfusions.

Bleeding Thrombocytopenic bleeding requires platelet transfusions, unless the bleeding is trivial. Recent trials have confirmed that in acute leukaemia prophylactic platelet transfusion should be given to maintain the platelet count above 10 × 10^9/L. Coagulation abnormalities occur and need accurate diagnosis and treatment, especially in APML (see above).

Infection So-called neutropenic sepsis is a major complication of acute leukaemia and its treatment. Every leukaemia centre will have a written definition and management policy for this common event. UK NICE guidelines define neutropenic sepsis as fever (> 38°C) lasting over 1 hour in a neutropenic patient (neutrophils < 0.5 × 10^9/L) or with other signs or symptoms of significant sepsis (see also p. 178). Parenteral broad-spectrum antibiotic therapy is essential. Empirical therapy is given according to the perceived severity of the sepsis illness and local bacteriological resistance patterns. Increasingly, low-risk cases of neutropenic sepsis are treated with single antibiotics, e.g. piperacillin/tazobactam. Higher-risk cases are managed with regimens such as a combination of an aminoglycoside (e.g. gentamicin) and a broad-spectrum penicillin (e.g. piperacillin/tazobactam) or a single-agent β-lactam (e.g. meropenem). The organisms most associated with neutropenic sepsis are gram-positive bacteria, such as *Staphylococcus aureus* and *Staphylococcus epidermidis*, which are present on the skin and gain entry via cannulae and central lines. Gram-negative infections often originate from the gastrointestinal tract, which is affected by chemotherapy-induced mucositis; organisms such as *Escherichia coli*, *Pseudomonas* and *Klebsiella* spp. are likely to cause rapid clinical deterioration and must be covered with initially empirical antibiotic therapy. Gram-positive infection may require vancomycin or teicoplanin therapy. If fever has not resolved after 3–5 days and there is evidence for a disseminated fungal infection on CT scans or sensitive blood tests, antifungal therapy (e.g. a liposomal amphotericin B preparation, voriconazole or caspofungin) is added.

Patients with ALL are susceptible to infection with *Pneumocystis jirovecii* (Ch. 14), which causes a severe pneumonia. Prophylaxis with co-trimoxazole is given during chemotherapy. Diagnosis may require induced sputum, bronchoalveolar lavage or open lung biopsy. Treatment is with high-dose co-trimoxazole, initially intravenously, changing to oral treatment as soon as possible.

Oral and pharyngeal *Candida* infections are common. Fluconazole is effective for the treatment of established local infection and for prophylaxis against systemic candidaemia. Prophylaxis against other systemic fungal infections including *Aspergillus*, for example with itraconazole or posaconazole, is usual practice during high-risk intensive chemotherapy and stem cell transplantation. Markers of early fungal infection to guide treatment initiation in at-risk patients include *Aspergillus* antigen and β-D-glucan (BDG), but their use remains non-standardised with issues around sensitivity and specificity. As noted above, most centres rely on early CT scanning to identify radiological features of fungal infection, especially in the lungs (a 'pre-emptive approach').

For suspected or confirmed systemic fungal infection with *Candida* or aspergillosis, intravenous liposomal amphotericin, caspofungin or voriconazole is required for up to 3 weeks. In systemic *Candida* infection, intravenous catheters should be removed.

Reactivation of herpes simplex infection (Ch. 14) occurs frequently around the lips and nose during ablative therapy for acute leukaemia and is treated with aciclovir. This can be prescribed prophylactically to patients with a history of cold sores or elevated antibody titres to herpes simplex. Herpes zoster manifesting as chickenpox or, after reactivation, as shingles (Ch. 14) is treated promptly with high-dose aciclovir, as it can be fatal in immunocompromised patients.

The value of isolation facilities, such as laminar flow rooms, is debatable, but may contribute to staff awareness of careful reverse barrier nursing practice. Isolation can be psychologically stressful for the patient.

Metabolic problems Frequent monitoring of fluid balance and renal, hepatic and haemostatic function is necessary. Patients are often severely anorexic and diarrhoea is common because of the side-effects of therapy; they may find drinking difficult and hence require intravenous fluids and electrolytes. Renal toxicity occurs with some antibiotics (e.g. aminoglycosides) and antifungal agents (amphotericin). Cellular breakdown during induction therapy (tumour lysis syndrome; p. 178) releases intracellular ions and nucleic acid breakdown products, causing hyperkalaemia, hyperuricaemia, hyperphosphataemia and hypocalcaemia. This may lead to renal failure. Allopurinol and intravenous hydration are given to try to prevent this. In patients at high risk of tumour lysis syndrome, e.g. acute leukaemia with a white cell count of more than 100 × 10^9/L, prophylactic rasburicase (a recombinant urate oxidase enzyme) is used. Occasionally, dialysis may be required.

Psychological problems Psychological support is a key aspect of care. Patients must be kept informed, and their questions answered, and fears allayed as far as possible. A multidisciplinary approach to patient care involves input from many services, including psychology. Key members of the team include haematology specialist nurses, who are often the central point of contact for patients and families throughout the illness.

Haematopoietic stem cell transplantation (HSCT)

Described on page 966, HSCT remains the most effective therapeutic strategy in difficult to treat acute leukaemia. In patients with high-risk acute leukaemia, allogeneic HSCT can improve 5-year survival from 20% to around 50%. Reduced-intensity conditioning has allowed delivery of allogeneic HSCT to a higher proportion of patients with acute leukaemias, up to the age of about 70 years, and therefore into age groups where AML is most prevalent. Improved knowledge of the biology of leukaemia alters the definition of high risk. For example, patients with AML with a normal karyotype and isolated *NPM1* gene mutations are considered good risk and are not routinely transplanted in first remission unless they demonstrate persistent MRD. However, otherwise similar patients with isolated *FLT3-ITD* mutations are intermediate risk and considered for transplant in first remission.

Prognosis

Without treatment, the median survival of patients with acute leukaemia is a few weeks. This is extended to a few months with supportive treatment. Patients who achieve remission with specific therapy have a better outlook. Around 80% of adult patients under 60 years of age with ALL or AML achieve remission, although remission rates are lower for older patients. However, the relapse rate continues to be high. Box 24.51 shows the survival in ALL and AML and the influence of prognostic features. The MRD can be a powerful prognostic tool and is now used routinely in some forms of acute leukaemia (e.g. ALL and AML with *NPM1* mutation) to determine subsequent consolidation therapy.

Advances in treatment have led to steady improvement in survival from acute leukaemia. Some 90% of children are cured from ALL and about 50%–60% of adults aged less than 60 years are cured from AML.

24.51 Examples of outcome in adult acute leukaemia

Disease/ cytogenetic risk	Risk factors	5-year overall survival
Acute myeloid leukaemia (AML)		
Favourable	Promyelocytic leukaemia t(15;17)	90%
		65%
		70%
Adverse	Cytogenetic abnormalities −5, −7, del 5q, abn(3q), complex (> 5)	21%
Intermediate risk	AML with none of the above	48%
Acute lymphoblastic leukaemia (ALL)		
Adverse	Philadelphia chromosome High white count > 100 × 10^9/L Abnormal short arm of chromosome 11 t(1;19)	20%
Standard	ALL with none of the above	37%

As discussed above, APML has a 90% cure rate. Prognosis remains poor in most other groups of patients with acute leukaemias, especially in old age. Current trials aim to improve survival, especially in intermediate and adverse risk disease, with strategies that include better use of allogeneic HSCT, better ability to predict relapse using MRD and new targeted therapies (see Figs. 24.29 and 24.30).

Chronic myeloid leukaemia

Chronic myeloid leukaemia (CML) is a myeloproliferative disorder arising from mutated stem cells and resulting in proliferation of all haematopoietic lineages, but manifesting predominantly in the granulocytic series. Maturation of blood cells generally proceeds normally; hence, bone marrow failure is not a feature. The disease occurs chiefly between the ages of 30 and 80 years, with a peak incidence at 55 years. It is rare, with an annual incidence in the UK of 1.8/100 000, and accounts for 15% of all leukaemias. It occurs in all races.

The defining characteristic of CML is the chromosome abnormality known as the Philadelphia (Ph) chromosome. This is a shortened chromosome 22 resulting from a reciprocal translocation of material with chromosome 9. The break on chromosome 22 occurs in the breakpoint cluster region (*BCR*). The fragment from chromosome 9 that joins the *BCR* carries the *abl* oncogene, which forms a fusion gene with the remains of the *BCR*. This *BCR::ABL1* fusion gene codes for a 210 kDa protein with tyrosine kinase activity, which plays a causative role in the disease as an oncogene, influencing cellular proliferation, differentiation and survival. This is also the target for very effective tyrosine kinase inhibitor (TKI) therapy (Fig. 24.31 and see Box 24.21). In some patients in whom conventional chromosomal analysis (karyotyping) does not detect a Ph chromosome, the *BCR::ABL1* mRNA product is detectable by molecular techniques (polymerase chain reaction, PCR).

Natural history

Traditionally, the disease has been described in three phases:

- *A chronic phase*, in which the disease is responsive to treatment and is easily controlled, which used to last 3–5 years. With the introduction of the tyrosine kinase inhibitors (TKIs) (Box 24.52), this phase is prolonged to encompass a normal life expectancy in many patients.
- *An accelerated phase* (not always seen or, indeed, nowadays included in classification systems such as WHO 5th edition), in which disease control becomes more difficult.
- *Blast crisis*, in which the disease transforms into an acute leukaemia, either myeloblastic (70%) or lymphoblastic (30%), which is relatively refractory to treatment. Prior to TKI therapy this was the cause of death in most patients; survival, therefore, depends on the timing of blast crisis, which historically could not be predicted. Prior to TKI therapy (see below), approximately 10% of patients per year would transform; the transformation rate has been reduced to 0.5%–2.5% per year with TKI therapy.

Clinical features

Symptoms at presentation may include lethargy, weight loss, abdominal discomfort, gout and sweating, but about 25% of patients are asymptomatic at diagnosis. Splenomegaly is present in 90%; in about 10% the enlargement is massive, extending to over 15 cm below the costal margin. A friction rub may be heard in cases of splenic infarction. Hepatomegaly occurs in about 50%. Lymphadenopathy is unusual. Patients with a very high white cell count ($>300 \times 10^9$/L) may present with symptoms of hyperviscosity, including headache, visual changes, somnolence, confusion, hypoxia and bleeding.

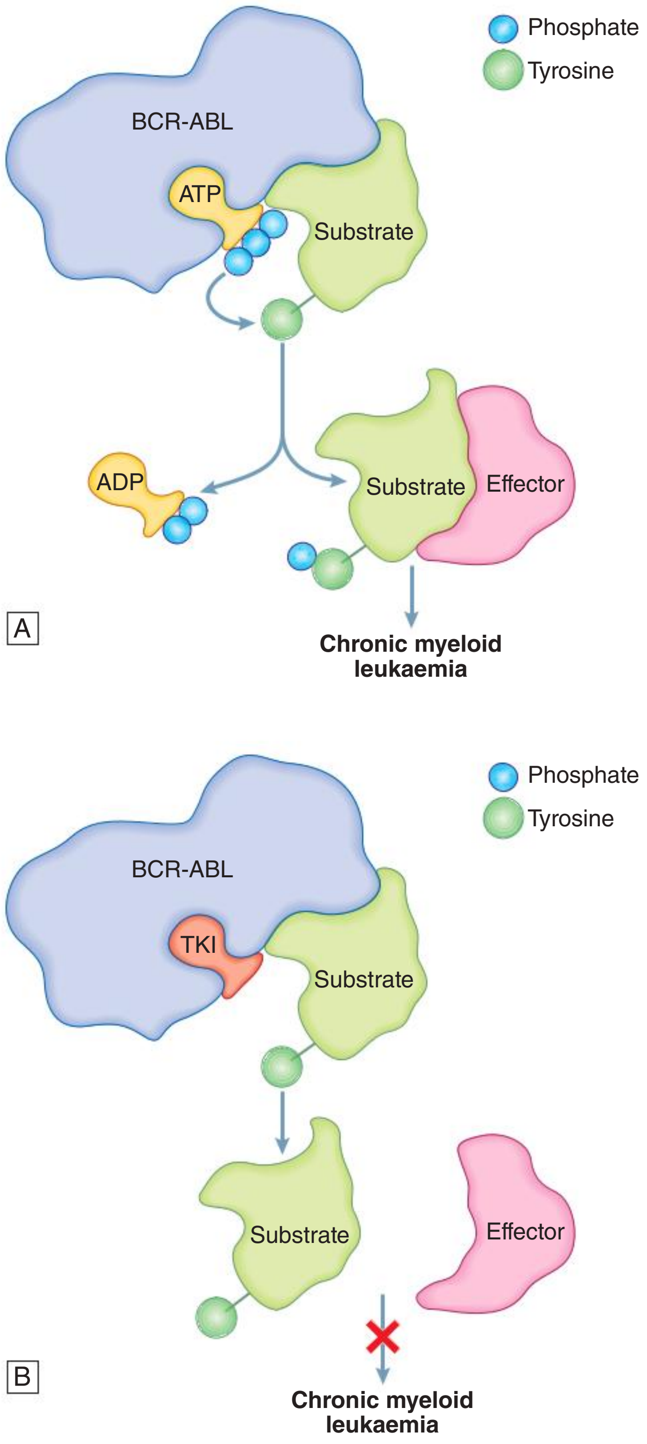

Fig. 24.31 Mode of action in tyrosine kinase inhibition of BCR-ABL. **A** Untreated CML. The BCR::ABL1 protein acts as 'rogue' tyrosine kinase. It phosphorylates tyrosine residues on substrate molecules, and hence activates these molecules, by transferring phosphate groups from ATP. In turn these molecules activate downstream effector molecules that cause CML. **B** Tyrosine kinase inhibitor (TKI) treatment (imatinib, dasatinib, nilotinib, ponatinib, bosutinib). These molecules bind to the tyrosine kinase domain of BCR::ABL1 and block the phosphorylation process and hence inhibit the downstream effector pathways, so reversing the process causing CML and leading to leukaemic cell death. (ATP = adenosine triphosphate; CML = chronic myeloid leukaemia)

Investigations

FBC results are variable between patients. There is usually a normocytic, normochromic anaemia. The leucocyte count can vary from 10 to 600 × 10^9/L. In about one-third of patients, there is a high platelet count, sometimes as high as 2000 × 10^9/L and occasionally a significant thrombocytosis is the only abnormality. The blood film demonstrates the full range of granulocyte precursors, from myeloblasts to mature neutrophils, but the predominant cells are neutrophils and myelocytes (see Fig. 24.3). Myeloblasts usually constitute less than 10% of all white cells.

24.52 Tyrosine kinase inhibition in chronic myeloid leukaemia

Agents

First-line
- Imatinib
- Nilotinib
- Dasatinib

Second-line
- Imatinib
- Nilotinib
- Dasatinib
- Bosutinib
- Ponatinib*

Third-line
- Asciminib (STAMP inhibitor)

Outcomes
- 90% achieve complete cytogenetic response
- Responses faster with nilotinib and dasatinib
- Median survival comparable to normal population

*For patients with T315I kinase domain mutations, use ponatinib.
(STAMP = specifically targeting the ABL myristoyl pocket)

There is often an absolute increase in eosinophils and basophils, and nucleated red cells are common. If the disease progresses through an accelerated phase, the percentage of more primitive cells increases. Blast transformation is characterised by a significant increase in the number of circulating blasts. In patients with thrombocytosis, very high platelet counts may persist during treatment, in both chronic and accelerated phases, but usually drop dramatically at blast transformation. Basophilia tends to increase as the disease progresses.

Bone marrow examination confirms the diagnosis and phase of disease by morphology, chromosome analysis to demonstrate the presence of the Ph chromosome, fluorescence in situ hybridisation (FISH) and RNA analysis to demonstrate the presence of the *BCR::ABL1* rearrangement. Blood LDH is elevated and uric acid may be high due to increased cell breakdown. Diagnosis can be made genetically on the peripheral blood, though most physicians still perform a marrow examination at diagnosis for morphology, particularly baseline blast enumeration and a karyotype looking for additional chromosomal abnormalities which may have prognostic significance.

Management

Chronic phase

There are now five available tyrosine kinase inhibitors (TKIs) for the treatment of CML (see Box 24.52), which specifically inhibit BCR::ABL1 protein tyrosine kinase domain activity leading to the death of leukaemia cells and normalisation of blood cell production. Imatinib (first-generation), nilotinib and dasatinib (second-generation) are licensed as first-line therapy in chronic phase of CML; they usually normalise the blood count within a month and within 3–6 months produce complete cytogenetic response (disappearance of the Ph chromosome) in some 90% of patients. Patients are monitored by 3-monthly real-time quantitative polymerase chain reaction (PCR) for *BCR::ABL1* mRNA transcripts in blood, a measure of the surviving number of leukaemia cells relative to normal cells. The European Leukaemia Net (ELN) guidelines have defined milestones for satisfactory response to TKI therapy using an international scale (Fig. 24.32). The aim is to reduce the *BCR::ABL1* transcript levels by 3–5 logs from baseline, called major molecular response (MR^3) and deep molecular response (MR^4–MR^5). A proportion of patients achieve a complete molecular response where the transcripts are not detectable by PCR. Up to 50% of patients with a prolonged complete or deep molecular response following five or more years of therapy may be able to discontinue TKIs without relapsing. For those failing to fulfill the response timelines, or who lose their response and progress on first-line therapy, options include switching to a different first-generation or a second- or third-generation TKI (see Box 24.52). A new drug, asciminib, is a first-in-class allosteric myristoyl inhibitor, which targets the myristoyl pocket of BCR::ABL1 protein rather than the tyrosine kinase domain. This is now available for patients who have failed two TKIs. Some patients develop detectable mutations in the *BCR::ABL1* gene, which causes resistance to one or more of the TKIs. The *T315I* mutation, known as the gatekeeper mutation, is particularly problematic as this causes wide-ranging resistance, but the third-generation TKI ponatinib and asciminib can be effective. Allogeneic HSCT (p. 966) is now reserved for patients who fail TKI and asciminib therapy. Hydroxycarbamide and interferon were previously used for control of disease. Hydroxycarbamide is still useful in palliative situations and interferon is available for women planning pregnancy.

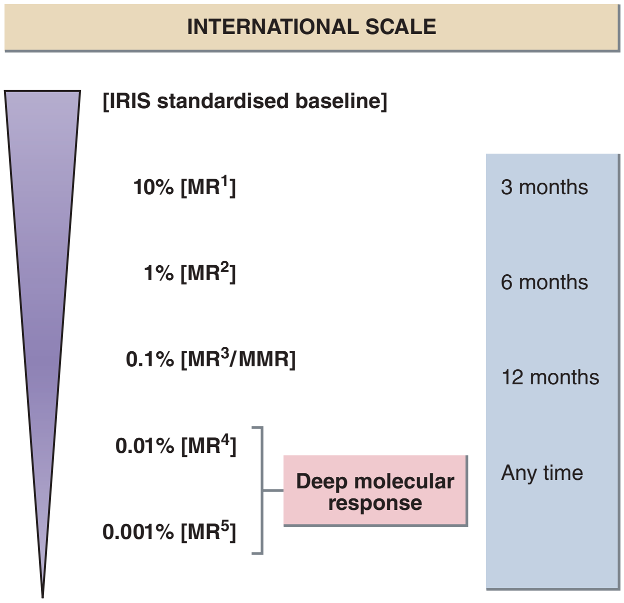

Fig. 24.32 **Response criteria and milestones in CML treated with TKIs.** IRIS (International Randomized Study of Interferon and STI571) baseline = 100% *BCR::ABL1* transcripts at diagnosis. MR = molecular response measured in percentage log reductions of *BCR::ABL1* from baseline. MR^3/MMR = major molecular response. MR^4/MR^5 = deep molecular response. ELN (European LeukemiaNet) optimal treatment milestones measured in months from start of treatment. *Adapted from Hochhaus A, Baccarani M, Silver RT, et al. European LeukemiaNet 2020 recommendations for treating chronic myeloid leukemia. Leukemia. 2020;34(4):966–984 and Cross NCP, Ernst T, Branford S, et al. European LeukemiaNet laboratory recommendations for the diagnosis and management of chronic myeloid leukemia. Leukemia. 2023;37(11):2150–2167, with permission.*

Accelerated phase and blast crisis Management is more difficult. For patients in accelerated phase, nilotinib, dasatinib or ponatinib are frequently used. When blast transformation occurs, the type of blast cell should be determined. Response to appropriate acute leukaemia treatment (see Box 24.52) is better if the disease is lymphoblastic rather than myeloblastic. Second- or third-generation TKIs such as dasatinib and ponatinib are combined with chemotherapy to try to achieve remission. In younger and fitter patients with myeloid blast crisis, ponatinib combined with FLAG-Ida chemotherapy (fludarabine, cytarabine, G–CSF and idarubicin) has become a favoured regimen. Allogeneic HSCT is appropriate consolidation therapy, providing a return to chronic phase has been achieved. Second- or third-generation TKIs, hydroxycarbamide and low-dose cytarabine are suitable as palliative therapy in older patients.

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common variety of leukaemia, accounting for 30% of cases. The male-to-female ratio is 2:1 and the median age at presentation is 65–70 years. CLL is characterised by the clonal expansion of small mature-looking B cells. Failure to apoptose because of overexpression of BCL-2 and in some cases mutations in *TP53* leads to an ever-increasing accumulation of immuno-incompetent leukaemic B cells. This is to the detriment of immune function and normal

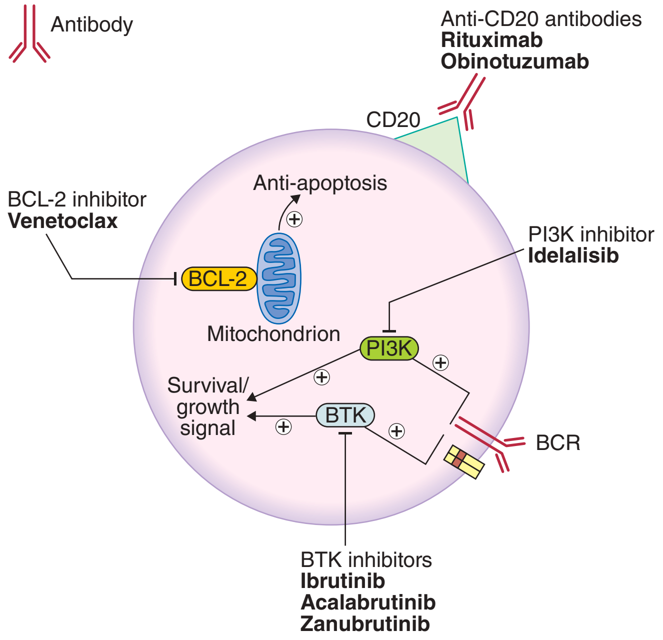

Fig. 24.33 **Targeted therapies for chronic lymphocytic leukaemia (CLL).** CLL cells are 'addicted' to stimulation of the B-cell receptor (BCR), which is surface immunoglobulin. This pathway can now be inhibited by drugs that block the downstream effector pathways of BCR involving BTK and PI3K molecules. CLL cells also depend on anti-apoptosis signals, especially increased BCL-2. Venetoclax inhibits BCL-2 and induces apoptosis. The anti-CD20 'naked' antibodies are used with chemotherapy or venetoclax to enhance CLL cell killing. (BCR = B-cell receptor; BTK = Bruton tyrosine kinase; PI3K = phosphatidylinositol-3-kinase)

bone marrow haematopoiesis. CLL cells are dependent on abnormal and persistent signalling through the B-cell receptor (BCR) pathway. Drugs that can inhibit these disease sustaining pathways are now the mainstay of chemotherapy-free treatment for most patients (Fig. 24.33).

Clinical features

The onset is usually insidious. Indeed, in around 70% of patients the diagnosis is made incidentally on a routine FBC. Presenting problems may be anaemia, infections, painless lymphadenopathy, and systemic symptoms such as night sweats or weight loss; these more often occur later in the course of the disease or in advanced disease at presentation.

Investigations

The diagnosis is based on the peripheral blood findings of a mature lymphocytosis ($>5 \times 10^9$/L) with characteristic morphology and cell surface markers. Immunophenotyping reveals the lymphocytes to be monoclonal B cells expressing the B-cell antigens CD19 and CD23, with either kappa or lambda immunoglobulin light chains and, characteristically, an aberrant T-cell antigen CD5. On flow cytometry, some people have circulating CLL cells at a level less than 5×10^9/L. This is known as monoclonal B lymphocytosis of uncertain significance (MBL) and is a frequent finding in old age. Such patients progress to CLL at a rate of 1% per year.

Other useful investigations in CLL include a reticulocyte count and a direct Coombs test, as autoimmune haemolytic anaemia may occur (p. 979). Serum immunoglobulin levels should be estimated to establish the degree of hypogammaglobulinaemia, which is common and progressive. Bone marrow examination by aspirate and trephine is not essential for the diagnosis of CLL, but may be helpful in difficult cases, for prognosis (patients with diffuse marrow involvement have a poorer prognosis) and to monitor response to therapy. Traditionally, the main prognostic factor was stage of disease (Box 24.53); however, so-called *TP53* disrupted CLL caused by loss of chromosome 17p or mutation in the *TP53* gene, which resides at this genetic locus, is a powerful prognostic marker of poor outcome and predictor of response to therapy. Disrupted *TP53* is present in $<10\%$ of patients at presentation, but rises to 30% of cases at relapse. This test should be performed in all patients prior to the initiation of therapy. Whether or not the immunoglobulin heavy variable chain gene (*IGHV*) has undergone somatic hypermutation by random base insertion is also a prognostic marker and can influence treatment decisions. Mutated (DNA sequence $\geq 2\%$ variation to the germline *IGHV*) carries a better prognosis than unmutated cases.

i 24.53 Staging of chronic lymphocytic leukaemia

Clinical stage A (60% patients)

- No anaemia or thrombocytopenia and fewer than three areas of lymphoid enlargement

Clinical stage B (30% patients)

- No anaemia or thrombocytopenia, with three or more involved areas of lymphoid enlargement

Clinical stage C (10% patients)

- Anaemia and/or thrombocytopenia, regardless of the number of areas of lymphoid enlargement

Management

No specific treatment is required for most clinical stage A patients, unless progression occurs. The patient should be offered clear information about CLL and be reassured about the indolent nature of the disease, as the diagnosis of leukaemia inevitably causes anxiety. Patients should be vaccinated against pneumococcus and receive annual influenza and COVID-19 vaccinations.

Despite tremendous advances in treatment in recent years, watch and wait remains the initial treatment of choice for a large majority of patients. Treatment is offered for symptomatic and progressive disease where there is evidence of bone marrow failure, massive or progressive lymphadenopathy or splenomegaly, systemic symptoms such as weight loss or night sweats, a rapidly increasing lymphocyte count, autoimmune haemolytic anaemia or thrombocytopenia.

Initial therapy in the UK for those requiring treatment is universally chemotherapy-free. Two approaches are considered; continuous therapy with oral ibrutinib, acalabrutinib or zanubrutinib, which inhibit Bruton tyrosine kinase (BTKi therapy), a component of the BCR pathway (see Fig. 24.33) or fixed duration therapy of one year with the oral BCL-2 inhibitor (BCL2i) venetoclax (see Fig. 24.33) in combination with the intravenous anti-CD20 antibody, obinutuzumab (VenO regimen) or the oral BTKi ibrutinib (IV regimen). These are all highly effective therapies, including in high-risk *TP53* disrupted cases, and the decision-making depends on several clinical factors and patient preference. All BTKis have, to varying degrees, class specific side-effects of increased bleeding tendency and risk of atrial fibrillation, hypertension and heart failure. However, they are oral medications and otherwise well tolerated, especially acalabrutinib and zanubrutinib. They must be continually taken, perhaps indefinitely until relapse or excess toxicity. On the other hand, venetoclax-based therapies are of fixed duration of one year but carry an increased risk of infections, cytopenias and prolonged immunosuppression. Venetoclax, as an inhibitor of BCL-2, is so effective at killing CLL cells that it frequently causes tumour lysis syndrome when first administered, as can obinutuzumab when the white cell count is high. The initiation of therapy is complex, therefore, with many patients admitted to hospital for the first dose of obinutuzumab followed in outpatients by ramp-up dosing of venetoclax over several weeks to avoid tumour lysis. A relatively young and fit patient, still working, will likely benefit from and opt for fixed duration therapy. An older and frailer patient with a long distance to travel to the clinic will likely opt for and benefit from single agent BTKi. In health services that do not have access to these newer agents, immunochemotherapy with FCR (fludarabine, cyclophosphamide and rituximab) in young, fit patients or BR (bendamustine and rituximab) or ChO (chlorambucil and obinutuzumab) in less fit patients remain treatment options, especially in *TP53* non-disrupted patients.

At relapse, an alternative strategy to that selected at first line is used. Venetoclax with rituximab is licensed for second-line therapy for a fixed duration of two years.

Bone marrow failure or autoimmune cytopenias may respond to glucocorticoid treatment or rituximab. Supportive care is increasingly required in progressive disease, such as transfusions for symptomatic anaemia or thrombocytopenia, prompt treatment of infections and, for some patients with hypogammaglobulinaemia, immunoglobulin replacement. Radiotherapy may be used for lymphadenopathy that is causing discomfort or local obstruction and for symptomatic splenomegaly. Splenectomy may be required to improve low blood counts due to autoimmune destruction or to hypersplenism and can relieve massive splenomegaly, but is rarely used with the advent of modern therapies. Occasional young and fit patients with difficult, relapsed disease may benefit from allogeneic HSCT.

Prognosis

Whilst still considered incurable, the prognosis for all patients with CLL has been improved by these modern treatments. Most clinical stage A patients have a normal life expectancy, but patients with advanced CLL are more likely to die from their disease or infectious complications. Prognostic features of the leukaemia, particularly *TP53* disruption status, influence survival. As in other haematological malignancies, the presence of MRD is important. The new therapies, especially venetoclax-based treatments, are more likely to produce an MRD negative state and prolong survival. Response rates with the new treatments are more than 80% and median PFS longer than 5 years for most patients, often considerably so. Rarely (3% of cases), CLL transforms to an aggressive high-grade lymphoma, called Richter transformation. Treatment is challenging and involves immunochemotherapy, autologous HSCT and more recently CAR-T cell therapy in selected patients.

Prolymphocytic leukaemia

Prolymphocytic leukaemia (PLL) is a very rare form of chronic leukaemia found mainly in males over the age of 60 years; 25% are of T-cell origin (T-PLL). There is typically massive splenomegaly with little lymphadenopathy and a very high leucocyte count, often more than 400 × 10^9/L. Effusions and involvement of skin are well recognised. The characteristic cell is a large lymphocyte with a prominent nucleolus. Treatment is generally unsuccessful and the prognosis very poor. Leukapheresis, splenectomy and chemotherapy may be tried. The anti-CD52 antibody alemtuzumab, when given intravenously, has produced responses in some 90% of patients with T-PLL and BTKi produce responses in those of B-cell origin (B-PLL). Younger patients who respond to treatment are considered for allogeneic HSCT.

Hairy cell leukaemia

This is a rare chronic B-cell lymphoproliferative disorder. The male-to-female ratio is 6:1 and the median age at diagnosis is 50 years. Presenting symptoms are general ill health and recurrent infections. Splenomegaly occurs in 90%, but lymph node enlargement is unusual.

Severe neutropenia, monocytopenia and the characteristic hairy cells in the blood and bone marrow are typical. These cells usually have a B-lymphocyte phenotype, but they also characteristically express CD25 and CD103. Recently, all patients with hairy cell leukaemia have been found to have a mutation in the *BRAF* gene; a potential therapeutic target. Chemotherapy treatments such as a single cycle of cladribine, often used on multiple occasions over time, can produce long-lasting remissions.

Myelodysplastic syndromes

Myelodysplastic syndromes (MDSs) constitute a group of clonal haematopoietic malignancies with the common features of ineffective blood cell production and a tendency to progress to AML. As such, they are pre-leukaemic and represent genetic steps in the development of leukaemia. These genetic abnormalities have been identified and some have been shown to be increasingly present with age. This so-called clonal haematopoiesis occurs in about 20% of people over the age of 80 years. Such individuals have normal blood counts (clonal haematopoiesis of indeterminate potential, CHIP), but there is an increased risk of developing MDS, AML or non-haematological disease such as coronary artery disease and chronic inflammation. The common CHIP pathogenic variants include *DNMT3a*, *TET2* and *ASXL1*.

Some 80% of patients with MDS have one or more acquired mutations in specific genes and these are now routinely identified by multigene next-generation sequencing (NGS) using a so-called ‘myeloid gene panel’. As with AML, classification systems are increasingly based on these pathogenic variants. Some are associated with specific phenotypes of MDS, e.g. 80% of cases with ring sideroblasts have a mutation in the splice factor gene *SF3B1*. Others have prognostic significance, e.g. mutations in *TP53* or the presence of two or more mutations carry a poor prognosis. Chromosome analysis (karyotyping) frequently reveals abnormalities, particularly of chromosome 5 or 7, and contribute to prognostic scoring systems.

Clinical features

MDS predominantly affects the elderly with a median age of 73 years, though MDS is diagnosed in all age groups, rarely including children. The overall incidence is 4/100 000 in the population, rising to more than 30/100 000 in the over-70s. MDS presents with consequences of bone marrow failure (anaemia, recurrent infections or bleeding), though some patients are diagnosed whilst asymptomatic following routine FBC. The blood film is characterised by one or more cytopenias and abnormal-looking (dysplastic) blood cells, including macrocytic red cells and hypogranular neutrophils with nuclear hyper- or hyposegmentation. The bone marrow is hypercellular, with dysplastic changes in at least 10% of cells of one or more cell lines. Blast cells may be increased, but do not reach the 20% level that traditionally is used to define acute leukaemia. However, recent classification systems, the 5th edition of the WHO classification of myeloid malignancies and the International Consensus Classification (ICC) of myeloid malignancies, use variable blast percentages to define AML in different genetic subtypes. ICC has introduced a new term, MDS/AML, for patients with 10%–19% blasts (Box 24.54).

Prognosis

The natural history of MDS is progressive worsening of dysplasia leading to fatal bone marrow failure or progression to AML in 30% of cases. The time to progression varies (from months to years) with the subtype of MDS, being slowest in MDS with ring sideroblasts/*SF3B1* mutation and single-lineage dysplasia, and most rapid in MDS with increased blasts. The revised International Prognostic Scoring System (IPSS-R) predicts clinical outcome based on karyotype and cytopenias in blood, as well as percentage of bone marrow blasts (Box 24.55). There are five prognostic groups. The median survival for low-risk patients (IPSS-R very low and low) is 5–9 years, that for the intermediate group is 3 years and that for high-risk patients (IPSS-R high and very high) is 1–1.5 years. Recently pathogenic variants have been included in prognostication to produce the IPSS-Molecular (IPSS-M). Based on a complex algorithm, this is accessible through online calculators. Each development of the IPSS has improved the definition of risk groups and IPSS-M has moved a proportion of patients from less informative intermediate prognostic groups into low- and high-risk groups.

Management

Low-risk MDS

For most patients who are elderly, MDS is incurable and supportive care with red cell and platelet transfusions remains the backbone of treatment. A trial of erythropoiesis stimulating agents (ESAs), which promote early stages of erythropoiesis, is the first-line treatment of choice in anaemic patients with low-risk MDS (IPSS-R very low, low and intermediate) to attempt to improve haemoglobin levels. Erythropoietin-alpha is licensed for this indication. Other unlicensed ESA treatments commonly used include erythropoietin-beta and darbepoetin. Responders have delayed red cell transfusion dependency, better quality of life, lower

24.54 WHO 5th edition classification of myelodysplastic syndromes (MDS)

	Blasts	Cytogenetics	Mutations
MDS with defining genetic abnormalities			
MDS with low blasts and isolated 5q deletion (MDS-5q)	< 5% BM and < 2% PB	5q deletion alone, or with 1 other abnormality other than monosomy 7 or 7q deletion	
MDS with low blasts and *SF3B1* mutation (MDS-SF3B1)		Absence of 5q deletion, monosomy 7 or complex karyotype	*SF3B1*
MDS with biallelic *TP53* inactivation (MDS-biTP53)	< 20% BM and PB	Usually complex	Two or more *TP53* mutations, or 1 mutation with evidence of *TP53* copy number loss or cnLOH
MDS, morphologically defined			
MDS with low blasts (MDS-LB)	< 5% BM and < 2% PB		
MDS, hypoplastic (MDS-h)			
MDS with increased blasts (MDS-IB)			
MDS-IB1	5%–9% BM or 2%–4% PB		
MDS-IB2	10%–19% BM or 5%–19% PB or Auer rods		
MDS with fibrosis (MDS-f)	5%–19% BM; 2%–19% PB		

(BM = bone marrow; cnLOH = copy neutral loss of heterozygosity; PB = peripheral blood)
Adapted from Khoury JD, Solary E, Abla O, et al. The 5th edition of the World Health Organization Classification of Haematolymphoid Tumours: Myeloid and Histiocytic/Dendritic Neoplasms. Leukemia. 2022;36(7):1703–1719.

24.55 Revised International Prognostic Scoring System and outcomes in myelodysplasia*

Risk category	Overall score	Median survival (years)	25% progression to acute myeloid leukaemia (years)
Very low	≤1.5	8.8	Not reached
Low	>1.5–3	5.3	10.8
Intermediate	>3–4.5	3.0	3.2
High	>4.5–6	1.6	1.4
Very high	>6	0.8	0.73

*The IPSS-R is based on three prognostic factors: the blast percentage in bone marrow; karyotype; and number and degree of blood cytopenias. A score is derived, from which patients can be stratified into five risk categories for survival and leukaemic transformation.

risk of progression to AML and probably better overall survival based on analyses of large prospective data sets such as the European Union MDS Registry Study (EUMDS). The ligand trap, luspatercept, binds ligands of the TGF-β superfamily promoting late-stage erythropoiesis and hence red blood cell production (Fig. 24.34). This drug is licensed for patients with MDS and ring sideroblasts who have failed ESA therapy. Recent data suggests luspatercept is more effective than ESA in first-line treatment of anaemia in low-risk MDS, and a license extension may follow. Newer treatments may also be beneficial after ESA failure, including imetelstat (a telomerase inhibitor), which has been approved by the FDA. Some patients with low-risk MDS on long-term red cell transfusion programmes may benefit from iron chelation, most conveniently oral deferasirox. Granulocyte colony-stimulating factor (G–CSF) is recommended for short-term use in neutropenic patients with active infection. A rare subtype called MDS with isolated del(5q) responds well to lenalidomide (an immunomodulatory drug), with two-thirds of anaemic patients becoming transfusion-independent for up to 2 years.

High-risk MDS

Allogeneic HSCT may afford a cure in patients with a good performance status and high-risk disease (IPSS-R high and very high) and some intermediate- and low-risk patients, especially younger patients with marked cytopenias or transfusion dependence. Some 50% of transplanted patients are long-term survivors, though relapse of MDS remains the biggest problem. Azacitidine (a hypomethylating agent) has improved survival by a median of 9 months compared to supportive care or low-intensity chemotherapy for high-risk patients and remains a recommended standard of care for those not eligible for transplantation. Whether or not the addition of venetoclax to azacitidine is beneficial in high-risk MDS, as it has been in AML, remains to be seen.

Lymphomas

Lymphomas are neoplasms arising from cells of the lymphocyte lineage and a majority involve a more mature stage of lymphocyte development than seen in ALL. They are diagnosed from the pathological findings on lymph node or tissue biopsy as Hodgkin or non-Hodgkin lymphoma. The vast majority are of B-cell origin with approximately 10% of cases being of T-cell origin in Western data sets. Higher rates of T-cell lymphomas are reported in other parts of the world, though selection bias has confounded some studies. Non-Hodgkin lymphomas are classified as low- or high-grade tumours based on their proliferation rate. The normal architecture of the lymph node is outlined in Fig. 24.35.

- *High-grade lymphomas* divide rapidly, are typically present for a matter of weeks before diagnosis and often progress rapidly. They may be life-threatening with high risk of extranodal involvement.
- *Low-grade lymphomas* divide slowly, may be present for many months before diagnosis, and typically behave in an indolent fashion. They are frequently widely disseminated in lymph node groups and other tissues of the lymphoreticular system.

Hodgkin lymphoma

The histological hallmark of Hodgkin lymphoma (HL) is the presence of Reed–Sternberg cells: large, malignant lymphoid cells of B-cell origin (Fig. 24.36). They are often present only in small numbers, but are surrounded by large numbers of reactive non-malignant T cells, plasma cells and granulocytes, including eosinophils.

The epidemiology of HL is shown in Box 24.56 and its histological WHO classification in Box 24.57.

Nodular lymphocyte-predominant HL is slow-growing, localised and rarely fatal. It has biological features such as CD20-positive malignant cells, and in some patients, the feature of a relapsing and remitting clinical course that makes it more akin to a low-grade B-cell non-Hodgkin lymphoma. As such, this entity has been re-classified as nodular lymphocyte predominant B-cell lymphoma in ICC, though remains unchanged in WHO 5th edition. Classical HL is divided into four histological subtypes from the appearance of the Reed–Sternberg cells and surrounding reactive cells. The nodular sclerosing type is more common in young patients and in women. Mixed cellularity is more common in older patients. Lymphocyte-rich HL usually presents in men. Lymphocyte-depleted HL is rare.

Clinical features

The peak age of presentation in high-income countries is 18 to 35 years of age. There is painless, rubbery, lymphadenopathy usually in the neck, supraclavicular fossae and mediastinum, i.e. presenting in the upper

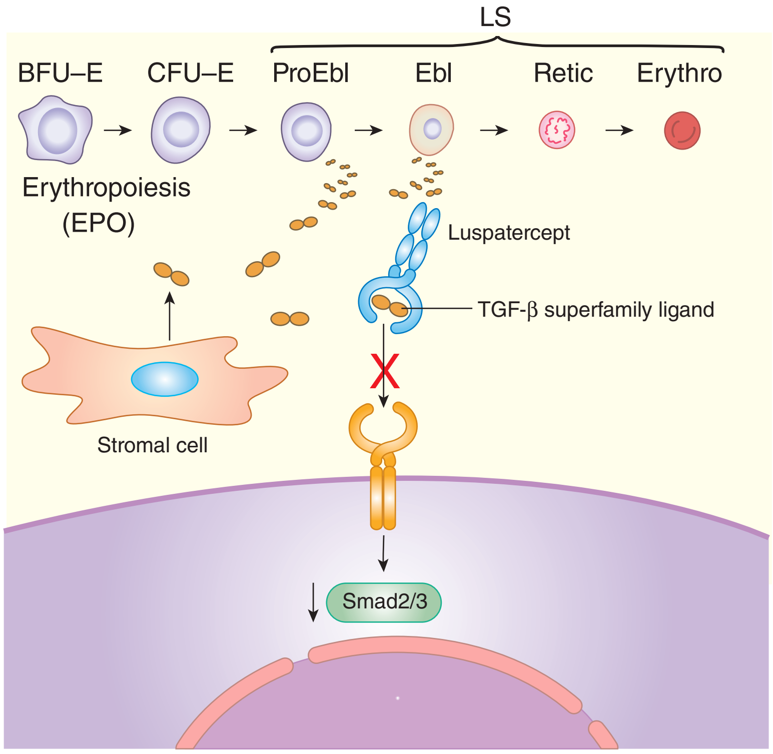

Fig. 24.34 Early stages of erythropoiesis regulated by erythropoietin. Later stages of erythropoiesis (LS) negatively regulated by members of the TGF-β superfamily signalling through the Smad2/3 pathway. Luspatercept binds these TGF-β ligands allowing erythropoiesis to progress through later stages and produce mature red blood cells. (BFU–E = burst-forming unit – erythroid; CFU–E = colony-forming unit – erythroid; Ebl = erythroblast; EPO = erythropoietin; Erythro = erythrocyte; ProEbl = proerythroblast; Retic = reticulocyte; TGF = transforming growth factor)

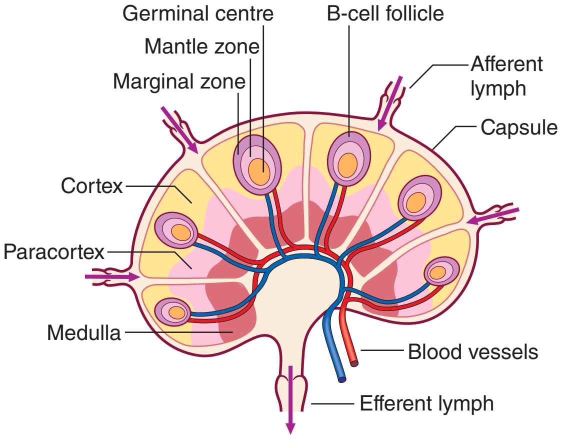

Fig. 24.35 Schema of lymph node architecture. Different lymphocyte populations reside in different areas of the node: B cells in the follicles, T cells in the paracortex and plasma cells in the medulla. B cells are selected for antigen in the follicle centre. Errors during this process result in B-cell lymphomas, which are by far the most common type.

body. The lymph nodes may fluctuate in size. Young patients with nodular sclerosing disease may have large mediastinal masses that are surprisingly asymptomatic, but may cause dry cough and some breathlessness. Spread is contiguous from one lymph node to the next along lymphatic chains and progressing from the upper body to below the diaphragm. Isolated subdiaphragmatic nodes occur in fewer than 10% at diagnosis. Hepatosplenomegaly may be present but does not always indicate disease in those organs and can be reactive. Extranodal disease, such as bone, brain or skin involvement, is rare. Systemic symptoms include so-called ‘B symptoms’ of drenching night sweats, fever and loss of 10% body weight. Other symptoms can include pruritus and rarely, but dramatically, alcohol-induced pain within lymph nodes.

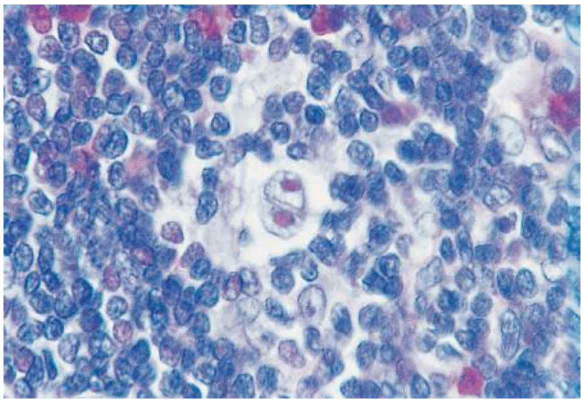

Fig. 24.36 Hodgkin lymphoma. In the centre of this lymph node biopsy is a large typical Reed–Sternberg cell with two nuclei containing a prominent eosinophilic nucleolus.

24.56 Epidemiology and aetiology of Hodgkin lymphoma

Incidence

- Approximately 4 new cases/100 000 population/year

Sex ratio

- Slight male excess (1.5:1) except nodular sclerosing subtype, with a female excess

Age

- Median age 31 years; first peak at 20–35 years and second at 50–70 years

Aetiology

- Unknown
- More common in patients from well-educated backgrounds and small families
- Three times more likely with a history of infectious mononucleosis but no definitive causal link to Epstein–Barr virus infection proven

24.57 WHO 5th edition pathological classification of Hodgkin lymphoma (HL)

Type	Histology classification	Proportion of HL
Nodular lymphocyte-predominant HL		5%
Classical HL	Nodular sclerosing Mixed cellularity Lymphocyte-rich Lymphocyte-depleted	70% 20% 5% Rare

24.58 Clinical stages of Hodgkin lymphoma (Ann Arbor classification)

Stage	Definition
I	Involvement of a single lymph node region (I) or extralymphatic* site (I_E)
II	Involvement of two or more lymph node regions (II) or an extralymphatic site and lymph node regions on the same side of (above or below) the diaphragm (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm with (III_E) or without (III) localised extralymphatic involvement or involvement of the spleen (III_S), or both (III_{SE})
IV	Diffuse involvement of one or more extralymphatic tissues, e.g. liver or bone marrow
Each stage is subclassified	
A	No systemic symptoms
B	Weight loss > 10%, drenching sweats, fever

*The lymphatic structures are defined as the lymph nodes, spleen, thymus, Waldeyer ring, appendix and Peyer patches.

Investigations

Treatment of HL depends on the stage at presentation; investigations therefore aim not only to diagnose lymphoma, but also to determine the extent of disease (Box 24.58).

- *FBC* may be normal. If a normochromic, normocytic anaemia or lymphopenia is present, this is a poor prognostic factor, particularly in advanced disease. Eosinophilia, neutrophilia or thrombocytosis may be present.
- *ESR* may be raised and is an adverse prognostic factor.
- *Renal function tests* are required to ensure function is normal prior to treatment.
- *Liver function* may be abnormal in the absence of disease or may reflect hepatic infiltration. An obstructive pattern may be caused by nodes at the porta hepatis.
- *LDH* may be raised and is an adverse prognostic factor.
- *Chest X-ray* may show a mediastinal mass.
- *CT scan* of chest, abdomen and pelvis permits staging. Bulky disease (> 10 cm in a single nodal mass or a mediastinal mass > one third the maximum diameter of thorax on chest X-ray) is an adverse prognostic feature.
- *Lymph node biopsy* is crucial for diagnosis and may be undertaken surgically or by percutaneous needle biopsy under radiological guidance (Fig. 24.37).
- *Positron emission tomography–CT (PET-CT) scanning* has become standard of care. This identifies nodes involved with HL that are ^{18}F-fluorodeoxyglucose (FDG)-avid and this allows more accurate staging and monitoring of early and end-of-treatment responses, which increasingly dictate therapeutic strategy (Fig. 24.38).

Management

Given the high cure rate and excellent prognosis of a majority of young and middle-aged patients with HL, the aim is to maintain maximum cure rates while minimising long-term treatment-related toxicity. Treatment approaches involve defining patients as early-stage disease (stages IA/IB and IIA) or advanced stage disease (IIB, III and IV). The ABVD regimen (doxorubicin (Adriamycin), bleomycin, vinblastine and dacarbazine) continues to be used in the UK, while the more intensive BEACOPP or BEACOPDAC regimens (bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (oncovin), prednisolone, procarbazine or dacarbazine) is a more effective and increasingly favoured alternative, though with an increased risk of side-effects including infertility and treatment-related MDS and AML. Radiotherapy is a very effective modality of treatment in combination with chemotherapy, However, long-term toxicity has led to more judicious use in recent times.

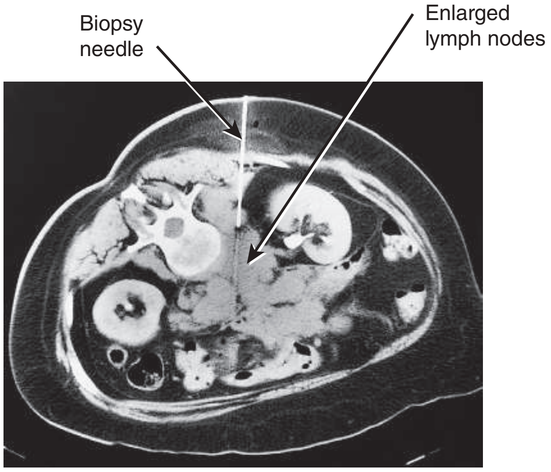

Fig. 24.37 CT-guided percutaneous needle biopsy of retroperitoneal nodes involved by lymphoma.

Early-stage disease

Standard therapy for early-stage patients without additional risk factors, such as bulk disease or high ESR, is two cycles of ABVD combined with 20 Gy radiotherapy to the involved sites of disease. Standard therapy for early-stage patients with additional risk factors is four cycles of ABVD combined with 30 Gy radiotherapy. Careful planning of radiotherapy is required to limit the doses delivered to normal tissues, and new planning techniques continue to improve targeting of radiotherapy. Nevertheless, the long-term risks of second cancers and heart and lung disease within the radiation fields remain a concern, especially for young people with a high cure rate and potentially decades of life ahead of them. Early-stage patients who have a negative FDG PET-CT scan after two to four cycles of combination chemotherapy can safely omit radiotherapy. For example, the UK RAPID trial showed that three cycles of ABVD leading to a negative PET produced an overall survival rate of greater than 90% without radiotherapy, though the relapse rate requiring additional therapy was about 7% higher than in patients who received radiotherapy. The German HD17 trial in early-stage patients with additional unfavourable risk factors similarly had a > 90% progression-free and overall survival rate with two cycles of BEACOPP and two cycles of ABVD without radiotherapy in patients with a negative PET scan at the end of treatment. Such PET-adapted therapy can spare a large majority of young patients from the long-term effects of radiotherapy, though at the cost of a slightly increased relapse risk in some studies.

Advanced-stage disease

Patients with advanced-stage disease are commonly managed with chemotherapy alone. Standard treatment in the UK has been 6–8 cycles of ABVD, followed by an assessment of response. A negative FDG PET-CT after two cycles of ABVD (interim PET-2 response) predicts a very good outcome from continuing with up to six cycles of ABVD. Indeed, the same outcome is achieved by omitting the bleomycin from the last four cycles and using AVD alone, thus reducing the risk of lung toxicity (RATHL trial). Even more impressive results of > 90%

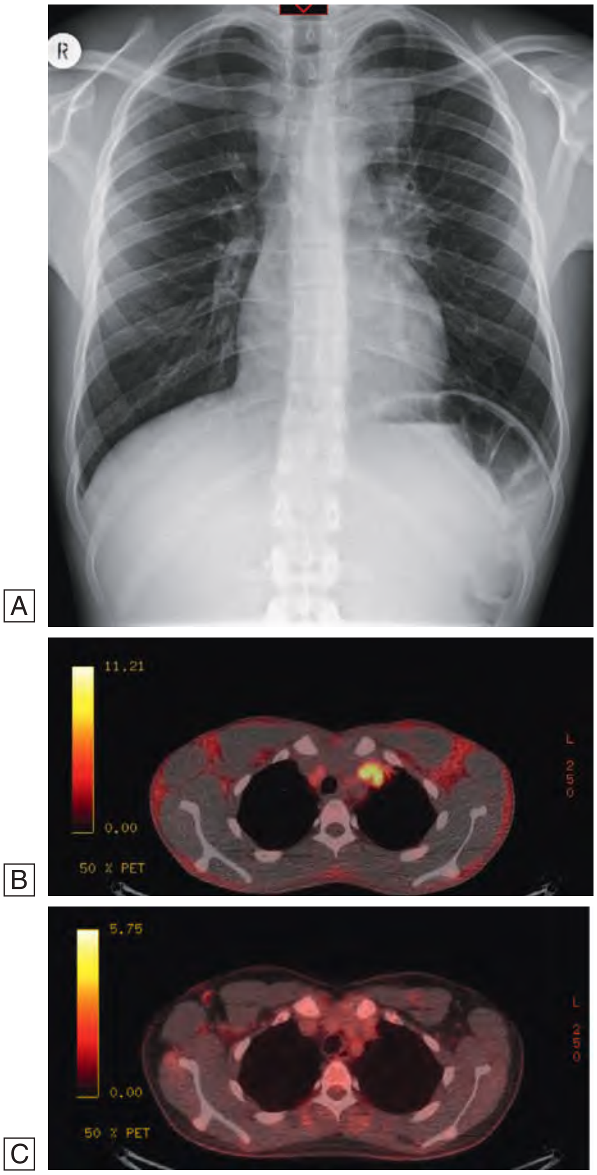

Fig. 24.38 **Positron emission tomography (PET) scans in Hodgkin lymphoma, demonstrating response to treatment.** **A** Chest X-ray from a young man with Hodgkin lymphoma at presentation, showing a left-sided anterior–superior mediastinal mass with tracheal deviation to the right. **B** Fused PET-CT image showing intense ^{18}F-fluorodeoxyglucose (FDG) uptake (avidity) in the mass at presentation. **C** Fused PET-CT image showing no FDG uptake (PET negativity), representing complete response at the end of treatment.

5-year progression-free survival can be achieved with just four cycles of BEACOPP if the interim PET-2 scan is negative (German HD18 trial). Patients who have a positive FDG PET-CT after two cycles of ABVD, however, have a high relapse risk if they continue with ABVD, with only 13% being relapse-free at 2 years. Switching to BEACOPP/DAC from ABVD or continuing with BEACOPP/DAC for six cycles in these patients improves the relapse-free survival to approximately 65%–90%. Adding the immunochemotherapy drug brentuximab vedotin (see below) to AVD (A^{2}VD) also produces better overall survival compared to ABVD, though this has not been widely adopted in the UK to date.

Elderly, frail patients tolerate ABVD poorly and are at high risk of pulmonary toxicity with bleomycin. BEACOPP/DAC is not readily deliverable to patients over the age of 60 years or with comorbidities. Lower-intensity chemotherapies, such as AVD omitting bleomycin, or anthracycline and bleomycin free regimens, can produce prolonged remissions in some patients. Patients with relapsed disease that respond to salvage chemotherapy and ideally become FDG PET-CT-negative are considered for autologous HSCT (p. 966). Those with resistant disease might benefit from an allogeneic HSCT. Brentuximab vedotin is an antibody–drug conjugate directed against CD30 on the Reed–Sternberg cell surface. This antibody delivers the antimitotic toxin monomethyl auristatin E to the Hodgkin cells and, as a single agent, can produce good responses in patients who have failed, or are not suitable for an autologous transplant and can be a 'bridge' to an allogeneic transplant. Reed–Sternberg cells over-express the cell surface protein programmed death ligand 1 (PD-L1). This engages with programmed death protein 1 (PD-1) on T cells and leads to T-cell 'exhaustion'. This 'immune checkpoint' is an important survival mechanism for Reed–Sternberg cells. The immunotherapy drugs pembrolizumab and nivolumab can inhibit this 'checkpoint' in the immune response and allow T-cell killing of Reed–Sternberg cells. Both drugs are available for patients who have failed multiple lines of treatment and can produce further remissions. This class of drugs has recently been shown to be very effective in first-line treatment in combination with chemotherapy (e.g. nivolumab-AVD) and may become future treatments of choice.

Prognosis

Over 90% of patients with early-stage HL achieve complete remission when treated with chemotherapy followed by involved field radiotherapy, with the great majority cured. The major challenge is how to reduce treatment intensity, and hence long-term toxicity, without reducing the excellent cure rates in this group. Omitting radiotherapy in most FDG PET-CT-negative patients is one major step forward in this regard.

Historically, between 50% and 70% of those with advanced-stage HL were cured. The Hasenclever index (Box 24.59) can be helpful in assigning approximate chances of cure when discussing treatment plans with advanced-stage patients. Recent data using FDG PET-CT to direct therapy suggest that long-term survival is improving to beyond 80%, especially in the context of BEACOPP/DAC therapy. Patients who fail to respond to initial chemotherapy or relapse within a year of initial therapy have a poor prognosis, but some may achieve long-term survival after autologous HSCT. Patients relapsing after 1 year may obtain long-term survival with further immunochemotherapy alone, but fit patients who respond frequently proceed to autologous HSCT.

Survivorship

Young women receiving breast irradiation during the treatment of chest disease have an increased risk of breast cancer and should participate in a breast-screening programme. Patients continuing to smoke after lung irradiation are at particular risk of future lung cancer.

ABVD chemotherapy can cause cardiac and pulmonary toxicity, due to doxorubicin and bleomycin, respectively. Recommendations that patients attend survivorship clinics and have cardiac follow-up

i **24.59 The Hasenclever prognostic index for advanced Hodgkin lymphoma**

Score 1 for each of the following risk factors present at diagnosis:
- Age > 45 years
- Male gender
- Serum albumin < 40 g/L
- Hb < 105 g/L
- Stage IV disease
- White blood cell count > 15 × 10^9/L
- Lymphopenia < 0.6 × 10^9/L

Score	5-year rate of freedom from progression (%)	5-year rate of overall survival (%)
0–1	79	90
> 2	60	74
> 3	55	70
> 4	47	59

with echocardiography have generally been poorly implemented. The incidence of infertility and secondary myelodysplasia/AML is low with ABVD, but higher with BEACOPP. Recent UK data has demonstrated that replacing procarbazine with dacarbazine in the BEACOPP regimen (BEACOPDAC) is as effective in treating HL, improves female fertility and has less genotoxic effects on sperm. This has become a standard approach throughout the UK.

Non-Hodgkin lymphoma

Non-Hodgkin lymphoma (NHL) represents a monoclonal proliferation of lymphoid cells of B-cell (90%) or T-cell (10%) origin. The incidence of these tumours increases with age, to 62.8/million population per annum at age 75 years, and the overall rate is recorded as increasing at about 3% per year since the 1970s, though some of these data suffer from ascertainment bias.

The epidemiology of NHL is shown in Box 24.60. Previous classifications were based principally on histological appearances. The current WHO and ICC classifications stratify according to cell lineage (T or B cells) and incorporate clinical features, histology, genetic abnormalities and concepts related to the biology of the lymphoma. Clinically, the most important factor is grade, which reflects proliferation rate. High-grade NHL has high proliferation rates, rapidly produces symptoms, is fatal if untreated, but is potentially curable. Low-grade NHL has low proliferation rates, may be asymptomatic for many months or even years before presentation, runs an indolent course, but is frequently disseminated at diagnosis and not commonly curable by conventional therapy. Of all cases of NHL in the developed world, over 50% are either diffuse large B-cell NHL (high-grade) or follicular NHL (low-grade) (Fig. 24.39). Other forms of NHL, including Burkitt lymphoma, mantle cell lymphoma, marginal zone lymphomas including mucosa-associated lymphoid tissue (MALT) lymphomas and T-cell lymphomas are individually less common.

Clinical features

Unlike Hodgkin lymphoma, NHL is often widely disseminated at presentation, including in extranodal sites. Patients present with lymph node enlargement (Fig. 24.40), which may be associated with systemic upset: weight loss, sweat, fever and itching. Hepatosplenomegaly may

i 24.60 Epidemiology and aetiology of non-Hodgkin lymphoma

Incidence

- 12 new cases/100 000 people/year

Sex ratio

- Slight male excess

Age

- Median age 65–70 years

Aetiology

- No single causative abnormality described
- Lymphoma is a late manifestation of HIV infection (Ch. 14)
- Specific lymphoma types are associated with viruses: e.g. Epstein–Barr virus (EBV) with post-transplant lymphoproliferative disease, human herpesvirus 8 (HHV-8) with a primary effusion lymphoma, and human T-cell lymphotropic virus (HTLV-1) with adult T-cell leukaemia lymphoma
- Gastric lymphoma can be associated with *Helicobacter pylori* infection
- Some lymphomas are associated with specific chromosomal translocations:
    The t(14;18) in follicular lymphoma results in the dysregulated expression of the *BCL2* gene product, which inhibits apoptotic cell death
    The t(8;14) found in Burkitt lymphoma and the t(11;14) in mantle cell lymphoma alter function of *c-myc* and *cyclin D1*, respectively, resulting in malignant proliferation
    Large B-cell lymphomas with rearrangements of *c-myc* with *BCL-2* and/or *BCL-6* (double hit lymphoma)
- Lymphoma occurs in congenital immunodeficiency states and in immunosuppressed patients after organ transplantation

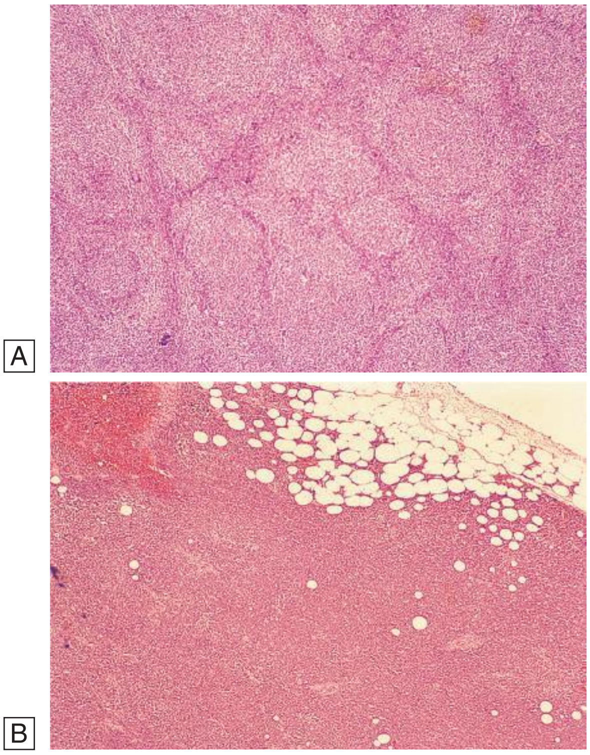

Fig. 24.39 **Histology of non-Hodgkin lymphoma.** **A** (Low-grade) follicular or nodular pattern. **B** (High-grade) diffuse pattern.

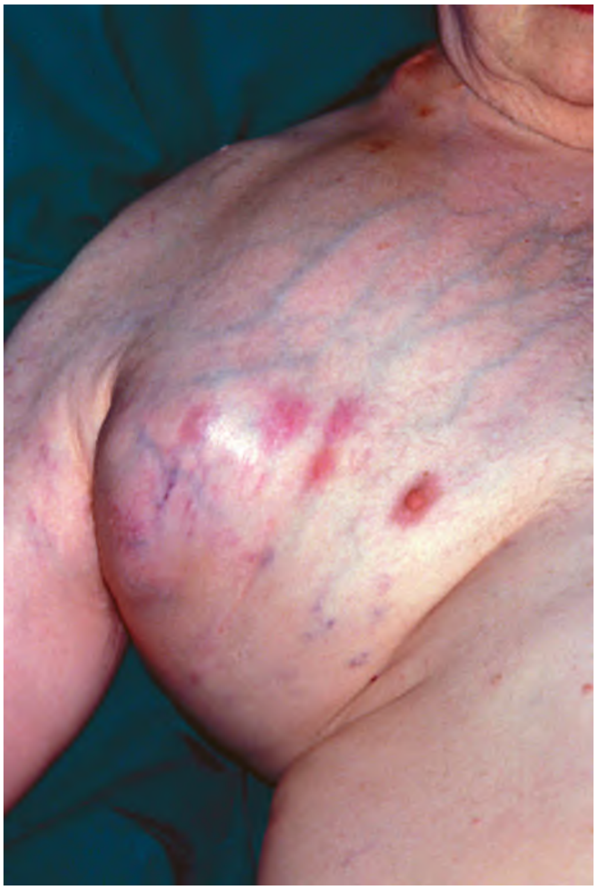

Fig. 24.40 **Massive axillary lymphadenopathy in a patient with high-grade diffuse large B-cell lymphoma.** *From Lim EKS, Loke YK, Thompson AM. Medicine and surgery: an integrated textbook. Churchill Livingstone; 2007.*

be present. Sites of extranodal involvement are protean and include the bone marrow, gut, thyroid, lung, skin, testis, breast, brain and, more rarely, bone and adrenal glands. Bone marrow involvement is more common in low-grade (50%–60%) than high-grade (10%) disease. Other extranodal sites tend to be more common in high-grade disease, particularly CNS involvement. Compression syndromes may occur, including gut obstruction, ascites, superior vena cava obstruction and spinal cord compression.

The same staging system (see Box 24.58) is used for both HL and NHL, but NHL is more likely to be stage III or IV at presentation.

Investigations

These are as for HL, but in addition the following should be performed:

- *Bone marrow aspiration and trephine* to identify bone marrow involvement.
- *Immunophenotyping of surface antigens to distinguish T-cell from B-cell tumours*. This may be done on blood, marrow or nodal material.
- *Cytogenetic analysis to detect chromosomal translocations*, particularly rearrangements of the oncogene *c-MYC* and partners including *BCL2* and molecular testing for T-cell receptor or immunoglobulin gene rearrangements. NGS lymphoid gene panels are available, but not routinely used in clinical practice.
- *Immunoglobulin determination*. Some lymphomas are associated with IgG or IgM paraproteins, which serve as markers for treatment response.
- *Measurement of urate levels*. Some very aggressive high-grade NHLs are associated with very high urate levels, which can precipitate renal failure when treatment is started because of tumour lysis syndrome.
- *HIV testing*. HIV is a risk factor for some lymphomas and affects treatment decisions.
- *Hepatitis B and C testing*. This should be done prior to therapy with rituximab.

Management

Low-grade NHL

Most patients (80%) present with advanced stage disease and will run a relapsing and remitting course over several years. Overall survival has improved in recent years with more treatment options. Asymptomatic patients may not require therapy and are managed by 'watching and waiting'. Indications for treatment include marked systemic symptoms, lymphadenopathy causing discomfort or disfigurement, bone marrow failure or compression syndromes. In follicular lymphoma the indications for treatment are covered in the Groupe d'Etude des Lymphomes Folliculaires (GELF) criteria. The treatment options for follicular lymphoma are:

- *Radiotherapy*. This can be used for localised stage I disease, which is rare. FDG PET-CT-confirmed stage I disease has a 70% cure rate with radiotherapy.
- *Chemotherapy*. Immunochemotherapy is the mainstay of treatment for patients with advanced stage disease requiring therapy.
- *Monoclonal antibody therapy*. Humanised monoclonal antibodies ('biologic therapy'; p. 963) can be used to target surface antigens on tumour cells and to induce tumour cell apoptosis directly. The anti-CD20 antibody rituximab has been shown to induce durable clinical responses in up to 60% of patients when given alone and acts synergistically when given with chemotherapy. The UK Watch and Wait trial showed that single agent rituximab (R) given over two years delayed the time to requiring chemotherapy by more than ten years on average and this is an option for some patients with asymptomatic advanced stage follicular lymphoma who would rather not watch and wait. Rituximab or a second-generation anti-CD20 antibody, obinutuzumab, in combination with cyclophosphamide, vincristine and prednisolone (R-CVP), cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin), prednisolone (R-CHOP) or bendamustine (R-bendamustine) are commonly used as first-line therapy. There is no clear advantage of one regimen over another, though R-CHOP and R-bendamustine are most used. Obinutuzumab combined with chemotherapy showed longer progression-free survival compared to similar chemotherapy with rituximab.

  Two years of maintenance therapy with single-agent rituximab, following achievement of first or second response, especially if this is only a partial response, delays the time to next treatment. However, rituximab maintenance has not shown a survival benefit.
- *Targeted therapy*. The PI3 kinase inhibitor idelalisib is approved for relapsed follicular lymphoma, but rarely used nowadays because of toxicity. Ibrutinib (see Fig. 24.33) is approved for relapsed mantle cell lymphoma (a poor-prognosis lymphoma with low-grade histology, but aggressive clinical behaviour). Ibrutinib and zanubrutinib are used in Waldenström macroglobulinaemia (also known as lymphoplasmacytic lymphoma, see below). Newer therapies are likely to become more widely used in low-grade lymphomas soon. These include bispecific antibodies and CAR-T cell therapy.
- *Transplantation*. High-dose chemotherapy and autologous HSCT can produce long remissions in patients with relapsed disease. Decisions on the timing of such treatment are complex in the context of rituximab maintenance and newer therapies. However, younger patients with short first remissions (progression of disease within 24 months, POD24) or second remissions or who relapse during rituximab maintenance should be considered. Some 25% of patients undergo high-grade transformation to DLBCL, and this is difficult to treat. R-CHOP or alternative salvage therapy followed by autologous HSCT is considered in fit patients. CAR-T is an option for some patients as outlined below.

High-grade NHL

Patients with diffuse large B-cell NHL need treatment at initial presentation:

- *Chemotherapy*. The majority (> 90%) are treated with intravenous combination chemotherapy, typically with the CHOP regimen (cyclophosphamide, doxorubicin (hydroxydaunorubicin), vincristine (oncovin) and prednisolone).
- *Monoclonal antibody therapy*. When combined with CHOP chemotherapy, rituximab (R) increases the complete response rates and improves overall survival. R-CHOP, 4–6 cycles, is recommended as first-line therapy for all relatively fit patients with an International Prognostic Index (IPI) of 0–1 (Box 24.61). Younger patients with stage I disease and a negative PET scan after four cycles of R-CHOP can avoid radiotherapy, though most older patients with stage I disease will receive dual modality therapy with R-CHOP 4–6 cycles and radiotherapy. For all patients beyond stage I, the treatment is based on 6 cycles of R-CHOP. The addition of a second antibody–drug conjugate against CD79 (polatuzumab vedotin) and removal of vincristine because of the combined neurotoxicity (R-Pola-CHP) demonstrated better progression-free survival than R-CHOP in patients with IPI > 1 (see Box 24.61). This is now the treatment of choice in many centres. More intensive chemotherapy combinations are considered for

24.61 The International Prognostic Index (IPI) for high-grade non-Hodgkin lymphoma

One point for each of:
- Age > 60 years
- ECOG PS > 1
- Ann Arbour stage III or IV
- > 1 extra nodal site
- LDH > normal

(ECOG PS = Eastern Cooperative Oncology Group Performance Status [see Box 8.6]; LDH = lactate dehydrogenase) aggressive lymphomas including Burkitt lymphoma, double hit large B-cell lymphoma (*MYC* and *BCL-2* rearrangements) and by some centres treating young patients with DLBCL with high IPI. Dose reduction (R-mini-CHOP) is preferable in those over 80 years of age and replacement of doxorubicin with gemcitabine (R-GCVP) in those with impaired cardiac function.

Fit patients with a high risk of CNS relapse based on a CNS IPI ≥5, or certain involved sites such as adrenal glands or testicles, may benefit from CNS prophylaxis during treatment. The preferred approach is two doses of high-dose methotrexate at the end of R-CHOP, though more intensive regimens have this built in.

- *Radiotherapy*. Stage I patients without bulky disease are treated with four cycles of R-CHOP, followed by involved site radiotherapy, unless PET negative when radiotherapy can be avoided for younger patients as discussed above. Radiotherapy is also considered for a residual localised site of bulk disease after chemotherapy, especially in the elderly with limited further treatment options if they relapse, and for spinal cord and other compression syndromes.
- *HSCT*. Autologous HSCT (p. 966) benefits patients with relapsed disease that is sensitive to salvage immunochemotherapy. As with HL, achieving a negative FDG PET scan prior to autologous transplantation is desirable.
- *CAR-T therapy* (see Fig. 24.17 and p. 967) is licensed for certain patients with relapsed DLBCL or high-grade transformation of follicular and other low-grade lymphomas and can salvage patients from a desperate situation. Specifically, CAR-T therapy is available in second-line therapy of DLBCL for patients who relapse within 12 months of initial therapy following randomised trials demonstrating superiority over autologous HSCT in this situation. CAR-T in third line of DLBCL therapy, after failure of autologous HSCT or in patients not fit for autograft, remains the commonest use at the present time.
- Two *licensed BiTE antibodies* (see Fig. 24.18 and p. 968), glofitamab and epcoritamab, are available as monotherapy after two or more failed lines of systemic therapy in DLBCL and have been effective in some patients following failed CAR-T.

Prognosis

A small proportion of stage I patients with low-grade NHL are cured by involved field radiotherapy. Advanced stage low-grade lymphomas are generally considered incurable and run a remitting and relapsing course, with an overall median survival of 12 years. Transformation to a high-grade NHL occurs at approximately 3% per annum and is associated with poor survival.

In diffuse large B-cell NHL treated with R-CHOP, some 75% of patients overall respond initially to therapy and 50% will have disease-free survival at 5 years. The prognosis for patients with high-grade NHL is further refined according to the IPI (see Box 24.61) For high-grade NHL, 5-year survival ranges from over 75% in those with low-risk scores (age <60 years, stage I or II, one or fewer extranodal sites, normal LDH and good performance status) to 25% in those with high-risk scores (increasing age, advanced stage, concomitant disease and a raised LDH).

Rearrangements of the *c-MYC* oncogene, either alone (more commonly seen in Burkitt lymphoma) or with rearrangements of *BCL2* and/or *BCL6* in high grade lymphomas are recognised entities. In the most recent WHO 5th edition classification, double hit *MYC and BCL-2* rearrangements are distinguished as carrying a poor prognosis and are increasingly treated more aggressively as outlined above, whilst *c-MYC* rearrangements alone or with *BCL-6* are not distinguished as separate entities with additional prognostic significance. Relapse is associated with a poor response to further chemotherapy (<10% 5-year survival). In fit patients, largely under 70 years, autologous HSCT improves survival in chemosensitive cases producing long-term remissions/cures of ~20%–30%, while CAR-T therapy is associated with ~40% cure within the licensed indications.

Paraproteinaemias

Gammopathy refers to over-production of one or more classes of immunoglobulin. It may be polyclonal in association with acute or chronic inflammation, such as infection including HIV, sarcoidosis, autoimmune disorders or some malignancies. Alternatively, a monoclonal increase in a single immunoglobulin class may occur in association with normal or reduced levels of the other immunoglobulins (immunoparesis). Such monoclonal proteins (also called M-proteins, paraproteins or monoclonal gammopathies) occur as a feature of myeloma, solitary plasmacytomas, lymphoma, amyloidosis and occasionally solid tumours. They also occur in benign conditions including connective tissue diseases such as rheumatoid arthritis or polymyalgia rheumatica and infections such as HIV. In addition, they may be present with no underlying disease (monoclonal gammopathy of uncertain significance). Gammopathies are detected by plasma immunoelectrophoresis.

Monoclonal gammopathy of uncertain significance

In monoclonal gammopathy of uncertain significance (MGUS, also known as benign monoclonal gammopathy), a paraprotein is present in the blood, but there are no other features of myeloma, Waldenström macroglobulinaemia (see below), lymphoma, amyloidosis or related disease. It is a common condition associated with increasing age; a paraprotein is present in 1% of the population aged over 50 years, increasing to 5% over 80 years.

Clinical features and investigations

Patients are usually asymptomatic and the paraprotein is found on blood testing for other reasons. The routine blood count and biochemistry are normal, the paraprotein is usually present in small amounts (<15 g/L) with no associated immunoparesis and there are no lytic bone lesions. The bone marrow may have increased plasma cells, but these constitute less than 10% of nucleated cells.

Prognosis

After follow-up of 20 years, only one-quarter of cases will progress to myeloma or a related disorder (i.e. around 1% per annum). There is no certain way of predicting progression in an individual patient. There have been several attempts to define high risk MGUS by identifying risk factors. The best known is the Mayo Clinic study identifying serum paraprotein >15 g/L, non-IgG paraprotein isotype (IgA predominantly) and abnormal serum free light chain ratio (SFLR). An abnormal SFLR increases the risk of progression and patients with an abnormal ratio should be monitored for progression on an annual basis.

Waldenström macroglobulinaemia

This is a low-grade lymphoplasmacytic lymphoma associated with an IgM paraprotein, sometimes causing clinical features of hyperviscosity syndrome. It is a rare tumour occurring in old age and more commonly affects males. It is important to remember that IgM paraproteins are associated with lymphoma, most commonly lymphoplasmacytic lymphoma, rather than myeloma. True IgM myeloma is very rare.

Patients classically present with features of hyperviscosity, such as headache, nosebleeds, bruising, delirium and visual disturbance. However, presentation is commonly with anaemia, systemic symptoms, splenomegaly or lymphadenopathy, or may be asymptomatic with an IgM paraprotein detected on routine screening. On investigation, patients have an IgM paraprotein associated with a raised plasma viscosity. The bone marrow has a characteristic appearance, with infiltration of lymphoid cells, plasma cells and sometimes prominent mast cells. A high proportion of patients have a mutation in the *MYD88* gene.

Management

If patients show symptoms of hyperviscosity and anaemia, plasmapheresis is required to remove IgM and make blood transfusion possible.

Chemotherapy with alkylating agents, such as chlorambucil, has historically been the mainstay of treatment, controlling disease in over 50%. Fludarabine may be more effective in this disease but has more side-effects. Rituximab in combination with chemotherapy, e.g. bendamustine (R-bendamustine) or cyclophosphamide and dexamethasone (RCD), is commonly used. BTK inhibitors, ibrutinib and zanubrutinib, are very effective and approved for use in second line and more recently first line for less fit patients. Rituximab alone can cause a rapid release of IgM and increase in viscosity, and rituximab is best avoided at the very start of treatment if the IgM paraprotein level is high. The improvement in treatments have led to four out of five patients living longer than 5 years.

Multiple myeloma

This is a malignant proliferation of plasma cells (derived from B cells), which is associated with paraproteinaemia. In most cases an excess of light chain is produced, and, in some cases, only light chain is produced (light-chain myeloma); this appears in the urine as Bence Jones proteinuria and can be measured in the urine or serum as free light chains. The frequency of different isotypes of monoclonal protein in myeloma is shown in Box 24.62. Some clinical features of myeloma, including renal impairment, infections and rarely hyperviscosity, relate to the effects of the paraproteins and associated immunoparesis.

Although a small number of malignant plasma cells are present in the circulation, the majority are present in the bone marrow. The malignant plasma cells produce a complex network of cytokines, which activate osteoclasts and result in net bone reabsorption. The resulting lytic lesions cause bone pain, fractures and hypercalcaemia. Marrow involvement can result in anaemia or pancytopenia.

Clinical features and investigations

The incidence of myeloma is 4/100 000 new cases per annum, with a male-to-female ratio of 2:1. The median age at diagnosis is 60–70 years and the disease is more common in people of African Caribbean origin. The clinical features are demonstrated in Figure 24.41.

Diagnosis of myeloma requires two of the following criteria to be fulfilled:

- increased malignant plasma cells in the bone marrow (> 10%)
- serum and/or urinary paraprotein
- skeletal lytic lesions or other end-organ damage, e.g. renal failure.

Bone marrow aspiration, plasma and urine electrophoresis, and a skeletal survey are thus required; the latter is classically a series of plain X-rays, but frequently nowadays low-dose CT scan or whole-body MRI is performed. Normal immunoglobulin levels, i.e. the absence of immunoparesis, should cast doubt on the diagnosis. Paraproteinaemia can cause an elevated ESR, but this is a non-specific test; only approximately

5% of patients with a persistently elevated ESR above 100 mm/hr have underlying myeloma. Serum albumin and β_2-microglobulin are prognostic, along with a cytogenetic analysis of the tumour cells.

Management

If patients are asymptomatic with no evidence of end-organ damage (e.g. to kidneys, bone marrow or bone), treatment may not be required. So-called asymptomatic myeloma is traditionally managed by close monitoring for the development of end-organ damage (symptomatic myeloma). High-risk features for progression in asymptomatic patients are generally defined as one or more of:

- Bone marrow plasma cells: more than 20% of bone marrow plasma cells
- Serum monoclonal protein: more than 2 g/dL
- Serum free light chain ratio: more than 20
- International Myeloma Working Group (IMWG) International Scoring System (ISS; Box 24.63): a high-risk score (III)

Such high-risk patients have been shown to benefit from treatment with the anti-CD38 monoclonal antibody daratumumab. In a recent trial, progression-free survival at 5 years was 63.1% with daratumumab and 40.8% with active monitoring.

For all symptomatic myeloma patients, initial therapy involves supportive care.

Immediate support

- High fluid intake to treat renal impairment and hypercalcaemia (p. 171)
- Analgesia for bone pain
- Bisphosphonates for hypercalcaemia and to delay other skeletal-related events (p. 171)
- Allopurinol to prevent urate nephropathy
- Plasmapheresis, if necessary, for hyperviscosity
- Antibiotic prophylaxis with levofloxacin during the first 3 months of therapy.

Therapy with or without HSCT

Myeloma remains incurable and follows a relapsing and remitting disease course over several years. Patients will receive multiple lines of therapy interspersed with periods of remission or stable disease off therapy. Patients are initially assessed for their fitness and eligibility for autologous HSCT, and treatment pathways vary accordingly. Autologous HSCT remains a treatment goal for fit patients, despite newer therapies. Myeloma therapy has improved with the use of novel agents, which now provide the backbone of therapy and have led to a complex array of treatment regimens and sequence in which they are used. The availability of these drugs and regimens varies considerably in different health-care environments. The key classes of drugs include immunomodulatory drugs (thalidomide, lenalidomide and pomalidomide), proteosome inhibitors (bortezomib, carfilzomib and ixazomib) and anti-CD38 monoclonal antibodies (daratumumab and isatuximab) (Fig. 24.42). Chemotherapy, e.g. cyclophosphamide, is combined with these drugs in some regimens. The most recently introduced therapies include the BiTE antibodies teclistamab (anti-BCMA) and talquetamab (anti-GPRC5D) and CAR-T therapy directed at the BCMA antigen. The combination of drugs and the sequencing varies by centre based on availability and clinicians' preferences and has changed frequently in recent years with the growth of available novel agents. Patient preferences based on the considerable side-effect profiles of novel therapies and the need to travel long distances for certain treatments are important considerations, especially in frail elderly patients.

i 24.63 The International Myeloma Working Group (IMWG) International Staging System (ISS) for myeloma at diagnosis

Stage	I	II	III
Criteria	Serum β_2-microglobulin < 3.5 mg/L **AND** albumin ≥ 35 g/L	Not fitting criteria for stage I or III	Serum β_2-microglobulin ≥ 5.5 mg/L (irrespective of albumin)

Myeloma remains incurable. The aim of treatment for all patients is to maximise the depth and duration of response to improve symptoms and limit further end-organ damage, while minimising toxicity to lengthen survival and improve quality of life.

For first-line therapy in older patients who are unsuitable for autologous HSCT (transplant ineligible), the following regimens are commonly used in the UK:

- Bortezomib (Velcade), thalidomide or lenalidomide, and dexamethasone (VTD or VRD); or with the addition of daratumumab (Dara-VTD and Dara-VRD)
- Lenalidomide–dexamethasone, followed by lenalidomide alone
- Thalidomide in combination with an alkylating agent (melphalan) and a glucocorticoid (MPT)

Thalidomide and lenalidomide both have anti-angiogenic effects against tumour blood vessels and immunomodulatory effects. Both can cause somnolence, constipation, peripheral neuropathy and thrombosis, though lenalidomide has a better side-effect profile. It is vital that females of child-bearing age use adequate contraception, as thalidomide and lenalidomide are teratogenic. Bortezomib is associated with significant neuropathy, including autonomic neuropathy and constipation. Treatment is administered until paraprotein levels have stopped falling. This is termed 'plateau phase' and can last for weeks or years. Lenalidomide maintenance can prolong the plateau phase.

In younger, fitter patients considered eligible for transplant, standard treatments include first-line therapies, such as cyclophosphamide, thalidomide and dexamethasone (CTD), VTD or VRD as above, to maximum response followed by autologous HSCT. More recently, a fourth drug, the anti-CD38 monoclonal antibody daratumumab, added to these regimens to produce Dara-VTD, and Dara-VRD followed with autologous HSCT, has extended remission and survival by 50% and is the standard approach in many centres. In all patients who have achieved maximal response, lenalidomide maintenance prolongs the response.

When myeloma progresses, treatment is given to induce a further plateau phase. The increasing movement of novel agents to first-line use

(BCMA = B-cell maturation antigen; BiTE = B-specific T-cell engager; CD = cluster of differentiation; GPRC5D = G-protein coupled receptor class C group 5 member D; IMIDs = immunomodulatory imide drugs; SLAMF7 = signaling lymphocyte activation molecule family member 7)

has led to re-evaluation of second and subsequent lines of therapies. Pomalidomide, carfilzomib, ixazomib, daratumumab and the BiTE antibodies, teclistamab and talquetamab, are options in relapsed/refractory disease, depending on which agents have been used previously. Patients who respond may benefit from a second autologous HSCT. CAR-T therapy is likely to play an increasing role in coming years.

Radiotherapy

This is effective for localised bone pain not responding to simple analgesia and for pathological fractures. It is also useful for the emergency treatment of spinal cord compression complicating extradural plasmacytomas.

Bisphosphonates

Long-term bisphosphonate therapy reduces bone pain and skeletal events. These drugs protect bone and may cause apoptosis of malignant plasma cells. There is evidence that intravenous zoledronate in combination with anti-myeloma therapy confers a survival advantage over oral bisphosphonates. Osteonecrosis of the jaw may be associated with long-term use or poor oral hygiene and gum sepsis; regular dental review, including a check before starting therapy, is therefore important.

Prognosis

The IMWG ISS (see Box 24.63) identifies poor prognostic features, including a high β_2-microglobulin and low albumin at diagnosis (ISS stage III, median survival 29 months). Those with a normal albumin and a low β_2-microglobulin (ISS stage I) have a median survival of 62 months. Increasingly, cytogenetic analysis is used to identify poor-risk patients, e.g. t(4;14), del(17/17p), t(14;16), t(14;20), non-hyperdiploidy and gain(1q). Use of autologous HSCT and advances in drug therapy with the newer agents have increased survival. Over one-third of patients are now surviving for 5 years, compared with only one-quarter 10 years ago. The outlook may improve further with new immune effector cell therapies and combinations of treatments.

Solitary plasmacytomas

These are rare presentations of plasma cell malignancy in which an isolated tumour occurs in soft tissues or bone. Two-thirds of cases occur in soft tissues and are commonly centred around the upper aerodigestive tract, but can occur anywhere. Others present as bone tumours, commonly in long bones and vertebrae. Patients present with pain, palpable lumps or compression symptoms, such as difficulty swallowing, shortness of breath or cord compression.

Diagnosis involves tissue biopsy, which demonstrates a solid tumour of monoclonal plasma cells, and staging to exclude disseminated multiple myeloma. Some cases are associated with a low-level paraprotein, but other features of myeloma are absent.

Primary treatment is usually with radiotherapy. This can be curative, especially in soft tissue plasmacytomas, which less frequently progress to myeloma. Plasmacytomas of bone have a high rate of progression to myeloma and must be monitored carefully or treated as myeloma from the outset. Rarely myeloma presents as multiple plasmacytomas of bone.

Histiocytic disorders

These are a group of rare tissue-infiltrating conditions affecting children and less commonly adults. Histiocytes are immune cells found in various tissues throughout the body, whose functions include phagocytosis (tissue macrophages), activation of the immune system and promoting immune tolerance via antigen presentation to T cells (Fig. 24.43). Disorders resulting from pathological infiltration of tissues by histocytes are shown in Box 24.64.

Langerhans cell histiocytosis (LCH) is the commonest type and is caused by mutations in cell signalling known as the MAP kinase pathway. Key genes mutated in this pathway include *BRAF* (65%–70%) and *MAP2K* (20%). LCH can present with isolated painless lumps, e.g. of bone (eosinophilic granuloma) or with symptoms of disseminated tissue involvement including bone, lung, skin (e.g. persistent nappy rash), lymphadenopathy, splenomegaly and periodontal disease. Diagnosis can be difficult because of the rarity and multiple symptoms at presentation. Management includes surgical excision or radiotherapy of an isolated lesion or topical or systemic chemotherapy drugs, including methotrexate, etoposide and cladribine in disseminated LCH. The *BRAF* inhibitors, e.g. vemurafenib, have shown promising activity in relapsed LCH.

Haemophagocytic lymphohistiocytosis (HLH) results from mutations in immune genes, e.g. *PRF-1*. Presentation is predominantly in children with tissue infiltration by histiocytes and macrophages. Abnormal cytokine production, e.g. interferon-gamma and activation of complement, leads to hyperinflammation and associated haemophagocytosis of blood cells producing pancytopenia. Treatment is based around immunosuppression with glucocorticoids, chemotherapy or ciclosporin, all with the aim of proceeding to allogeneic stem cell transplantation. Newer treatments aimed at inhibiting cytokines or complement activation are being studied.

An acquired form of reactive haemophagocytosis called macrophage activation syndrome (MAS) or secondary HLH is associated with a range of conditions including rheumatological conditions, e.g. juvenile idiopathic arthritis, systemic lupus erythematosus (SLE) and Kawasaki disease, acute viral infections, e.g. EBV, CMV, HHV-6, SARS-CoV-2 and T-cell lymphomas. These diverse conditions generate a cytokine storm, which drives the MAS. Patients present very unwell with fever,

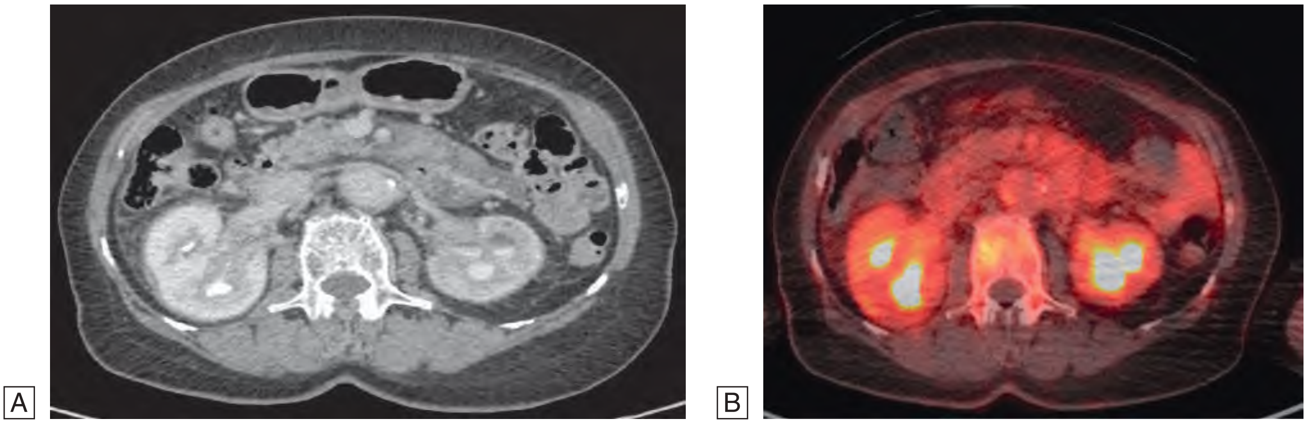

Fig. 24.43 Histiocytic disorder. **A** CT scan demonstrating bilateral histiocytic infiltration of the kidneys with typical 'hair on end' appearance of the renal cortex. The patient is an older woman with Langerhans cell histiocytosis involving kidneys, lymph nodes and skin. **B** PET scan of the same patient showing PET positivity in the renal cortex, most noticeable on the right. The intense PET signal relates to excretion of radioactive glucose in urine into the renal pelvis. *Courtesy of Dr Mark Gandhi, Radiology Department, Aberdeen Royal Infirmary.*

24.64 Histiocytic disorders

- Langerhans cell histiocytosis (LCH)
- Cutaneous and mucocutaneous histiocytosis (C)
- Malignant histiocytosis (M)
- Rosai–Dorfman disease (RD)
- Haemophagocytic lymphohistiocytosis (HLH)

severe pancytopenia, deranged coagulation tests, hepatomegaly and a very high ferritin level (often measured in the tens of thousands μg/L). Management includes supportive care, glucocorticoids or other immunosuppression, inhibition of IL-1 with anakinra and, if possible, treatment of the underlying condition.

Aplastic anaemia

Primary idiopathic acquired aplastic anaemia

This is a rare disorder in Europe and North America, with 2–4 new cases per million population per annum. The disease is much more common in certain other parts of the world, e.g. east Asia. The basic problem is failure of the pluripotent stem cells because of an autoimmune attack, producing hypoplasia of the bone marrow with pancytopenia in the blood. As such, this is an autoimmune disease, but the trigger is unknown in primary acquired aplastic anaemia (AA). The diagnosis rests on exclusion of other causes of secondary aplastic anaemia (see below) and rare congenital causes, such as Fanconi anaemia.

Clinical features and investigations

Patients present with symptoms of bone marrow failure, usually anaemia or bleeding, and less commonly, infections. A FBC demonstrates pancytopenia, low reticulocytes and often macrocytosis. A proportion of patients have abnormal LFTs as a manifestation of autoimmune hepatitis. A PNH clone (p. 961) is identified in some patients. Bone marrow aspiration and trephine reveal hypocellularity. The severity of aplastic anaemia is graded according to the Camitta criteria (Box 24.65).

Management

Except some patients with non-severe AA, patients will require blood product support and aggressive management of infection. The prognosis of severe AA managed with supportive therapy only is poor, and more than 50% of patients die, usually in the first year. The curative treatment for relatively young and fit patients (traditionally < 35 years) with severe idiopathic AA is allogeneic HSCT (p. 966). Older patients aged approximately up to 50 years may be candidates if they have no comorbidities. Those with a compatible sibling, or increasingly matched unrelated donor, should proceed to transplantation as soon as possible; they have a 75%–90% chance of long-term cure. In older and less fit patients and those without a suitable donor, immunosuppressive therapy (IST) with horse anti-thymocyte globulin (ATG) and ciclosporin is the treatment of choice and gives 5-year survival rates of 75%. Unrelated donor allografts have been reserved for suitable patients who fail IST, but are increasingly used first line. The thrombopoietin receptor agonist eltrombopag has produced trilineage responses in patients who fail IST and is licensed for this indication. More recently, the addition of eltrombopag to ATG and ciclosporin A (CsA) has been shown beneficial in improving responses and this is standard of care in many centres. During the COVID pandemic, older and frailer patients were treated with single agent eltrombopag as first-line therapy, to avoid the high risk from COVID of immunosuppression with ATG and CsA. This proved effective in a proportion of patients and continues to be used off licence in some centres. Non-transplanted patients may relapse, or other clonal disorders of haematopoiesis may evolve, such as paroxysmal nocturnal haemoglobinuria (p. 961), myelodysplastic syndrome (p. 993) and AML (p. 986). Patients with aplastic anaemia are followed up long-term.

24.65 Camitta criteria

Severe AA (SAA)

- Marrow cellularity $< 25\%$ (or 25%–50% with $< 30\%$ residual haematopoietic cells), plus at least two of:
  Neutrophils $< 0.5 \times 10^9$/L
  Platelets $< 20 \times 10^9$/L
  Reticulocyte count $< 20 \times 10^9$/L

Very severe AA (VSAA)

- As for SAA but neutrophils $< 0.2 \times 10^9$/L

Non-severe AA (NSAA)

- AA not fulfilling the criteria for SAA or VSAA

(AA = aplastic anaemia)

24.66 Causes of secondary aplastic anaemia

- Drugs:
  - Cytotoxic drugs
  - Antibiotics – chloramphenicol, sulphonamides
  - Antirheumatic agents – penicillamine, gold, phenylbutazone, indometacin
  - Antithyroid drugs – carbimazole, propylthiouracil
  - Anticonvulsants
  - Immunosuppressants – azathioprine
- Chemicals:
  - Benzene, toluene solvent misuse – glue-sniffing
  - Insecticides – chlorinated hydrocarbons (DDT), organophosphates and carbamates (Ch. 11)
- Radiation
- Viral hepatitis
- Pregnancy
- Paroxysmal nocturnal haemoglobinuria

Secondary aplastic anaemia

Causes of this condition are listed in Box 24.66. It is not practical to list all the drugs that have been suspected of causing aplasia. It is important to check the reported side-effects of all drugs taken over the preceding months. In some instances, the cytopenia is more selective and affects only one cell line, most often the neutrophils. Frequently, this is an incidental finding, with no ill-health. It probably has an immune basis, but this is difficult to prove.

The clinical features and methods of diagnosis are the same as for primary idiopathic aplastic anaemia. An underlying cause should be treated or removed, but otherwise management is as for the idiopathic form.

Myeloproliferative neoplasms

These are a group of chronic conditions characterised by clonal proliferation of marrow stem/precursor cells. Polycythaemia vera (PV), essential thrombocythaemia (ET) and primary myelofibrosis (PMF) are the non-leukaemic myeloproliferative neoplasms. Although most patients are classifiable as having one of these disorders, some have overlapping features, and there is often progression from one to another, e.g. PV to myelofibrosis. A mutation in the gene on chromosome 9 encoding the signal transduction molecule *JAK-2* (*JAK-2 V617F*) has been found in more than 90% of PV cases and 50% of those with essential thrombocythaemia and myelofibrosis; less frequently, mutations may be identified in exon 12 of *JAK-2*. Mutations in the calreticulin gene (*CALR*), which produces a chaperone protein that protects proteins moving from the endoplasmic reticulin to the cytoplasm, have been found in a further 25% of patients with essential thrombocythaemia. Less commonly, mutations can be detected in the thrombopoietin receptor gene *MPL*.

Myelofibrosis

In myelofibrosis, the marrow is initially hypercellular, with an excess of abnormal megakaryocytes that release growth factors, such as platelet-derived growth factor, to the marrow microenvironment, resulting in a reactive proliferation of fibroblasts. As the disease progresses, the marrow becomes fibrosed.

Most patients present over the age of 50 years, with lassitude, weight loss and night sweats. The spleen can be massively enlarged due to extramedullary haematopoiesis (blood cell formation outside the bone marrow), and painful splenic infarcts may occur.

The characteristic blood picture is leucoerythroblastic anaemia, with circulating immature red blood cells (increased reticulocytes and nucleated red blood cells) and granulocyte precursors (myelocytes). The red cells are shaped like teardrops (teardrop poikilocytes), and giant platelets may be seen in the blood. The white count varies from low to moderately high and the platelet count may be high, normal or low. Urate levels may be high due to increased cell breakdown, and folate deficiency is common. The marrow is often difficult to aspirate and a trephine biopsy shows an excess of megakaryocytes, increased reticulin and fibrous tissue replacement. The presence of a pathological *JAK-2* mutation supports the diagnosis.

Management and prognosis

Median survival is 4 years from diagnosis, but ranges from 1 year to over 20 years. Treatment is directed at control of symptoms, e.g. red cell transfusions for anaemia. Folic acid should be given to prevent deficiency. Cytotoxic therapy with hydroxycarbamide may help control spleen size, the white cell counts or systemic symptoms. Splenectomy may be required for a grossly enlarged spleen or symptomatic pancytopenia secondary to splenic pooling of cells and hypersplenism. Allogeneic HSCT may be considered for younger patients. Ruxolitinib, an inhibitor of *JAK-1* and *JAK-2*, is effective at reducing systemic symptoms and splenomegaly and may improve life expectancy with longer-term use. Momelotinib is an inhibitor of *JAK* and activin A receptor type 1 (*ACVR1*), which has been shown to improve anaemia and reduce transfusion requirements. Fedratinib, a *JAK-2* inhibitor, also reduces splenomegaly and improves symptom burden and has demonstrated efficacy in those refractory to, or intolerant of, ruxolitinib.

Essential thrombocythaemia

Uncontrolled proliferation of megakaryocytes results in a raised level of circulating platelets that are often dysfunctional. Prior to a diagnosis of essential thrombocythaemia being made, reactive causes of thrombocytosis must be excluded (see Box 24.15). The presence of pathogenic *JAK-2 V617F, CALR* or, rarely, *MPL* mutations supports the diagnosis, but is not universal. Patients present at a median age of 60 years with vascular occlusion, acrocyanosis (painful discoloured fingertips) or bleeding, or with an asymptomatic isolated raised platelet count. A small percentage (around 5%) will transform to acute leukaemia and others to myelofibrosis.

It is likely that most patients with essential thrombocythaemia benefit from low-dose aspirin to reduce the risk of occlusive vascular events. Low-risk patients (age <40 years, platelet count $<1500 \times 10^9$/L and no bleeding or thrombosis) may not require treatment to reduce the platelet count. For those with a platelet count above 1500×10^9/L, with symptoms, or with other risk factors for thrombosis such as diabetes or hypertension, treatment to control platelet counts should be given. Agents include oral hydroxycarbamide or anagrelide, an inhibitor of megakaryocyte maturation. Intravenous radioactive phosphorus (^{32}P) may be useful in old age, but is rarely available nowadays, and interferon-alfa has a role in younger patients, including pregnant women and women planning to conceive.

Polycythaemia vera

PV occurs mainly in patients over the age of 40 years and presents either as an incidental finding of a high haemoglobin, or with symptoms of hyperviscosity, such as lassitude, loss of concentration, headaches, dizziness, blackouts, pruritus and epistaxis. Some patients present with manifestations of peripheral arterial or cerebrovascular disease. Venous thromboembolism may also occur. Peptic ulceration is common, sometimes complicated by bleeding. Patients are often plethoric, and many have a palpable spleen at diagnosis.

Investigation of polycythaemia is discussed on page 953. The diagnosis of PV now rests on the demonstration of a high haematocrit and the presence of a pathogenic *JAK-2* mutation (positive in 95% of cases). In the occasional *JAK-2*-negative cases, a raised red cell mass and absence of causes of secondary erythrocytosis must be established. The spleen may be enlarged and neutrophil and platelet counts are frequently raised, an abnormal karyotype may be found in the marrow and in vitro culture of the marrow can be used to demonstrate autonomous growth in the absence of added growth factors.

Management and prognosis

Aspirin reduces the risk of thrombosis. Venesection gives prompt relief of hyperviscosity symptoms. Between 400 and 500 mL of blood (less if the patient is in old age) are removed and the venesection is repeated every 5–7 days until the haematocrit is reduced to below 45%. Less frequent, regular venesection will maintain this level until the haemoglobin remains reduced because of iron deficiency.

Suppression of marrow proliferation with hydroxycarbamide or interferon-alfa may reduce the risk of vascular occlusion, control spleen size and reduce transformation to myelofibrosis. The *JAK-2* inhibitor ruxolitinib is licensed for patients whose disease is not controlled by hydroxycarbamide. Median survival after diagnosis in treated patients exceeds 10 years. Some patients survive more than 20 years; however, cerebrovascular or coronary events occur in up to 60% of patients. The disease may convert to another myeloproliferative disorder, with about 15% developing acute leukaemia or myelofibrosis.

Bleeding disorders

Disorders of primary haemostasis

The initial formation of the platelet plug (see Fig. 24.6A; also known as 'primary haemostasis') may fail in thrombocytopenia (p. 958), von Willebrand disease (p. 1009), and also in platelet function disorders and diseases affecting the vessel wall.

Vessel wall abnormalities

Vessel wall abnormalities may be:

- congenital, such as hereditary haemorrhagic telangiectasia
- acquired, as in vasculitis (Ch. 25) or scurvy.

Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited condition caused by pathogenic variants in the genes encoding endoglin and activin receptor-like kinase, which are endothelial cell receptors for transforming growth factor beta (TGF-β), a potent angiogenic cytokine. Telangiectasia and small aneurysms are found on the fingertips, face and tongue, and in the nasal passages, lung and gastrointestinal tract. A significant proportion of these patients develop larger pulmonary arteriovenous malformations (PAVMs) that cause arterial hypoxaemia due to a right-to-left shunt. These predispose to paradoxical embolism, resulting in stroke or cerebral abscess. All patients with HHT should be screened for PAVMs and cerebral AVMs; if these are found, ablation by embolisation should be considered.

Patients present either with recurrent bleeds, particularly epistaxis, or with iron deficiency due to occult gastrointestinal bleeding. Treatment can be difficult because of the multiple bleeding points, but regular iron therapy often allows the marrow to compensate for blood loss. Local cautery or laser therapy may prevent single lesions from bleeding. A variety of medical therapies have been tried, but none has been found to be universally effective.

Ehlers–Danlos disease

Vascular Ehlers–Danlos syndrome (type 4) is a rare autosomal dominant disorder (1/100 000) caused by a defect in type 3 collagen that results in fragile blood vessels and organ membranes, leading to bleeding and organ rupture. Classical joint hypermobility (Ch. 25) is often limited in this form of the disease, but skin changes and facial appearance are typical. The diagnosis should be considered when there is a history of bleeding with normal laboratory tests.

Scurvy

Vitamin C deficiency affects the normal synthesis of collagen and results in a bleeding disorder characterised by perifollicular and petechial haemorrhage, bruising and subperiosteal bleeding. The key to diagnosis is the dietary history (Ch. 5).

Platelet function disorders

Bleeding may result from thrombocytopenia (see Box 24.14) or from congenital or acquired abnormalities of platelet function. The most commonly acquired disorders are iatrogenic, resulting from the use of aspirin, clopidogrel, ticagrelor, dipyridamole and the glycoprotein IIb/IIIa inhibitors to prevent arterial thrombosis (see Box 24.27). Inherited platelet function abnormalities are relatively rare. Congenital abnormalities may be due to deficiency of the membrane glycoproteins, e.g. Glanzmann thrombasthenia (IIb/IIIa) or Bernard–Soulier syndrome (Ib), or due to the presence of defective platelet granules, e.g. a deficiency of dense (delta) granules (see Fig. 24.7) giving rise to storage pool disorders. The congenital macrothrombocytopathies that are due to mutations in the myosin heavy chain gene *MYH-9* are characterised by large platelets, inclusion bodies in the neutrophils (Döhle bodies) and a variety of other features, including sensorineural deafness and renal abnormalities. Other familial thrombocytopathies are important, as they can be associated with somatic features (thrombocytopenia with absent radii, TAR), and some are associated with a propensity for development of bone marrow failure or dysplasia (e.g. mutations in *RUNX-1* and *ANKRD 26*).

Apart from Glanzmann thrombasthenia, these conditions are mild disorders, with bleeding typically occurring after trauma or surgery, but rarely spontaneously. Glanzmann thrombasthenia is an autosomal recessive condition associated with a variable, but often severe bleeding disorder. These conditions are usually managed by local mechanical measures, but antifibrinolytics, such as tranexamic acid, may be useful and, in severe bleeding, platelet transfusion may be required. Recombinant VIIa is licensed for the treatment of resistant bleeding in Glanzmann thrombasthenia.

Thrombocytopenia

Thrombocytopenia occurs in many disease processes, as listed in Box 24.14, many of which are discussed elsewhere in this chapter.

Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) is immune-mediated with involvement of autoantibodies, most often directed against the platelet membrane glycoprotein IIb/IIIa, which sensitise the platelet, resulting in premature removal from the circulation by cells of the reticulo-endothelial system. It is not a single disorder; some cases occur in isolation while others are associated with underlying immune dysregulation in conditions such as connective tissue diseases, HIV infection, B-cell malignancies, pregnancy and certain drug therapies. The clinical presentation and pathogenesis are similar, whatever the cause of ITP.

Clinical features and investigations

The presentation depends on the degree of thrombocytopenia. Spontaneous bleeding typically occurs only when the platelet count is below 20×10^9/L. At higher counts, the patient may complain of easy bruising or sometimes epistaxis or menorrhagia. Many cases with counts of more than 50×10^9/L are discovered by chance.

In adults, ITP more commonly affects females and may have an insidious onset. Unlike ITP in children, it is unusual for there to be a history of a preceding viral infection. The development of ITP in the context of COVID-19 infection has been documented. Symptoms or signs of a connective tissue disease may be apparent at presentation or emerge several years later. Patients aged over 65 years should be considered for a bone marrow examination to look for an accompanying B-cell malignancy and appropriate autoantibody testing performed if a diagnosis of connective tissue disease is suspected. HIV testing should be considered because a positive result will have major implications for appropriate therapy. The peripheral blood film is normal, apart from a greatly reduced platelet number, while the bone marrow typically demonstrates an increase in megakaryocytes.

Management

Many patients with stable compensated ITP and a platelet count of more than 30×10^9/L do not require treatment to raise the platelet count, except at times of increased bleeding risk, such as surgery and biopsy. First-line therapy for patients with spontaneous bleeding is with high doses of glucocorticoids, either prednisolone (1 mg/kg daily) or dexamethasone (40 mg daily for 4 days), to suppress antibody production and inhibit phagocytosis of sensitised platelets by reticulo-endothelial cells. Administration of intravenous immunoglobulin can raise the platelet count by blocking antibody receptors on reticulo-endothelial cells and is combined with glucocorticoid therapy if there is severe haemostatic failure, especially with evidence of significant mucosal bleeding or a slow response to glucocorticoids alone. Persistent or potentially life-threatening bleeding should be treated with platelet transfusion in addition to the other therapies.

The condition may become chronic, with remissions and relapses. Relapses should be treated either with further glucocorticoids or second-line therapies. The options for second-line therapy include the thrombopoietin receptor agonists (TPO-RA) eltrombopag, avatrombopag and romiplostim (which stimulate new platelet formation), the splenic tyrosine kinase inhibitor fostamatinib, splenectomy and immunosuppression. Where splenectomy is considered, the precautions shown in Box 24.40 need to be in place. Splenectomy produces complete remission in about 70% of patients and improvement in a further 20%–25% in favourable cases. The TPO-RAs induce response in around 75% of cases, usually within 10–14 days. Low-dose glucocorticoid therapy and immunosuppressants such as rituximab, ciclosporin, mycophenolate and tacrolimus may also produce remissions. The order in which therapies should be used is not entirely clear, although the TPO-RAs and fostamatinib are licensed for this indication, while the immunosuppressive agents are not.

Coagulation disorders

Normal coagulation is explained in Figure 24.6 and the effects of age are discussed in Box 24.67. Coagulation factor deficiency may be congenital or acquired and may affect one or several of the coagulation factors (Box 24.68). Inherited disorders are almost uniformly related to decreased synthesis, as a result of mutation in the gene encoding a key protein in coagulation. Von Willebrand disease is the most common inherited bleeding disorder. Haemophilia A and B are the most common single coagulation factor deficiencies, but inherited deficiencies of all the other coagulation factors are seen. Acquired disorders may be due to under-production (e.g. in liver failure), increased consumption (e.g. in DIC) or inhibition of function of coagulation factors (such as heparin therapy or immune inhibitors of coagulation, e.g. acquired haemophilia A).

Haemophilia A and haemophila B (Christmas disease)

Factor VIII deficiency resulting in haemophilia A affects 1/10 000 individuals. It is the most common congenital coagulation factor deficiency.

24.67 Haemostasis and thrombosis in old age

- **Thrombocytopenia**: reasonably common because of the rising prevalence of disorders in which it may be a secondary feature and also because of the greater use of drugs that can cause it.
- **'Senile' purpura**: presumed to be due to an age-associated loss of subcutaneous fat and the collagenous support of small blood vessels, making them more prone to damage from minor trauma.
- **Thrombosis**: incidence of thromboembolic disease rises with increasing age. This may be due to stasis and concurrent illness, to which older people are prone. Some studies show increased platelet aggregation with age and others age-associated hyperactivity of the haemostatic system, which could contribute to a prothrombotic state.
- **Thromboprophylaxis**: should be considered in all older patients who are immobile as a result of acute illness. Prophylaxis is not required in chronic immobility without a medical cause, as there is no associated increase in thromboembolism.
- **Anticoagulation**: older patients are more sensitive to the anticoagulant effects of warfarin, partly due to the concurrent use of other drugs and the presence of other pathology. Life-threatening or fatal bleeds on warfarin are significantly more common in those over 80 years.

24.68 Causes of coagulopathy

Congenital

X-linked

- Haemophilia A and B

Autosomal

- Von Willebrand disease
- Factor II, V, VII, X, XI and XIII deficiencies
- Combined II, VII, IX and X deficiency
- Combined V and VIII deficiency
- Hypofibrinogenaemia
- Dysfibrinogenaemia

Acquired

Under-production

- Liver failure
- Vitamin K deficiency

Increased consumption

- Coagulation activation:
  - Disseminated intravascular coagulation (DIC)
- Immune-mediated:
  - Acquired haemophilia and von Willebrand syndrome
- Others:
  - Acquired factor X deficiency (in amyloid)
  - Acquired von Willebrand syndrome in Wilms tumour
  - Acquired factor VII deficiency in sepsis

Drug-induced

- Inhibition of function:
  - Heparins
  - Argatroban
  - Bivalirudin
  - Fondaparinux
  - Rivaroxaban
  - Apixaban
  - Dabigatran
  - Edoxaban
- Inhibition of post-translational modification:
  - Warfarin

Factor VIII is primarily synthesised by the liver and endothelial cells and has a half-life of about 12 hours. It is protected from proteolysis in the circulation by binding to von Willebrand factor (vWF).

Aberrations of the factor IX gene result in a reduction of the plasma factor IX level, giving rise to haemophilia B. This disorder is clinically indistinguishable from haemophilia A, but is less common. The frequency of bleeding episodes is related to the severity of the deficiency of the plasma factor IX level.

24.69 Severity of haemophilia (ISTH criteria)

Severity	Factor VIII or IX level	Clinical presentation
Severe	< 1 IU/dL	Spontaneous haemarthroses and muscle haematomas
Moderate	1–5 IU/dL	Mild trauma or surgery causes bleeding
Mild	> 5–40 IU/dL	Major injury or surgery results in excess bleeding

(ISTH = International Society on Thrombosis and Haemostasis)

Genetics

Haemophilia is associated with a range of mutations in the factor VIII and IX genes; these include major inversions, large deletions and missense, nonsense and splice site abnormalities. The factor VIII and IX genes are both located on the X chromosome; thus haemophilia A and B are sex-linked disorders (Ch. 3). Thus, all daughters of a patient with haemophilia A or B are obligate carriers and they, in turn, have a 1 in 4 chance of each pregnancy resulting in the birth of an affected male baby, a normal male baby, a carrier female or a normal female. Antenatal diagnosis by chorionic villous sampling is possible in families with a known mutation.

Haemophilia 'breeds true' within a family; all members have the same factor VIII/IX pathogenic variant and a similarly severe or mild phenotype. Female carriers of haemophilia may have reduced factor VIII/IX levels because of random inactivation of their normal X chromosome in the developing fetus. This can result in a mild bleeding disorder; thus, all known or suspected carriers of haemophilia A/B should have their factor VIII/IX levels measured.

Clinical features

The extent and patterns of bleeding are closely related to residual factor VIII/IX levels (Box 24.69). Patients with severe haemophilia (factor VIII or IX levels < 1 IU/dL) present with spontaneous bleeding into skin, muscle and joints. Retroperitoneal and intracranial bleeding is also a feature. Babies with severe haemophilia have an increased risk of intracranial haemorrhage and, although there is insufficient evidence to recommend routine caesarean section for these births, it is appropriate to avoid head trauma and to perform cranial imaging of the newborn within the first 24 hours of life. Individuals with moderately severe and mild haemophilia (factor VIII or IX levels 1–5 IU/dL and > 5 IU/dL, respectively) present with the same pattern of bleeding, but usually after trauma or surgery when bleeding is disproportionate to the severity of the insult.

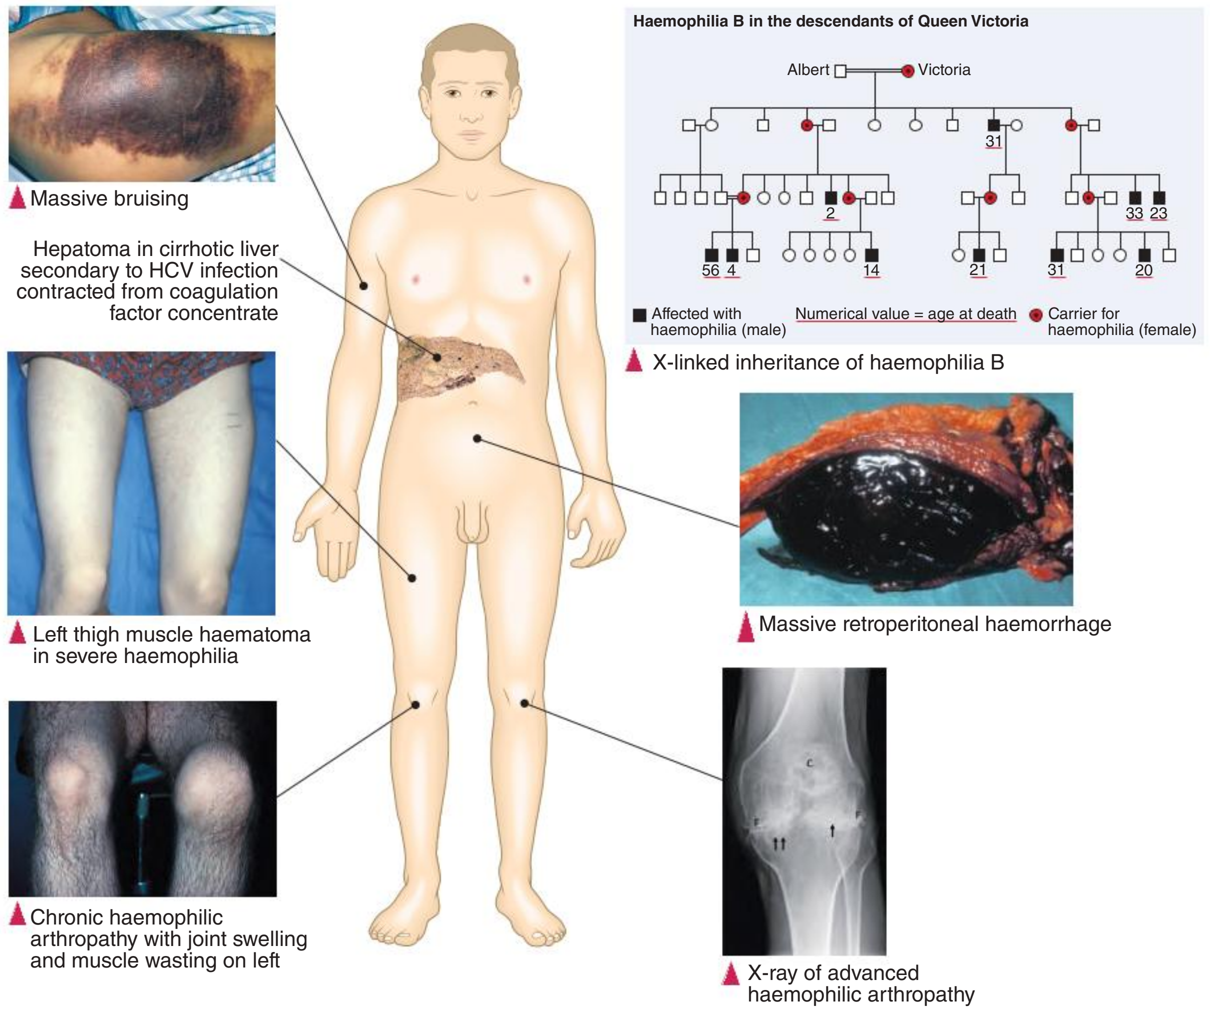
The major morbidity of recurrent bleeding in severe haemophilia is musculoskeletal. Bleeding is typically into large joints, especially knees, elbows, ankles and hips. Muscle haematomas are also characteristic, most commonly in the calf and psoas muscles. If early treatment is not given to arrest bleeding, a hot, swollen and very painful joint or muscle haematoma develops. Recurrent bleeding into joints leads to synovial hypertrophy, destruction of the cartilage and chronic haemophilic arthropathy (Fig. 24.44). Complications of muscle haematomas depend on their location. A large psoas bleed may extend to compress the femoral nerve; calf haematomas may increase pressure within the inflexible fascial sheath, causing a compartment syndrome with ischaemia, necrosis, fibrosis, and subsequent contraction and shortening of the Achilles tendon.

Management

The aim of management of severe haemophilia A and B in high-income countries is to render patients 'bleed free'. This can be achieved by replacement of the deficient coagulation factor. In addition to factor concentrates, non-replacement therapies and gene therapy are also options.

Coagulation factor therapy

Prophylaxis using concentrates aims to achieve trough levels of factor VIII or IX that protect the patient against spontaneous bleeding. There is debate about optimal trough values needed to achieve this aim. Prophylaxis can be provided in many ways: daily, on alternate days, or on information from



Massive bruising
Hepatoma in cirrhotic liver secondary to HCV infection contracted from coagulation factor concentrate

pharmacokinetic studies that inform on the best way of scheduling prophylaxis. Practice in haemophilia A and B is also changing due to the introduction of recombinant factor concentrates that have been manipulated to alter their half-life. In addition to standard half-life recombinant factor VIII and IX, there are new products produced by Fc fusion and pegylation/glycopegylation that extend the half-life of the coagulation factor to the degree that it can be used to alter dosing schedules for prophylaxis.

An alternative approach used in low- and middle-income countries is to treat on demand. In severe haemophilia A/B, bleeding episodes should be treated by raising the factor VIII/IX level, usually by intravenous infusion of factor VIII/IX concentrate. Factor VIII/IX concentrates are freeze-dried and stable at 4°C and can therefore be stored in domestic refrigerators, allowing patients to treat themselves at home at the earliest indication of bleeding. Coagulation factor concentrates prepared from blood donor plasma are now screened for many blood-borne pathogens including HBV, HCV and HIV, and undergo two separate virus inactivation or removal processes during manufacture; these preparations have a good safety record. However, factor concentrates prepared by recombinant technology are now widely available and, although more expensive, are perceived as being safer than those derived from human plasma in relation to infection risk. In addition to raising factor VIII or IX concentrations, resting of the bleeding site with either bed rest or a splint reduces continuing haemorrhage. Once bleeding has settled, the patient should be mobilised and physiotherapy used to restore strength to the surrounding muscles. All non-immune potential recipients of pooled blood products should be offered hepatitis A and B immunisation.

The arginine vasopressin receptor agonist desmopressin raises vWF and factor VIII levels 3- to 4-fold, which is useful in arresting bleeding in patients with mild or moderate haemophilia A. The dose required for this purpose is higher than that used in arginine vasopressin deficiency (cranial diabetes insipidus), usually 0.3 µg/kg, and is given intravenously or subcutaneously. Alternatively, the same effect can be achieved by intranasal administration of a 300 µg dose. Following repeated administration of desmopressin, patients need to be monitored for evidence of water retention, which can result in significant hyponatraemia. Desmopressin is contraindicated in patients with a history of severe arterial disease, because of a propensity to provoke a thrombotic event, and in young children where hyponatraemia can result in fits.

Complications of coagulation factor therapy Before 1986, coagulation factor concentrates from human plasma were not fully virus-inactivated and many patients became infected with HIV and HBV/HCV. Concern that the infectious agent that causes variant Creutzfeldt–Jakob disease (vCJD) (Ch. 27) might be transmissible by blood and blood products has been confirmed in recipients of red cell transfusion (p. 960), and in one recipient of factor VIII. Another serious complication of factor VIII treatment is the development of anti-factor VIII antibodies, which arise in about 25% of those with severe haemophilia. These antibodies rapidly neutralise therapeutic infusions, making treatment relatively ineffective. Antibodies against factor IX are much less common (<1%), but when they do occur may be heralded by the development of a severe allergic reaction. Infusions of activated clotting factors, e.g. VIIa or factor VIII inhibitor bypass activity (FEIBA), may stop bleeding.

Non-replacement therapy

Emicizumab is a bispecific monoclonal antibody that mimics factor VIII activity and binds to both activated factor IX and factor X to allow the formation of the tenase complex, which results in thrombin and clot formation (Fig. 24.45). It is a subcutaneous injection obviating the need for patients to cannulate veins regularly or have definite intravenous access such as a portacath. Emicizumab is licensed for use in patients with moderate to severe haemophilia A, including those with factor VIII inhibitors.

There is emerging data on the efficacy of fitusiran, a small interfering RNA (siRNA) that binds to mRNA in the liver and inhibits antithrombin translation. Reduced antithrombin production leads to rebalancing of haemostasis in people with haemophilia A and B.

Concizumab and marstacimab are anti-tissue factor pathway inhibitor (TFPI) monoclonal antibodies, which have been trialled in haemophilia A and B. They block TFPI binding to factor Xa, thereby allowing ongoing thrombin generation and restoration of haemostasis.

Gene therapy

Gene therapy approaches in haemophilia have focused on a transgene being delivered directly to the patient via intravenous infusion using a liver-directed viral vector. Recombinant adeno-associated viral vectors have most commonly been used. Valoctocogene (containing the gene for factor VIII) and etranacogene (containing the gene for factor IX) have shown efficacy in haemophilia A and B, respectively, by increasing the expression of the deficient coagulation factor to a level that ameliorates bleeding symptoms. Gene therapy is a transformative treatment as it can obviate the need for factor replacement or non-replacement therapies.

Von Willebrand disease

Von Willebrand disease is a common and usually mild bleeding disorder caused by a quantitative (types 1 and 3) or qualitative (type 2) deficiency of von Willebrand factor (vWF). This protein is synthesised by endothelial cells and megakaryocytes and is involved in both platelet function and coagulation. It normally forms a multimeric structure that is essential for its interaction with subendothelial collagen and platelets (see Figs. 24.6 and 24.7). vWF acts as a carrier protein for factor VIII, to which it is non-covalently bound; deficiency of vWF lowers the plasma factor VIII level. vWF also forms bridges between platelets and subendothelial components (e.g. collagen; see Fig. 24.6B), allowing platelets to adhere to damaged vessel walls; deficiency of vWF therefore leads to impaired platelet plug formation. Blood group antigens (A and B) are expressed on vWF, reducing its susceptibility to proteolysis; as a result, people with blood group O have lower circulating vWF levels than individuals with non-O groups.

Platelet

Fig. 24.45 Mechanism of action of novel agents in haemostasis and thrombosis. Emicizumab is a bispecific antibody that acts in a similar manner to factor VIIIa by binding to factor IXa and factor X and so can be used in haemophilia A. Caplacizumab inhibits the A1 domain on von Willebrand factor (vWF), preventing binding to platelets and subsequent platelet aggregation. It is increasingly used in the treatment of thrombotic thrombocytopenic purpura (TTP).

Most patients with von Willebrand disease have a type 1 disorder, characterised by a quantitative decrease in a normal functional protein. This usually arises through reduced synthesis or increased clearance of vWF. Patients with type 2 disorders inherit vWF molecules that are functionally abnormal. The type of abnormality depends on the site of the mutation in the *vWF* gene and how it affects binding to platelets, collagen and factor VIII. Patients with type 2A disease have abnormalities in vWF-dependent platelet adhesion; those with mutations in the platelet glycoprotein Ib binding site, resulting in increased affinity for glycoprotein Ib, have type 2B disease; those with mutations in the factor VIII binding site have type 2N disease; and those with other abnormalities in platelet binding, but with normal vWF multimeric structure, have type 2M disease. The patterns of laboratory abnormality accompanying these types are described in Box 24.70. The gene for vWF is located on chromosome 12 and the disease is usually autosomal dominantly inherited, except in type 2N and type 3, where inheritance is autosomal recessive.

Clinical features

Patients present with haemorrhagic manifestations similar to those in individuals with reduced platelet function. Superficial bruising, epistaxis, menorrhagia and gastrointestinal haemorrhage are common. Bleeding episodes are usually much less frequent than in severe haemophilia, and excessive haemorrhage may be observed only after trauma or surgery. Within a single family, the disease has variable penetrance, so that some members may have quite severe and frequent bleeds, whereas others are relatively asymptomatic.

Investigations

The disorder is characterised by reduced activity of vWF and factor VIII. The disease can be classified using a combination of assays that include functional and antigenic measures of vWF, multimeric analysis of the protein, and specific tests of function to determine binding to platelet glycoprotein Ib (RIPA) and factor VIII (see Box 24.70). In addition, analysis for mutations in the *vWF* gene can be informative.

24.70 Classification of von Willebrand disease

Type	Defect	Inheritance	Investigations/patterns
1	Partial quantitative	AD	Parallel decrease in vWF:Ag, RiCoF and VIII:c
2A	Qualitative	AD	Absent HWM of vWF Ratio of vWF activity to antigen < 0.7
2B	Qualitative	AD	Reduced HWM of vWF Enhanced platelet agglutination (RIPA)
2M	Qualitative	AD	Ratio of vWF activity to antigen < 0.7 Normal multimers of vWF Abnormal vWF/platelet interactions
2N	Qualitative	AR	Defective binding of vWF to VIII Low VIII
3	Severe quantitative	AR or CH	Very low vWF and VIII:c activity Absent multimers

(AD = autosomal dominant; AR = autosomal recessive; CH = compound heterozygote; HWM = high-weight multimers of vWF; RiCoF = ristocetin co-factor; RIPA = ristocetin-induced platelet agglutination; VIII:c = coagulation factor VIII activity in functional assay; vWF = von Willebrand factor; vWF:Ag = vWF antigen measured by ELISA)

Management

Many episodes of mild haemorrhage can be successfully treated by local means or with desmopressin, which raises the vWF level, resulting in a secondary increase in factor VIII. Tranexamic acid may be useful in mucosal bleeding. For more serious or persistent bleeds, haemostasis can be achieved with selected factor VIII concentrates, which contain considerable quantities of vWF in addition to factor VIII. Pure plasma-derived and recombinant vWF concentrates are now available, improving the options and the perceived safety of treatment. Young children and patients with severe arterial disease should not receive desmopressin, and patients with type 2B disease develop thrombocytopenia that may be troublesome following desmopressin. Bleeding in type 3 patients responds only to factor VIII/vWF concentrate.

Rare inherited bleeding disorders

Severe deficiencies of factors VII, X and XIII occur as autosomal recessive disorders. They are rare, but are associated with severe bleeding. Typical features include haemorrhage from the umbilical stump and intracranial haemorrhage. Factor XIII deficiency in women is typically associated with recurrent fetal loss.

Factor XI deficiency may occur in heterozygous or homozygous individuals. Bleeding is very variable and is not accurately predicted by coagulation factor levels. In general, severe bleeding is confined to patients with levels below 15% of normal.

Acquired bleeding disorders

DIC is an important cause of bleeding that begins with exaggerated and inappropriate intravascular coagulation. It is discussed later under thrombotic disorders.

Liver disease

Although chronic liver disease can be associated with an excess of bleeding, it is now clear that these patients also have an increased risk of venous thrombosis. The description of end-stage liver disease as a state of auto-anticoagulation is misleading. Although there is reduced hepatic synthesis of procoagulant factors, this is balanced to a degree by the reduced production of natural anticoagulant proteins and reduced fibrinolytic activity in patients with advanced liver disease. In severe parenchymal liver disease, bleeding may arise from many different causes. Major bleeding is often from structural abnormalities such as oesophageal varices or peptic ulcer, and sepsis and volume overload are common precipitants of bleeding. There is reduced hepatic synthesis, for example, of factors V, VII, VIII, IX, X, XI, prothrombin and fibrinogen. Clearance of plasminogen activator is reduced. Thrombocytopenia may occur secondary to hypersplenism in the presence of portal hypertension and due to reduced production and activity of thrombopoietin in advanced liver disease. In cholestatic jaundice, there is reduced vitamin K absorption, leading to deficiency of factors II, VII, IX and X, but also of proteins C and S. Treatment with plasma products or platelet transfusion should be reserved for acute bleeds or to cover interventional procedures such as liver biopsy. Vitamin K deficiency can be readily corrected with parenteral administration of vitamin K.

Renal failure

The severity of the haemorrhagic state in renal failure is proportional to the plasma urea concentration. Bleeding manifestations are those of platelet dysfunction, with gastrointestinal haemorrhage being particularly common. The causes are multifactorial and include anaemia, mild thrombocytopenia and the accumulation of low-molecular-weight waste products, normally excreted by the kidney, that inhibit platelet function. Treatment is by dialysis to reduce the urea concentration. Rarely, in severe or persistent bleeding, platelet concentrate infusions and red cell transfusions are indicated. Increasing the concentration of vWF, either by cryoprecipitate or by desmopressin, may promote haemostasis. Patients with significant renal impairment have an increased risk of anticoagulant-related bleeding, particularly with drugs that are at least partially renally excreted.

Thrombotic disorders

Venous thromboembolic disease (venous thromboembolism)

While the most common presentations of venous thromboembolism (VTE) are deep vein thrombosis (DVT) of the leg (p. 225) and/or pulmonary embolism (PE; see also p. 586), similar management principles apply to rarer manifestations such as jugular vein thrombosis, upper limb DVT, cerebral sinus thrombosis (p. 1196) and intra-abdominal venous thrombosis (e.g. Budd–Chiari syndrome; p. 928).

VTE has an annual incidence of approximately 1:1000 in high-income populations. The relative incidence of DVT:PE is approximately 2:1. Mortality 30 days after DVT is approximately 10%, compared to 15% for PE. All forms of VTE are increasingly common with age and many of the deaths are related to coexisting medical conditions, such as active cancer or inflammatory disease, which predispose the patient to thrombosis in the first place. Risk factors for VTE are often present (Box 24.71) and it is appropriate to seek evidence of these risk factors in determining the long-term management strategy. Figure 24.46 illustrates some of the

24.71 Factors predisposing to venous thrombosis

Patient factors

- Increasing age
- Obesity
- Varicose veins
- Previous deep vein thrombosis
- Family history, especially of unprovoked venous thromboembolism when young
- Transient additional risk factors:
  Pregnancy/puerperium
  Oestrogen-containing oral contraceptives and hormone replacement therapy
  Immobility, e.g. long-distance travel (> 4 hrs)
  Intravenous drug use involving the femoral vein
  Surgery (see below)
  Medical illnesses (see below)

Surgical conditions

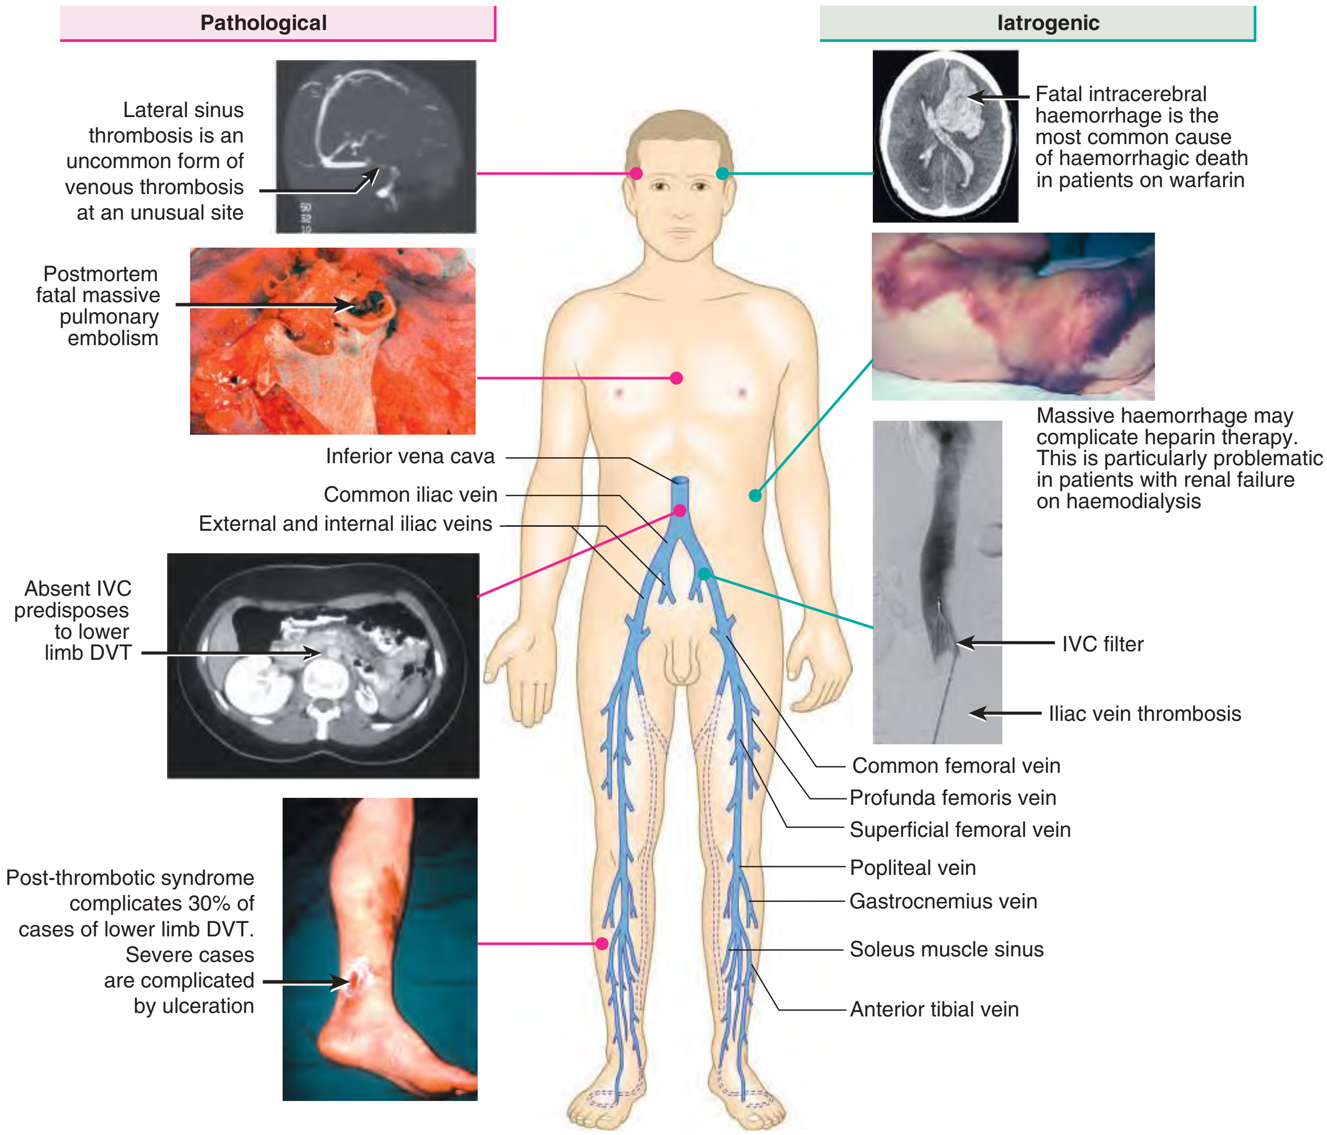
- Major surgery, especially if > 30 mins' duration
- Abdominal or pelvic surgery, especially for cancer
- Major lower limb orthopaedic surgery, e.g. joint replacement and hip fracture surgery

Medical conditions

- Myocardial infarction/heart failure
- Inflammatory conditions: inflammatory bowel disease, connective tissue disorders and vasculitis
- Malignancy (anti-cancer chemotherapy increases the risk of venous thromboembolism compared with cancer alone)
- Nephrotic syndrome
- Chronic obstructive pulmonary disease
- Severe infection, bacterial or viral
- Neurological conditions associated with immobility, e.g. stroke, paraplegia, Guillain–Barré syndrome
- Any high-dependency admission

Haematological disorders

- Polycythaemia vera
- Essential thrombocythaemia
- Deficiency of natural anticoagulants: antithrombin, protein C, protein S
- Paroxysmal nocturnal haemoglobinuria
- Gain-of-function prothrombotic mutations: factor V Leiden, prothrombin gene *G20210A*
- Myelofibrosis
- Antiphospholipid syndrome



Pathological
Iatrogenic
Lateral sinus thrombosis is an uncommon form of venous thrombosis at an unusual site
Fatal intracerebral haemorrhage is the most common cause of haemorrhagic death in patients on warfarin
Postmortem fatal massive pulmonary embolism
Massive haemorrhage may complicate heparin therapy. This is particularly problematic in patients with renal failure on haemodialysis
Inferior vena cava
Common iliac vein
External and internal iliac veins
Absent IVC predisposes to lower limb DVT
IVC filter
Iliac vein thrombosis
Common femoral vein
Profunda femoris vein
Superficial femoral vein
Popliteal vein
Gastrocnemius vein
Soleus muscle sinus
Anterior tibial vein
Post-thrombotic syndrome complicates 30% of cases of lower limb DVT. Severe cases are complicated by ulceration

Fig. 24.46 **Causes and consequences of venous thromboembolic disease and its treatment.** (DVT = deep vein thrombosis; IVC = inferior vena cava)

causes and consequences of VTE. The diagnosis of DVT and PE are discussed on pages 225 and 586, respectively.

Management of VTE

The mainstay of treatment for all forms of VTE is anticoagulation. This can be achieved in several ways. One option is to use LMWH followed by a coumarin anticoagulant, such as warfarin. Treatment of acute VTE with LMWH should continue for a minimum of 5 days. Patients treated with warfarin should achieve a target INR of 2.5 (range 2–3; p. 950 and Box 24.26) with LMWH continuing until the INR is above 2. Alternatively, patients may be treated with a DOAC. Rivaroxaban and apixaban may be used immediately from diagnosis without the need for LMWH, while the licences for dabigatran and edoxaban include initial treatment with LMWH for a minimum of 5 days before commencing the DOAC (see Fig. 24.45). In patients with active cancer and VTE, maintenance anticoagulation with LMWH is associated with a lower recurrence rate than warfarin. The use of DOACs in cancer-associated thrombosis has been studied. Apixaban, rivaroxaban and edoxaban demonstrate efficacy in this context although bleeding rates were higher for rivaroxaban and edoxaban when compared to LMWH.

Patients who have had VTE and have a strong contraindication to anticoagulation and those who continue to have new pulmonary emboli despite therapeutic anticoagulation should have an inferior vena cava (IVC) filter inserted to prevent life-threatening PE.

With the exception of cancer-associated thrombosis, the initial period of anticoagulation is generally 3 months, at which point a decision is made as to whether anticoagulation is continued or not. Patients with a provoked VTE in the presence of a temporary risk factor, which is then removed, can usually be treated for 3 months. If there are ongoing risk factors that cannot be alleviated, such as active cancer, long-term anticoagulation is usually recommended, provided that the risk of bleeding is not deemed excessive.

For patients with unprovoked VTE, the optimum duration of anticoagulation can be difficult to establish. Recurrence of VTE is about 2%–3% per annum in patients who have a temporary medical risk factor at presentation and about 7%–10% per annum in those with apparently unprovoked VTE. This plateaus at around 30%–40% recurrence at 5 years. As such, many patients who have had unprovoked episodes of VTE will benefit from long-term anticoagulation. Several factors predict risk of recurrence following an episode of unprovoked VTE. The strongest predictors of recurrence are male sex and a positive D-dimer assay measured 1 month after stopping anticoagulant therapy. These factors are incorporated into scoring systems to predict recurrence, such as the DASH score, HERDOO2 score and the Vienna prediction model.

The management of DVT of the leg should also include elevation and analgesia; in limb-threatening DVT, thrombolysis may also be considered. Thrombolysis for PE is discussed in Chapter 17. Post-thrombotic syndrome is due to damage of venous valves by the thrombus. It occurs

24.72 Antithrombotic prophylaxis

Indications

Patients in the following categories should be considered for specific antithrombotic prophylaxis:

Moderate risk of DVT

- Major surgery:
  In patients > 40 years or with other risk factor for VTE
- Major medical illness, e.g.:
  Heart failure
  Myocardial infarction with complications
  Sepsis
  Inflammatory conditions, including inflammatory bowel disease
  Active malignancy
  Nephrotic syndrome
  Stroke and other conditions leading to lower limb paralysis

High risk of DVT

- Major abdominal or pelvic surgery for malignancy or with history of DVT or known thrombophilia (see Box 24.4)
- Major hip or knee surgery
- Neurosurgery

Methods of VTE prophylaxis

Mechanical

- Intermittent pneumatic compression
- Mechanical foot pumps
- Graduated compression stockings

Pharmacological

- LMWHs
- Unfractionated heparin
- Fondaparinux
- Dabigatran
- Rivaroxaban
- Apixaban
- Warfarin

(DVT = deep vein thrombosis; VTE = venous thromboembolism)

in around 30% of patients who sustain a proximal lower limb DVT and results in persistent leg swelling, heaviness and discoloration. The most severe complication of this syndrome is ulceration around the medial malleolus (see Fig. 24.46). Use of elastic compression stockings following a DVT does not reduce the incidence of post-thrombotic syndrome, but may alleviate the symptoms.

Prophylaxis of VTE

All patients admitted to hospital should be assessed for their risk of developing VTE, and appropriate prophylactic measures should be put in place. Both medical and surgical patients are at increased risk. A summary of the risk categories is given in Box 24.72. Early mobilisation of patients is important to prevent DVT, and those at medium or high risk require additional antithrombotic measures; these may be pharmacological or mechanical. There is increasing evidence in high-risk groups, such as patients who have had major lower limb orthopaedic surgery and abdominal or pelvic cancer surgery, for protracted thromboprophylaxis for as long as 30 days or so after the procedure. Care should be taken with the use of pharmacological prophylaxis in patients with a high risk of bleeding or with specific risks of haemorrhage related to the site of surgery or the use of spinal or epidural anaesthesia.

Inherited and acquired thrombophilia and prothrombotic states

Several inherited conditions predispose to VTE (see Box 24.71), and have several points in common that are worth noting:

- None of them is strongly associated with arterial thrombosis.
- All are associated with a slightly increased incidence of adverse outcome of pregnancy, including recurrent early fetal loss, but there are no data to indicate that any specific intervention changes that outcome.
- Apart from in antithrombin deficiency and homozygous factor V Leiden, most carriers of these genes will never have an episode of VTE; if they do, it will be associated with the presence of an additional temporary risk factor.
- There is little evidence that detection of these abnormalities predicts recurrence of VTE over and above the validated scoring systems mentioned above.
- None of these conditions per se requires treatment with anticoagulants. Patients with thrombosis should receive anticoagulation, as discussed earlier. Patients who are deemed to be at high risk of thrombosis, e.g. those with antithrombin deficiency in pregnancy, should receive treatment or prophylactic doses of unfractionated or LMWH to cover the period of risk only.

Antithrombin deficiency

Antithrombin (AT) is a serine protease inhibitor (serpin) that inactivates the activated coagulation factors IIa, IXa, Xa and XIa. Heparins and fondaparinux achieve their therapeutic effect by potentiating the activity of AT. Familial deficiency of AT is inherited in an autosomal dominant manner; homozygosity for mutant alleles is not compatible with life. Around 70% of affected individuals will have an episode of VTE before the age of 60 years and the relative risk for thrombosis compared with the background population is 10- to 20-fold. Pregnancy is a high-risk period for VTE and this requires aggressive management with doses of LMWH that are greater than the usual prophylactic doses (≥ 100 U/kg/day). AT concentrate (either plasma-derived or recombinant) is available; this is required for cardiopulmonary bypass and may be used as an adjunct to heparin in surgical prophylaxis and in the peripartum period.

Protein C and S deficiencies

Protein C and its co-factor protein S are vitamin K–dependent natural anticoagulants involved in switching off coagulation factor activation (factors Va and VIIIa) and so thrombin generation (see Fig. 24.6F). Inherited deficiency of either protein C or S results in a prothrombotic state with a fivefold relative risk of VTE compared with the background population.

Factor V Leiden

Factor V Leiden results from a gain-of-function, single-base-pair mutation, which prevents the cleavage and hence inactivation of activated factor V. This results in a relative risk of venous thrombosis of 5 in heterozygotes and 50 or more in rare homozygotes. The mutation is found in about 5% of Northern Europeans, 2% of Hispanics, 1.2% of African Americans, 0.5% of Asian Americans and 1.25% of Indigenous Americans, and is rare in Chinese and Malay people.

Prothrombin G20210A

This gain-of-function mutation in the non-coding 3′ end of the prothrombin gene is associated with an increased plasma level of prothrombin. It is present in about 2% of Northern Europeans, but is rare in native populations of Korea, China, India and Africa. In the heterozygous state, it is associated with a two- to threefold increase in risk of VTE compared with the background population.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is a clinicopathological entity in which a constellation of clinical conditions, alone or in combination, is found in association with a persistently positive test for an antiphospholipid antibody. The antiphospholipid antibodies are heterogeneous and typically are directed against proteins that bind to phospholipids (Box 24.73). Although causal roles for these antibodies have been proposed, the mechanisms underlying the clinical features of APS are not clear. In clinical practice, two types of test are used, which detect:

- ELISA assays which detect IgG and IgM antibodies directed against cardiolipin and β_2-glycoprotein 1 (β_2-GP1)

- those that interfere with phospholipid-dependent coagulation tests like the APTT or the dilute Russell viper venom time (DRVVT; called a lupus anticoagulant test).

The term antiphospholipid antibody encompasses both a lupus anticoagulant and anticardiolipin or anti-β_2-GP1 antibodies; individuals may be positive for one, two or all three of these activities. It has been shown that patients who are 'triple positive' have an increased likelihood of thrombotic events compared with single or double positives.

Clinical features and management

APS may present in isolation (primary APS) or in association with one of the conditions shown in Box 24.73, most typically systemic lupus erythematosus (secondary APS). Most patients present with a single manifestation and APS is now most frequently diagnosed in women with adverse outcomes of pregnancy. It is extremely important to make the diagnosis in patients with APS, whatever the manifestation, because it affects the prognosis and management of arterial thrombosis, VTE and pregnancy.

Arterial thrombosis, typically stroke, associated with APS should probably be treated with anticoagulation, as opposed to antiplatelet therapy. APS-associated VTE is one of the situations in which the predicted recurrence rate is high enough to indicate long-term anticoagulation after a first event. Recent evidence suggests that patients with APS presenting with thrombotic events should receive warfarin as opposed to a DOAC as the anticoagulant of choice. In women with obstetric presentations of APS, intervention with heparin and aspirin is almost routinely prescribed, although there is little evidence from clinical trials that it is an effective therapy in increasing the chance of a successful pregnancy outcome.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) may complicate a range of illnesses (Box 24.74). It is characterised by systemic activation of the pathways involved in coagulation and its regulation. This may result in the generation of intravascular fibrin clots causing multi-organ failure, with simultaneous coagulation factor and platelet consumption, causing bleeding. The systemic coagulation activation is induced either through cytokine pathways, which are activated as part of a systemic inflammatory response, or by the release of procoagulant substances such as tissue factor. In addition, suboptimal function of the natural anticoagulant pathways and dysregulated fibrinolysis contribute to DIC. There is consumption of platelets, coagulation factors (notably factors V and VIII) and fibrinogen. The lysis of fibrin clot results in production of fibrin degradation products (FDPs), including D-dimers.

24.73 Antiphospholipid syndrome (APS)

Clinical manifestations

- Adverse pregnancy outcome
  - Recurrent first trimester abortion (≥ 3)
  - Unexplained death of morphologically normal fetus after 10 weeks' gestation
  - Severe early pre-eclampsia
- Venous thromboembolism
- Arterial thromboembolism
- Livedo reticularis, catastrophic APS, transverse myelitis, skin necrosis, chorea

Conditions associated with secondary APS

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Systemic sclerosis
- Behçet disease
- Temporal arteritis
- Sjögren syndrome

Targets for antiphospholipid antibodies

- β_2-glycoprotein 1
- Protein C
- Annexin V
- Prothrombin (may result in haemorrhagic presentation)

Investigations

DIC should be suspected when any of the conditions listed in Box 24.74 are met. Measurement of coagulation times (APTT and PT; see Box 24.3) along with fibrinogen, platelet count and FDPs, helps in the assessment of prognosis and aids clinical decision-making with regard to both bleeding and thrombotic complications.

Management

Therapy is primarily aimed at the underlying cause. These patients will often require intensive care to deal with concomitant issues, such as acidosis, dehydration, renal failure and hypoxia. Blood component therapy, such as fresh frozen plasma, cryoprecipitate and platelets, should be given if the patient is bleeding or to cover interventions with a high bleeding risk, but should not be prescribed routinely based on coagulation tests and platelet counts alone. Prophylactic doses of heparin should be given, unless there is a clear contraindication. Established thrombosis should be treated cautiously with therapeutic doses of unfractionated heparin, unless clearly contraindicated. Patients with DIC should not, in general, be treated with antifibrinolytic therapy, e.g. tranexamic acid.

Thrombotic thrombocytopenic purpura

Like DIC and heparin-induced thrombocytopenia (p. 957), thrombotic thrombocytopenic purpura (TTP) is a disorder in which thrombosis is accompanied by paradoxical thrombocytopenia. TTP is characterised by a pentad of findings, although few patients have all five components:

- thrombocytopenia
- microangiopathic haemolytic anaemia
- neurological sequelae
- fever
- renal impairment.

24.74 Disseminated intravascular coagulation (DIC)

Underlying conditions

- Infection/sepsis
- Trauma
- Obstetric, e.g. amniotic fluid embolism, placental abruption, pre-eclampsia
- Severe liver failure
- Malignancy, e.g. solid tumours and leukaemias
- Tissue destruction, e.g. pancreatitis, burns
- Vascular abnormalities, e.g. vascular aneurysms, liver haemangiomas
- Toxic/immunological, e.g. ABO incompatibility, snake bites, recreational drugs

ISTH scoring system for diagnosis of DIC

Presence of an associated disorder	Essential
Platelets ($\times 10^9$/L)	$> 100 = 0$ $< 100 = 1$ $< 50 = 2$
Elevated fibrin degradation products	No increase = 0 Moderate = 2 Strong = 3
Prolonged prothrombin time	< 3 secs = 0 > 3 secs but < 6 secs = 1 > 6 secs = 2
Fibrinogen	> 1 g/L = 0 < 1 g/L = 1

Total score
≥ 5 = Compatible with overt DIC
< 5 = Repeat monitoring over 1–2 days

(ISTH = International Society for Thrombosis and Haemostasis)

It is an acute autoimmune disorder mediated by antibodies against ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif).

This enzyme normally cleaves vWF multimers to produce normal functional units, and its deficiency results in large vWF multimers that cross-link platelets. The features are of microvascular occlusion by platelet thrombi affecting key organs, principally brain and kidneys. It is a rare disorder (1 in 750 000 per annum), which may occur alone or in association with drugs (ticlopidine, ciclosporin), HIV, shiga toxins (Ch. 14) and malignancy. It should be treated by emergency plasma exchange. Glucocorticoids, aspirin and rituximab also have a role in management. Caplacizumab, a monoclonal antibody directed against the A domain of vWF, is associated with improved outcomes, less relapse and faster recovery time in patients with acquired TTP. Untreated mortality rates are 90% in the first 10 days, and even with appropriate therapy, the mortality rate is 20%–30% at 6 months.

Multiple Choice Questions

24.1. Which of the following is not true of emicizumab?

A. It emulates the role of factor VIII by allowing formation of the tenase complex
B. It is useful in the management of haemophilia A
C. It is useful in the management of haemophilia A patients with inhibitors
D. It is a bispecific monoclonal antibody
E. It is given intravenously 3 times weekly to provide prophylaxis

Answer: E.

Emicizumab is a bispecific monoclonal antibody which replicates the action of factor VIII in making the tenase complex. This results in downstream activation of factor X and subsequently thrombin and clot generation. Emicizumab can therefore be used in all categories of haemophilia A and has had its greatest effect on patients with inhibitors. Its great clinical advantage is that it is a subcutaneous preparation.

24.2. A 20-year-old woman who has sustained an apparently unprovoked pulmonary embolism has a positive test for a lupus anticoagulant on admission. Both anticardiolipin and anti-β_2-GP1 antibodies are negative. She has no history of SLE or any connective tissue disease. Which of the following best describes the diagnosis and management?

A. She has antiphospholipid syndrome and she should be anticoagulated indefinitely with low-molecular-weight heparin, which is the drug of choice in APS
B. She does not have antiphospholipid syndrome because anticardiolipin and anti-β_2-GP1 are both negative
C. She has antiphospholipid syndrome and she should be anticoagulated indefinitely with warfarin, which is the drug of choice in APS
D. She may have APS but only if she has a repeated positive lupus anticoagulant test 12 weeks after the first positive
E. She does not have proven APS and should be anticoagulated indefinitely with rivaroxaban

Answer: D.

APS is a clinicopathological entity comprising a clinical event (thrombosis in arterial or venous circulation or adverse outcome of pregnancy) accompanied by a persistent positive antiphospholipid antibody test (any) on two occasions at least 12 weeks apart. Recent data from the TRAPs study has resulted in the regulatory bodies indicating that warfarin is the optimal anticoagulant for patients with VTE associated with APS.

24.3. A 7-year-old Italian boy attends the local hospital. He has been unwell for 5 days with a mild fever, low energy and poor appetite. On examination he is listless with conjunctival pallor. His cheeks appear flushed. A widespread, fine erythematous rash over the trunk and limbs is noted. Bloods show:
WBC 14.9 × 109/L (4–11)
Hb 51 g/L (113–141)
MCV 72 fL (80–100)
Reticulocytes 12 × 109/L (25–85)
Bilirubin 62 μmol/L (3–21)
Blood film: many spherocytes and atypical lymphocytes
What is the most likely diagnosis?

A. Hereditary spherocytosis with acute haemolytic crisis
B. Infectious mononucleosis
C. Hereditary spherocytosis with megaloblastic crisis
D. Hereditary elliptocytosis with acute haemolytic crisis
E. Hereditary spherocytosis with aplastic crisis

Answer: E.

Parvovirus B19 (erythrovirus) will precipitate an aplastic crisis in hereditary spherocytosis. There is a characteristic ‘flushed cheeks’ rash. The virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count. An elevated MCV is associated with a megaloblastic crisis and an acute haemolytic crisis where a reticulocytosis will also be prominent. Elliptocytes are found in hereditary elliptocytosis. Infection mononucleosis presents with sore throat, lymphadenopathy and atypical mononuclear cells on the blood film in the absence of spherocytes.

24.4. A 55-year-old man presents with further relapse of diffuse large B-cell non-Hodgkin lymphoma (DLBCL), having failed previous treatments with R-CHOP chemotherapy and R-DHAP chemotherapy followed by autologous stem cell transplantation. In considering further treatment with CAR-T therapy, which of the following statements is true?

A. The patient must achieve a negative FDG PET-CT prior to CAR-T therapy
B. CAR-T cells can be prepared and delivered within one week
C. The T cells are most commonly provided by an unrelated donor
D. A chimeric antigen receptor (CAR) is composed of part antibody molecule and part T-cell receptor
E. The treatment works by exhausting cytotoxic T-cell function

Answer: D.

The patient fulfils one of the currently licensed indications for CAR-T therapy of multiply relapsed DLBCL. The patient does not have to be in remission but the disease needs to be controlled enough for the patient to be fit enough for the procedure. The process of preparing CAR-T cells is complex and takes about 8 weeks in total. Current CAR-T cells use autologous T cells taken from the patient. Future CAR-T products may be prepared from donor T cells as so-called ‘off-the-shelf CAR-T cells’. The CAR-T cells work by enhanced recognition and killing of lymphoma cells by the modified T cells. T-cell exhaustion is a process by which tumours protect themselves. Checkpoint inhibitors reverse this process.

24.5. A 40-year-old woman presents with a persistent blocked nose associated with swelling of the left cheek. A CT scan shows a mass in the post-nasal space involving the left maxillary sinus. A biopsy confirms plasmacytoma. Which of the following is in keeping with a diagnosis of solitary plasmacytoma?

A. Multiple lytic bone lesions on an MRI scan
B. 20% plasma cells in a bone marrow sample taken from the posterior iliac crest
C. Pancytopenia
D. Hypercalcaemia associated with acute renal failure
E. Low-level IgG paraprotein

Answer: E.

Extramedullary solitary plasmacytomas most commonly occur in the upper aerodigestive tract. They present as isolated tumours of plasma cells, and other features of disseminated myeloma including multiple lytic lesions, hypercalcaemia, widespread marrow involvement and cytopenias are absent. A low-level intact paraprotein is commonly seen.

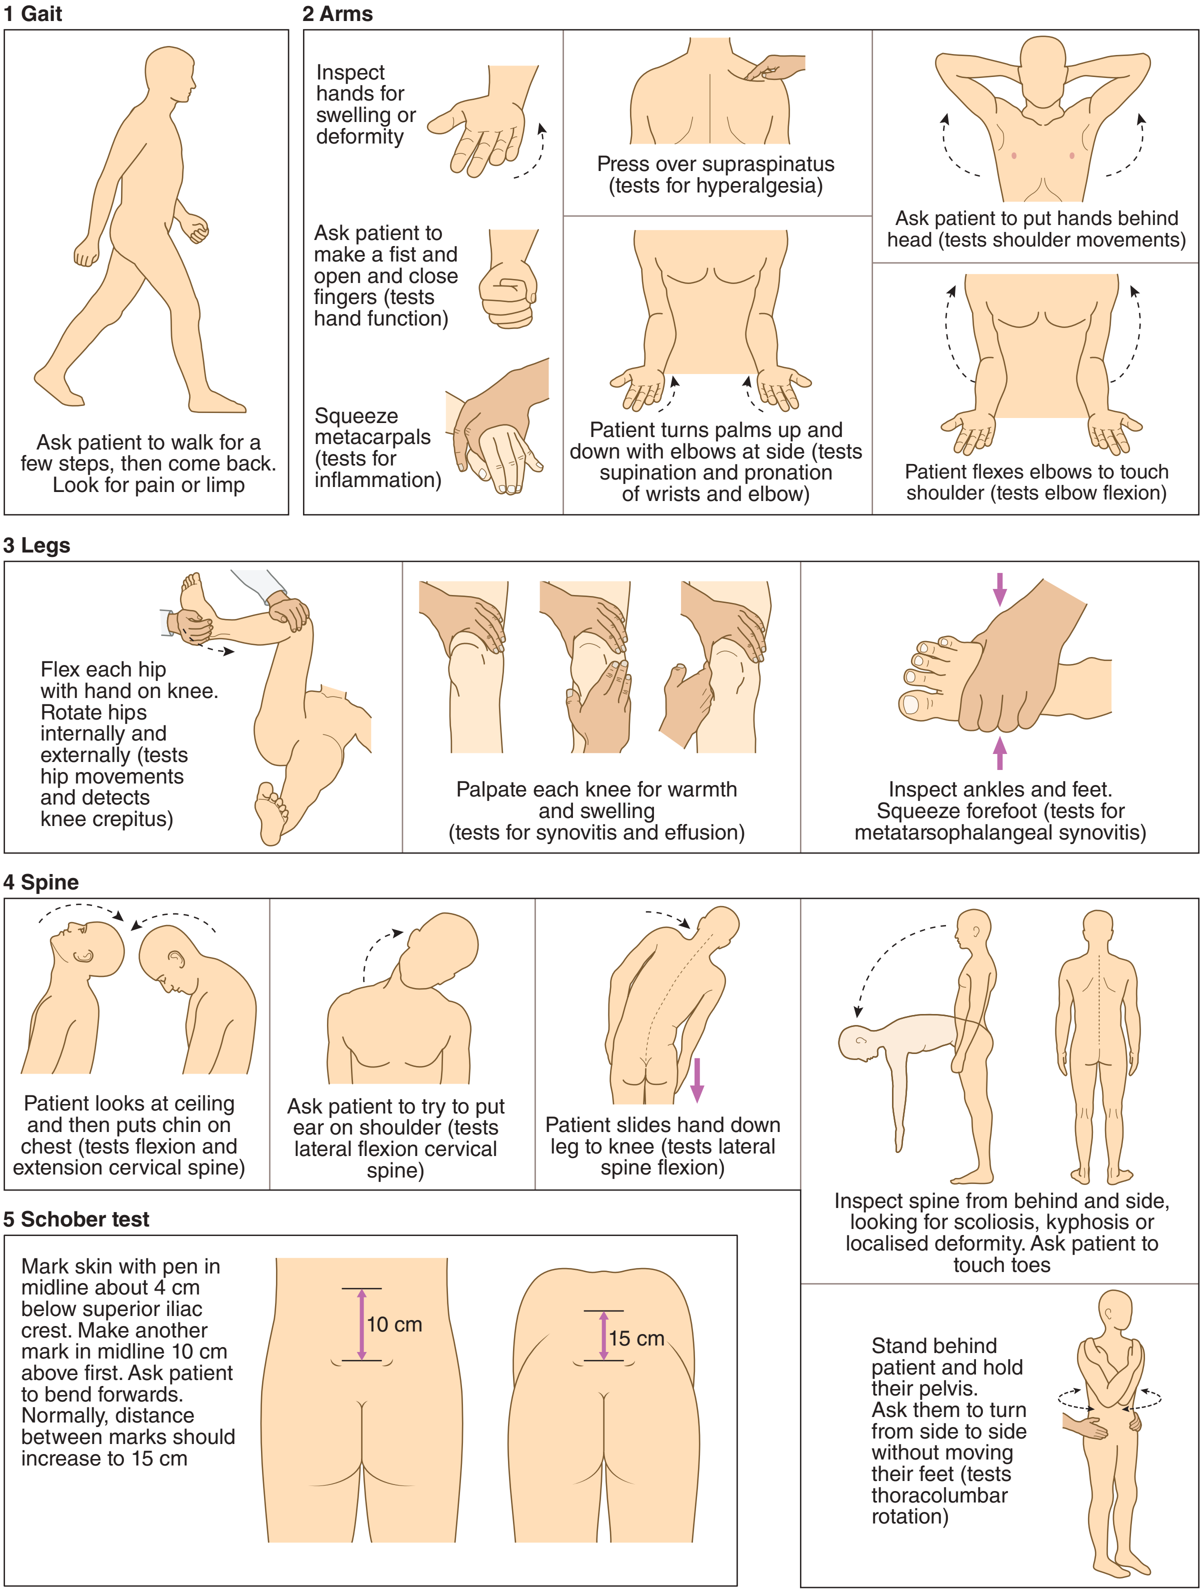
General Assessment of Locomotor System (GALS) and Schober test



1 Gait

Ask patient to walk for a few steps, then come back. Look for pain or limp

2 Arms

Inspect hands for swelling or deformity

Ask patient to make a fist and open and close fingers (tests hand function)

Squeeze metacarpals (tests for inflammation)

Press over supraspinatus (tests for hyperalgesia)

Patient turns palms up and down with elbows at side (tests supination and pronation of wrists and elbow)

Ask patient to put hands behind head (tests shoulder movements)

Patient flexes elbows to touch shoulder (tests elbow flexion)

3 Legs

Flex each hip with hand on knee. Rotate hips internally and externally (tests hip movements and detects knee crepitus)

Palpate each knee for warmth and swelling (tests for synovitis and effusion)

Inspect ankles and feet. Squeeze forefoot (tests for metatarsophalangeal synovitis)

4 Spine

Patient looks at ceiling and then puts chin on chest (tests flexion and extension cervical spine)

Ask patient to try to put ear on shoulder (tests lateral flexion cervical spine)

Patient slides hand down leg to knee (tests lateral spine flexion)

Inspect spine from behind and side, looking for scoliosis, kyphosis or localised deformity. Ask patient to touch toes

Stand behind patient and hold their pelvis. Ask them to turn from side to side without moving their feet (tests thoracolumbar rotation)

5 Schober test

Mark skin with pen in midline about 4 cm below superior iliac crest. Make another mark in midline 10 cm above first. Ask patient to bend forwards. Normally, distance between marks should increase to 15 cm

Disorders of the musculoskeletal (MSK) system affect all ages and ethnic groups. In the UK, about 25% of new consultations in general practice are for musculoskeletal symptoms. MSK diseases may arise from processes affecting bones, joints, muscles, or connective tissues such as skin and tendon. The principal manifestations are pain and impairment of locomotor function. Severe and/or chronic MSK disorders can have considerable functional impacts and affect work presenteeism, socioeconomic health and long-term quality of life.

Diseases of the MSK system tend to be more common in women and most increase in frequency with increasing age. They are the most common cause of physical disability in older people and account for one-third of physical disability at all ages.

Functional anatomy and physiology

The MSK system is responsible for movement of the body, provides a structural framework to protect internal organs and acts as a reservoir for storage of calcium and phosphate in the regulation of mineral homeostasis. The main components of the musculoskeletal system are depicted in Figure 25.1.

Bone

Bones are divided into two main types, based on their embryonic development. Flat bones, such as the skull, develop by intramembranous ossification, in which embryonic fibroblasts differentiate directly into bone within condensations of mesenchymal tissue during early fetal life. Long bones, such as the femur and radius, develop by endochondral ossification from a cartilage template. During development, the cartilage is invaded by vascular tissue containing osteoprogenitor cells and is gradually replaced by bone from centres of ossification situated in the middle and at the ends of the bone. A thin remnant of cartilage called the growth plate or epiphyseal plate remains at each end of long bones, and chondrocyte proliferation here is responsible for skeletal growth during childhood and adolescence. At the end of puberty, the increased levels of sex hormones halt cell division in the growth plate. The cartilage remnant then disappears as longitudinal bone growth ceases.

Two types of bone tissue are present in the normal skeleton (see Fig. 25.1). Cortical bone is formed from Haversian systems, comprising concentric lamellae of bone tissue surrounding a central canal that contains blood vessels. Cortical bone is dense and forms a hard envelope around the long bones. Trabecular or cancellous bone fills the centre of the bone and consists of an interconnecting meshwork of trabeculae, separated by spaces filled with bone marrow. Important cell types in bone are:

- *Osteoclasts*: multinucleated cells of haematopoietic origin, responsible for bone resorption.
- *Osteoblasts*: mononuclear cells derived from marrow stromal cells responsible for bone formation.
- *Osteocytes*: cells that differentiate from osteoblasts that become embedded in bone matrix during bone formation. They are responsible for sensing and responding to mechanical stimuli and for coordinating osteoclast and osteoblast activity by producing receptor activator of nuclear factor kappa B ligand (RANKL) and sclerostin (SOST).
- *Bone marrow stromal cells*: cells that produce RANKL and macrophage colony-stimulating factor (M-CSF), which act together to stimulate osteoclast formation, and other cytokines that support haematopoiesis.
- *Bone lining cells*: flattened cells lining the bone surface that differentiate from osteoblasts when bone formation is complete.

Fig. 25.1 Structure of the major musculoskeletal tissues.

Bone matrix and mineral

The most abundant protein of bone is type I collagen, which is formed from two α1 peptide chains and one α2 chain wound together in a triple helix. Type I collagen is proteolytically processed inside the cell before being laid down in the extracellular space, releasing propeptide fragments that can be used as biochemical markers of bone formation. Subsequently, the collagen fibrils become 'cross-linked' to one another by pyridinium molecules, a process that enhances bone strength. When bone is broken down by osteoclasts, the cross-links are released into the circulation. These can be measured biochemically and are sometimes used clinically to assess levels of bone resorption. Bone is normally laid down in an orderly fashion, but when bone turnover is high, as in Paget disease or severe hyperparathyroidism, it is laid down in a chaotic pattern, giving rise to 'woven bone' that is mechanically weak. Bone matrix also contains growth factors, other structural proteins and proteoglycans, thought to be involved in helping bone cells attach to bone matrix and in regulating bone cell activity. The other major component of bone is mineral, comprised of calcium and phosphate crystals deposited between the collagen fibrils in the form of hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$. Mineralisation is essential for bone rigidity and strength, but over-mineralisation causes bone to become brittle. In clinical practice, increased mineralisation can occur in some types of osteogenesis imperfecta and in response to long-term bisphosphonate therapy.

Bone remodelling

Bone remodelling is required for renewal and repair of the skeleton throughout life. This is a cyclical process that has four phases: quiescence, resorption, reversal and formation, as illustrated in Figure 25.2A. Remodelling starts with the attraction of osteoclast precursors in peripheral blood to the target site, probably by local release of chemotactic factors from areas of microdamage. The osteoclasts resorb bone and, after about 10 days, undergo programmed cell death (apoptosis), heralding the start of the reversal phase when osteoblast precursors are recruited to the resorption site. The osteoblast precursors differentiate into mature osteoblasts and form new bone during the formation phase. Initially, the matrix is not mineralised (osteoid) but eventually becomes mineralised to form mature bone. Some osteoblasts become trapped in bone matrix and differentiate into osteocytes, which play a key regulatory role in coordinating bone formation and resorption, whereas others differentiate into bone-lining cells.

The cellular and molecular mediators of this bone remodelling are shown in more detail in Figure 25.2B. Osteoclast precursors are derived from haematopoietic stem cells and differentiate into mature osteoclasts in response to M-CSF, produced by bone marrow stromal cells, and RANKL, produced by osteocytes, bone marrow stromal cells, T-cells and osteoblasts. The RANKL binds to and activates a receptor called RANK (receptor activator of nuclear factor kappa B) on osteoclast precursors, promoting osteoclast differentiation and bone resorption. This effect is blocked by osteoprotegerin (OPG), which is a decoy receptor for RANKL that inhibits osteoclast formation. Once formed, mature osteoclasts attach to the bone surface by a tight sealing zone and secrete hydrochloric acid and proteolytic enzymes, including cathepsin K, into the space underneath, which is known as the Howship lacuna. The acid dissolves the mineral and cathepsin K degrades collagen. Osteocytes also produce sclerostin (SOST), which is an inhibitor of bone formation and a stimulator of bone resorption. Under conditions of mechanical loading, sclerostin production by osteocytes is inhibited, allowing bone formation to proceed, stimulated by members of the Wnt family of signalling proteins. The Wnt molecules stimulate bone formation by activating members of the lipoprotein receptor-related protein (LRP) family, the most important of which are LRP4, LRP5 and LRP6. Sclerostin antagonises the effects of Wnt family members by blocking their interaction with LRP family members. Osteocytes also play a critical role in phosphate homeostasis by producing the hormone FGF23, which regulates renal

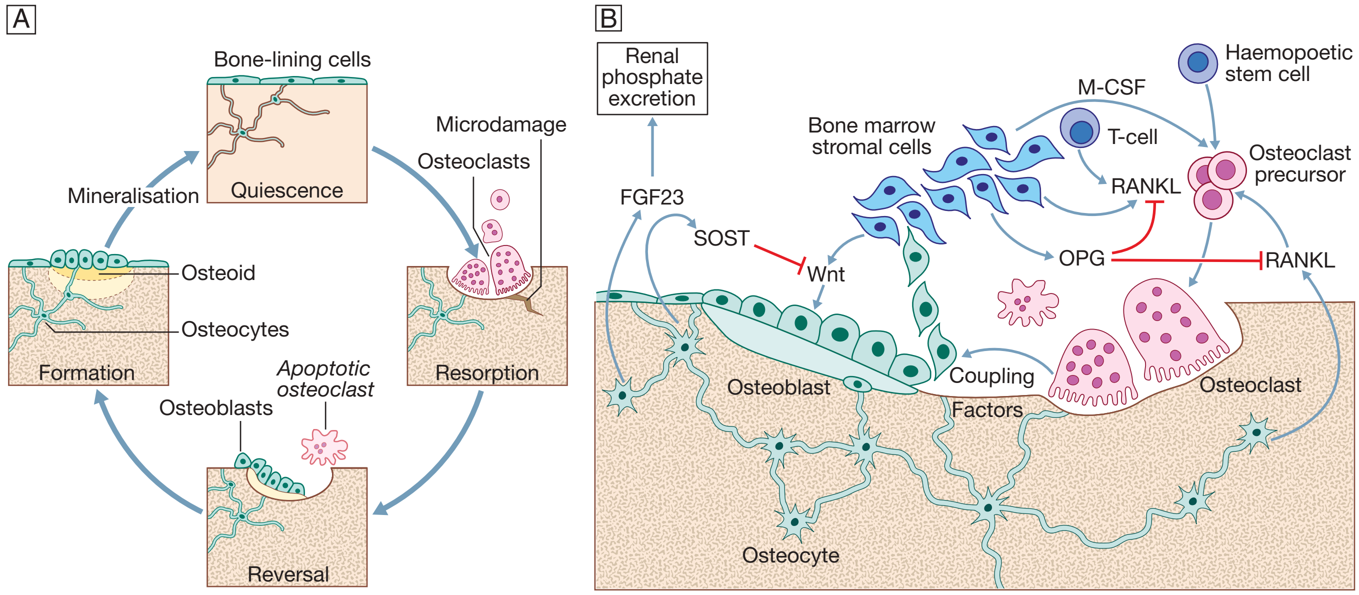

Fig. 25.2 Mechanisms and mediators of bone remodelling. **A** Bone is renewed and repaired by the process of bone remodelling. This begins by removal of old and damaged bone by osteoclasts during the phase of bone resorption. After about 10 days, the osteoclasts undergo programmed cell death (apoptosis) and during the reversal phase are replaced by osteoblasts, which begin to fill in the resorbed area with new bone matrix, heralding the start of bone formation. The bone matrix is initially uncalcified (osteoid) but then becomes mineralised to form mature bone. **B** Osteoclast precursors are derived from haematopoietic stem cells. They differentiate into mature osteoclasts in response to the receptor activator of nuclear factor kappa B ligand (RANKL), which is produced by osteocytes, bone marrow stromal cells, osteoblasts and activated T cells, and macrophage colony-stimulating factor (M-CSF), which is produced by bone marrow stromal cells. Osteoprotegerin (OPG) is also produced in the bone microenvironment, where it inhibits osteoclastic bone resorption by blocking the effect of RANKL. Osteoblasts, which are derived from bone marrow stromal cells, are responsible for bone formation. Osteoblast activity is stimulated by signalling molecules in the Wnt family and by coupling factors such as ephrin B2 secreted by osteoclasts or factors such as transforming growth factor beta (TGF-β), insulin-like growth factors (IGF) and bone morphogenic protein 2 (BMP2) released from bone matrix during bone resorption. Osteoblast activity is inhibited by sclerostin (SOST), which is produced by osteocytes. In addition to their role in regulating osteoclast and osteoblast activity, osteocytes have an endocrine function in regulating phosphate homeostasis by producing fibroblast growth factor 23 (FGF23), which acts on the kidney to promote phosphate excretion.

25.1 Key regulators of bone remodelling

Mediator	Main sources	Main effects	Comment
RANKL	Osteocytes Activated T cells Stromal cells Osteoblasts	Stimulates bone resorption	Activates RANK
Osteoprotegerin	Osteoblasts	Inhibits bone resorption	Decoy receptor for RANKL
Wnt	Stromal cells	Stimulates bone formation	Activates LRP receptors
Sclerostin	Osteocytes	Inhibits bone formation	Blocks effect of Wnt on LRP receptors
Parathyroid hormone	Parathyroid glands	Increases bone resorption and formation	
Thyroid hormone	Thyroid gland	Increases bone resorption and formation	
Oestrogen	Ovary	Inhibits bone resorption	
Glucocorticoids	Adrenal gland	Inhibits bone formation	
Ephrin B2	Osteoclasts	Stimulates bone formation	Coupling factor
TGF-β, IGF	Bone matrix	Stimulate bone formation	Coupling factors, released during bone resorption

(IGF = insulin like growth factors; LRP = lipoprotein receptor-related protein; RANKL = receptor activator of nuclear factor kappa B ligand; TGF-β = transforming growth factor beta)

tubular phosphate reabsorption. Key regulators of bone remodelling are summarised in Box 25.1.

Mineralisation of bone is critically dependent on the enzyme alkaline phosphatase (ALP), which is produced by osteoblasts and degrades pyrophosphate, an inhibitor of mineralisation. Bone remodelling is predominantly regulated at a local level but can be influenced by circulating hormones or mechanical loading, which can up-regulate or down-regulate remodelling across the whole skeleton (see Box 25.1).

Joints

There are three main types of joint: fibrous, fibrocartilaginous and synovial (Box 25.2).

Fibrous and fibrocartilaginous joints

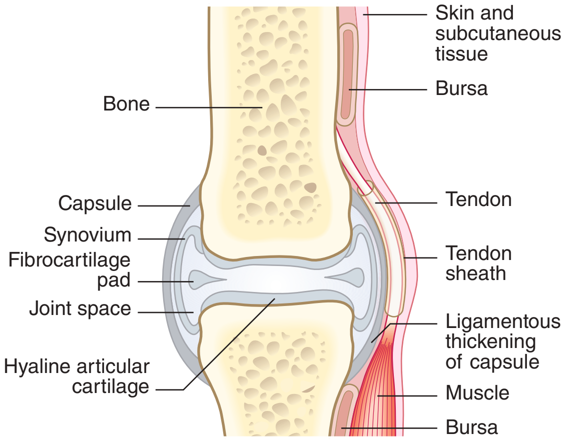
These comprise a simple bridge of fibrous or fibrocartilaginous tissue joining two bones together where there is little requirement for movement, such as the symphysis pubis. The intervertebral disc is a special type of fibrocartilaginous joint in which an amorphous area, called the nucleus pulposus, lies in the centre of the fibrocartilaginous bridge. The nucleus has a high water content and acts as a cushion to improve the disc's shock-absorbing properties.

Synovial joints

These are complex structures containing several cell types. They are found where a wide range of movement is needed (Fig. 25.3).

25.2 Types of joint

Type	Range of movement	Examples
Fibrous	Minimal	Skull sutures
Fibrocartilaginous	Limited	Symphysis pubis Costochondral junctions Intervertebral discs Sacroiliac joints
Synovial	Large	Most limb joints Temporomandibular Costovertebral



Skin and subcutaneous tissue

Hyaline articular cartilage
Muscle
Bursa

Fig. 25.3 Structure of a synovial joint.

Articular cartilage

This avascular tissue covers the bone ends in synovial joints. Cartilage cells (chondrocytes) are responsible for synthesis and turnover of cartilage, which consists of a mesh of type II collagen fibrils that extend through a hydrated 'gel' of proteoglycan molecules. The most important proteoglycan is aggrecan, which consists of a core protein to which several glycosaminoglycan (GAG) side chains are attached (Fig. 25.4). The GAGs are polysaccharides that consist of long chains of disaccharide repeats comprising one normal sugar and an amino sugar. The most abundant GAGs in aggrecan are chondroitin sulphate and keratan sulphate. Hyaluronan is another important GAG that binds to aggrecan molecules to form very large complexes with a total molecular weight of more than 100 million. Aggrecan has a strong negative charge and avidly binds water molecules to assume a shape that occupies the maximum possible volume available. The expansive force of the hydrated aggrecan, combined with the restrictive strength of the collagen mesh, gives articular cartilage excellent shock-absorbing properties.

With ageing, the concentration of chondroitin sulphate decreases, whereas that of keratan sulphate increases, resulting in reduced water content and shock-absorbing properties. These changes differ from those found in osteoarthritis, where there is abnormal chondrocyte division, loss of proteoglycan from matrix and an increase in water content. Cartilage matrix is constantly turning over and in health there is a perfect balance between synthesis and degradation. Degradation of cartilage matrix is carried out by aggrecanases and matrix metalloproteinases, responsible for the breakdown of proteins and proteoglycans, and by

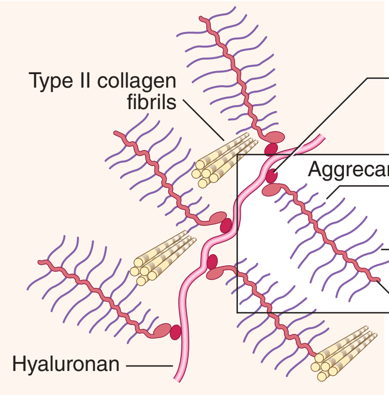

Fig. 25.4 Ultrastructure of articular cartilage.

glycosidases, responsible for the breakdown of GAGs. Pro-inflammatory cytokines, such as interleukin (IL)-1 and tumour necrosis factor (TNF), which are released during inflammation, stimulate production of aggrecanase and metalloproteinases, causing cartilage degradation.

Synovial fluid

The surfaces of articular cartilage are separated by a space filled with synovial fluid (SF), a viscous liquid that lubricates the joint. It is an ultrafiltrate of plasma, into which synovial cells secrete hyaluronan and proteoglycans.

Intra-articular discs

Some joints contain fibrocartilaginous discs within the joint space that act as shock absorbers. The most clinically important are the menisci of the knee. These are avascular structures that remain viable because of diffusion of oxygen and nutrients from the SF.

Synovial membrane, joint capsule and bursae

The bones of synovial joints are connected by the joint capsule, a fibrous structure richly supplied with blood vessels, nerves and lymphatics which encases the joint. Ligaments are discrete, regional thickenings of the capsule that act to stabilise joints (see Fig. 25.3). The inner surface of the joint capsule is the synovial membrane, comprising an outer layer of blood vessels and loose connective tissue that is rich in type I collagen, and an inner layer 1–4 cells thick consisting of two main cell types. Type A synoviocytes are phagocytic cells derived from the monocyte/macrophage lineage and are responsible for removing particulate matter from the joint cavity; type B synoviocytes are fibroblast-like cells that secrete SF. Most inflammatory and degenerative joint diseases are associated with thickening of the synovial membrane and infiltration by lymphocytes, polymorphs and macrophages.

Bursae are hollow sacs lined with synovium and contain a small amount of SF. They help tendons and muscles move smoothly in relation to bones and other articular structures.

Skeletal muscle

Skeletal muscles are responsible for body movements and respiration. Muscle consists of bundles of cells (myocytes) embedded in fine connective tissue containing nerves and blood vessels. Myocytes are large, elongated, multinucleated cells formed by fusion of mononuclear precursors (myoblasts) in early embryonic life. The nuclei lie peripherally, and the centre of the cell contains actin and myosin molecules, which interdigitate with one another to form the myofibrils that are responsible for muscle contraction. The molecular mechanisms of skeletal muscle contraction are the same as for cardiac muscle (p. 425). Myocytes contain many mitochondria that provide the large amounts of adenosine triphosphate (ATP) necessary for muscle contraction and are rich in the protein myoglobin, which acts as a reservoir for oxygen during contraction.

Individual myofibrils are organised into bundles (fasciculi) that are bound together by a thin layer of connective tissue (the perimysium). The surface of the muscle is surrounded by a thicker layer of connective tissue, the epimysium, which merges with the perimysium to form the muscle tendon. Tendons are tough, fibrous structures that attach muscles to a point of insertion on the bone surface called the enthesis. Entheses transmit tensile load from soft tissues to bone and are composed of either fibrous tissue or fibrocartilage, depending on the local needs of the tissue in adapting to physical stress. The entheses are particularly affected by inflammation in patients with spondyloarthritis, as discussed later in this chapter.

Investigation of musculoskeletal disease

Clinical history and examination usually provide sufficient information for the diagnosis and management of many musculoskeletal diseases. Investigations are helpful in confirming the diagnosis, assessing disease activity and indicating prognosis. Investigations that are commonly used in musculoskeletal disease are discussed in more detail below.

Joint aspiration

Joint aspiration with examination of SF is pivotal in patients with suspected septic arthritis, crystal arthritis or intra-articular bleeding. It should be carried out in all individuals with acute monoarthritis, and samples should be sent for microbiology and microscopy.

It is possible to obtain SF by aspiration from most peripheral joints, and only a small amount is required for diagnostic purposes. Normal SF is present in small volume, is clear and either colourless or pale yellow, and has a high viscosity. It contains few cells. With joint inflammation, the volume increases, the cell count and the proportion of neutrophils rise (causing turbidity), and the viscosity reduces (due to enzymatic degradation of hyaluronan and aggrecan). Turbid fluid with a high neutrophil count occurs in septic arthritis, crystal arthritis and reactive arthritis. High concentrations of urate crystals or cholesterol can make SF appear white. Non-uniform bloodstaining usually reflects needle trauma to the synovium. Uniform bloodstaining is most commonly due to a bleeding diathesis, trauma or pigmented villonodular synovitis, but can also occur in severe inflammatory synovitis. A lipid layer floating above blood-stained fluid is diagnostic of intra-articular fracture and is caused by release of bone marrow fat into the joint.

Crystals can be identified by compensated polarised light microscopy of fresh SF (to avoid crystal dissolution and post-aspiration crystallisation). Urate crystals are long and needle-shaped and show a strong light intensity and negative birefringence (Fig. 25.5A). Calcium pyrophosphate crystals are smaller, rhomboid in shape and usually less numerous than urate crystals; they have weak intensity and positive birefringence (Fig. 25.5B).

Imaging

Plain X-rays

X-rays show structural changes that are of value in the differential diagnosis and monitoring of many bone and joint diseases (Box 25.3).

They are of diagnostic value in osteoarthritis (OA), where they demonstrate joint space narrowing that tends to be focal rather than widespread (as seen in inflammatory arthritis). Other features of OA detected on X-rays include osteophytes, subchondral sclerosis, bone cysts and calcified loose bodies within the synovium (see Fig. 25.17). Erosions and sclerosis of the sacroiliac joints and syndesmophytes in the spine may be observed in spondyloarthritis (SpA; see Figs. 25.39 and 25.40). Erosions, associated with new bone formation and periosteal reaction, also occur in peripheral joints and at entheses in SpA. In tophaceous gout, well-defined punched-out erosions may occur (see Fig. 25.26). Calcification of cartilage, tendons and soft tissues or muscle occurs mainly in

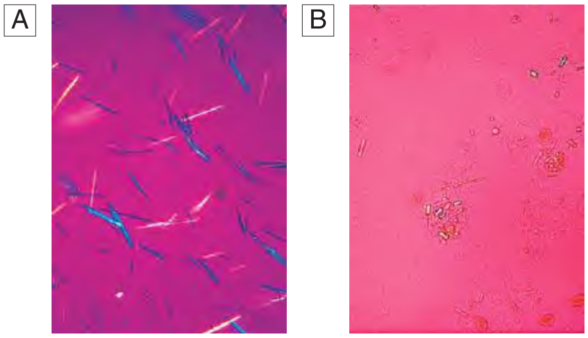

Fig. 25.5 Compensated polarised light microscopy of synovial fluid (×400). **A** Monosodium urate crystals show bright negative birefringence under polarised light and needle-shaped morphology. **B** Calcium pyrophosphate crystals are few and show weak positive birefringence under polarised light. They are more difficult to detect than urate crystals.

25.3 Radiographic abnormalities in selected rheumatic diseases

Rheumatoid arthritis

- Periarticular osteoporosis
- Marginal joint erosions
- Joint subluxation
- Joint space narrowing

Osteoporosis

- Osteopenia
- Vertebral fractures
- Non-vertebral fractures
- Cortical thinning

Paget disease

- Bone expansion
- Abnormal trabecular pattern
- Osteosclerosis and lysis
- Pseudofractures

Psoriatic arthritis

- Sacroiliitis
- Syndesmophytes
- Bone sclerosis
- Proliferative enthesis erosions
- Enthesophytes
- Juxta-articular new bone

Osteoarthritis

- Joint space narrowing
- Osteophytes
- Subchondral sclerosis
- Joint deformity
- Subchondral cysts

chondrocalcinosis (see Fig. 25.27), calcium-containing crystal diseases, tumoral calcinosis and autoimmune connective tissue diseases.

X-rays are of limited value in the diagnosis of rheumatoid arthritis (RA) because features such as erosions, joint space narrowing and periarticular osteoporosis may be detectable only after several months or even years. The main indication for X-rays in RA is in the assessment of disease over time when structural damage to the joints is suspected.

Radionuclide bone scintigraphy

Radionuclide bone scintigraphy is mainly used in the diagnosis of metastatic bone disease and Paget disease of bone. Abnormalities may also be observed in primary bone tumours, complex regional pain syndrome, OA and different types of inflammatory arthritis, but the changes are non-specific and other imaging modalities are more commonly used. Bone scintigraphy involves gamma-camera imaging following an intravenous injection of ^{99m}Tc-labelled bisphosphonate. Early post-injection images reflect blood flow and can show increased perfusion of inflamed synovium, Pagetic bone or primary or secondary bone tumours. Delayed images taken a few hours later reflect bone remodelling as the ^{99m}Tc-labelled bisphosphonate localises to sites of active bone turnover. Single photon emission computed tomography (SPECT) is a 3D volumetric radionuclide imaging technique from which images can be reconstructed in different anatomical planes and can be fused with standard CT images (SPECT/CT) to provide precise localisaton of abnormalities and can be of value in patients with chronic low back and pelvic pain where standard planar scintigraphy has yielded inconclusive results.

25.4 Conditions detected by magnetic resonance imaging

- Osteonecrosis
- Intervertebral disc disease
- Nerve root entrapment
- Spinal cord compression
- Spinal stenosis
- Infection
- Complex regional pain syndrome
- Malignancy
- Fractures
- Meniscal disease
- Synovitis
- Sacroiliitis and enthesitis
- Inflammatory myositis
- Rotator cuff tears, bursitis and tenosynovitis

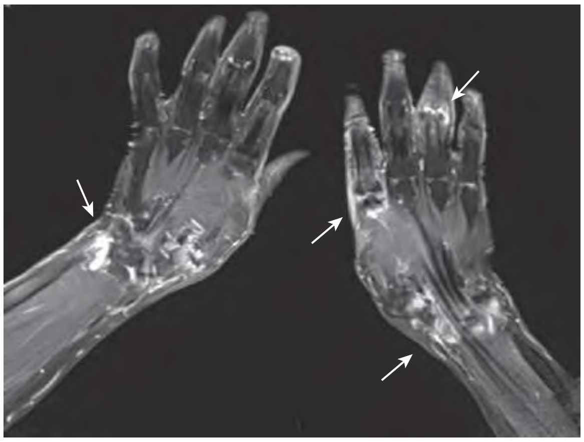

Fig. 25.6 Magnetic resonance image showing joint synovitis. Coronal post-contrast T1-weighted image shows extensive enhancement consistent with synovitis (white areas, arrowed) in both wrists, at the second metacarpophalangeal joint and proximal interphalangeal joints of the right hand. *Courtesy of Dr I. Beggs.*

Magnetic resonance imaging

Magnetic resonance imaging (MRI) gives detailed information on anatomy, allowing three-dimensional visualisation of bone and soft tissues that cannot be adequately assessed by plain X-rays. The technique is valuable in the assessment and diagnosis of many musculoskeletal diseases (Box 25.4). T1-weighted sequences are useful for defining anatomy, whereas T2-weighted sequences are useful for assessing tissue water content, which is often increased in synovitis and other inflammatory disorders (Fig. 25.6). MRI sequences that suppress signal from fat, such as short TI inversion recovery (STIR), are helpful when evaluating inflammatory disease. Contrast agents, such as gadolinium, can be administered to increase sensitivity in detecting erosions and synovitis.

Ultrasonography

Ultrasonography is a useful investigation for confirmation of small joint synovitis and erosions, for anatomical location of periarticular lesions, for characterisation of tendon lesions and for guided injection of joints and bursae. Ultrasonography is more sensitive than clinical examination for the detection of early synovitis and can be helpful in the diagnosis and assessment of patients with suspected inflammatory arthritis. In addition to locating synovial thickening and effusions, ultrasound can detect increased blood flow within synovium using power Doppler imaging, an option that is available on most modern ultrasound machines (Fig. 25.7). Ultrasound is also used in the differential diagnosis of giant cell arteritis (GCA) to look for evidence of thickening of the vessel wall in the temporal or axillary arteries.

Computed tomography

Computed tomography (CT) is used selectively for assessing patients with bone and joint disease. CT may be used when skeletal anatomy needs defining, when calcific lesions are being assessed, when MRI is contraindicated, or when articular regions are being evaluated in which

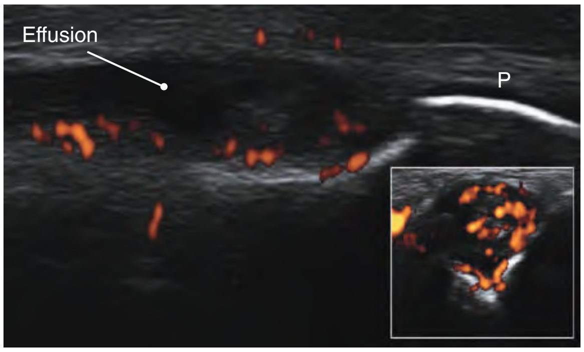

Fig. 25.7 **Ultrasound image showing synovitis.** Lateral image of a metacarpophalangeal joint in inflammatory arthritis. The periosteum (P) of the phalanx shows as a white line. The dark, hypo-echoic area indicates an effusion. The coloured areas demonstrated by power Doppler indicate increased vascularity. The inset shows a transverse image of the same joint. *Courtesy of Dr N. McKay.*

an adjacent joint replacement creates signal artefacts on MRI (using specific metal artefact reduction algorithms). Imaging with sodium fluoride (^{18}F Na) PET-CT can be of value in the diagnosis of chronic non-infectious osteomyelitis and in the detection of bone metastases.

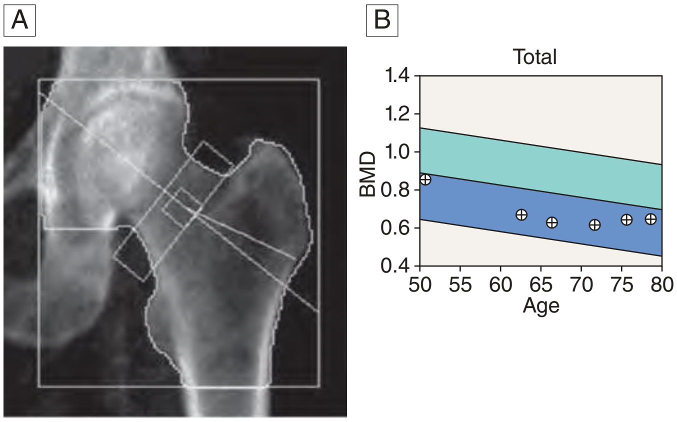
Dual X-ray absorptiometry

Dual X-ray absorptiometry (DXA) is used to measure bone mineral density (BMD) and has a key role in the diagnosis and management of osteoporosis. Measurements at lumbar spine, hip and sometimes forearm are obtained. DXA works on the principle that calcium in bone attenuates passage of X-rays through the tissue in proportion to the amount of mineral present: the more bone mineral present, the higher the BMD value. The results are presented in terms of BMD (in grams of hydroxyapatite per cm^2), the T-score, which reflects the number of standard deviations by which the patient's BMD value differs from that in a young healthy control (Fig. 25.8) and the Z-score, which reflects the number of standard deviations the BMD value differs from an age-matched control. Osteoporosis is defined to be present when the T-score is −2.5 or below; osteopenia is defined to be present when the T-score lies between −1.0 and −2.5; and normal BMD is defined to be present when the T-score lies between −1.0 and below +2.5. T-score values above +2.5 indicate high bone density. It is important to recognise that T-score values fall with age in the whole population as bone density falls, meaning that many people aged 50 and above have osteopenia or osteoporosis based on T-score, even though the BMD results are in the 'normal range' for that age group. In people under age 50, Z-scores are recommended as opposed to T-scores when reporting DXA results. In this situation, Z-scores of −2.0 or below are considered lower than expected for someone of that age. Bone density needs to be interpreted carefully considering coexisting conditions, such as aortic calcification, vertebral fractures, degenerative disc disease and OA, all of which can cause high BMD results even in the presence of osteoporosis. Radiographic correlation is helpful in these circumstances.

Blood tests

Haematology

Abnormalities in the full blood count (FBC) often occur in inflammatory rheumatic diseases, but changes are non-specific. Examples include neutrophilia in crystal arthritis and septic arthritis, neutropenia in systemic lupus erythematosus (SLE) and lymphopenia in autoimmune rheumatic and connective tissue diseases. Reduced levels of haemoglobin and raised platelets are a common and important finding in active inflammatory diseases. Some disease-modifying anti-rheumatic drugs (DMARDs) and biologics can cause marrow toxicity and require regular monitoring of the FBC. Additional tests that are useful in assessing rheumatic diseases include the direct antiglobulin test (which can indicate intravascular haemolysis in SLE).



Scan date	Age	BMD	T-score	BMD change vs baseline	BMD change vs previous
11.01.2021	78	0.648	−2.4	−24.5%#	0.5%
03.01.2018	75	0.645	−2.4	−24.8%#	3.9%
21.01.2014	71	0.620	−2.6	−27.7%#	−1.6%
05.09.2008	66	0.630	−2.6	−26.5%#	−5.7%*
13.12.2004	62	0.668	−2.2	−22.1%#	−22.1%#
21.01.1993	50	0.857	−0.7		

*Statistically significant change since the previous scan results.
#Statistically significant change since baseline data in 1993.

Fig. 25.8 **Left hip dual X-ray absorptiometry scan.** **A** The regions of interest (ROI) of the hip that are scanned. **B** Graph showing the changes in bone mineral density (BMD) of the total hip ROI over time. The extent of the blue panels above and below the central line represents ±2 standard deviations from the average BMD of the reference population for age. Data panel: BMD estimates, corresponding T-scores (see text for explanation) and changes in BMD over time (and with ageing) are shown. By 2008 this patient had become osteoporotic (T-score < −2.5). Since 2014 (age 71 years) the patient has been benefitting from effective osteoporosis treatment and BMD has increased.

Biochemistry

Routine biochemistry is useful for assessing metabolic bone disease, muscle diseases and gout, and is essential in monitoring DMARDs (bone marrow, renal and hepatic function). Several bone diseases, including Paget disease, renal bone disease and osteomalacia, give a characteristic pattern that can be helpful diagnostically (Box 25.5). Serum levels of uric acid are usually raised in gout, but a normal level does not exclude it, especially during an acute attack when uric acid levels temporarily fall. Equally, an elevated serum uric acid does not confirm the diagnosis, since most hyperuricaemic people never develop gout. Levels of C-reactive protein (CRP) are a useful marker of infection and inflammation and are more specific than the erythrocyte sedimentation rate (ESR). An exception is in connective tissue diseases, such as SLE and systemic sclerosis, where CRP is considered to be an unreliable marker of disease activity. A substantial elevation in CRP or ESR in a patient with SLE or systemic sclerosis suggests an intercurrent illness, such as sepsis. Serum creatine phosphokinase (CPK) levels are useful in the diagnosis of myopathy or myositis, but specificity and sensitivity are poor and raised levels may occur in other conditions (Box 25.6).

Immunology

Autoantibody tests are widely used in the diagnosis of rheumatic diseases. Whatever test is used, the results must be interpreted considering

25.5 Typical biochemical features in various bone diseases

	Calcium	Phosphate	ALP	PTH	FGF23	25(OH)D
Osteoporosis	N	N	N (↑ after fracture)	N or ↑	N	N or ↓
Paget disease	N	N	↑↑	N or ↑	N	N or ↓
Renal osteodystrophy	N or ↓	↑	↑	↑↑	↑↑	N or ↓
Vitamin D–deficient osteomalacia	N or ↓	N or ↓	↑	↑↑	N or ↓	↓↓
Hypophosphataemic rickets	N	↓↓	↑	N or ↑	↑↑	N or ↓
Primary hyperparathyroidism	↑/↑↑	N or ↓	N or ↑	↑/↑↑	N or ↑	N or ↓

(25(OH)D = 25 hydroxy-vitamin D; ALP = alkaline phosphatase; FGF23 = fibroblast growth factor 23; N = normal; single arrow = increased or decreased; double arrow = greatly increased or decreased; PTH = parathyroid hormone)

25.6 Causes of an elevated serum creatine phosphokinase (CPK)

- Inflammatory myositis ± vasculitis
- Muscular dystrophy
- Motor neuron disease
- Alcohol, drugs (especially statins)
- Myocardial infarction*
- Trauma, strenuous exercise, prolonged immobilisation after a fall
- Hypothyroidism, metabolic myopathy
- Viral myositis
- Macro-CK (normal variant)

*The CK-MB cardiac-specific isoform is disproportionately elevated compared with total CPK.

25.7 Conditions associated with a positive rheumatoid factor*

Condition	Approximate frequency (%)
Rheumatoid arthritis with nodules and extra-articular manifestations	100
Rheumatoid arthritis (overall)	70
Primary Sjögren disease	90
Mixed essential cryoglobulinaemia	90
Primary biliary cholangitis	50
Infective endocarditis	40
Systemic lupus erythematosus	30
Tuberculosis	15
Age > 65 years	20

*Healthy people can be positive for rheumatoid factor.

25.8 Conditions associated with a positive antinuclear antibody*

Condition	Approximate frequency (%)
Systemic lupus erythematosus	100
Systemic sclerosis	90–95
Sjögren disease	40–70
Dermatomyositis or polymyositis	30–80
Mixed connective tissue disease	100
Autoimmune hepatitis	100
Rheumatoid arthritis	30–50
Autoimmune thyroid disease	30–50
Malignancy	Varies widely
Infectious diseases	Varies widely

*It is common to detect positive antinuclear antibodies in people without autoimmune disease.

the clinical picture and the different detection and assay systems used in different hospitals. The reference ranges for commonly used immunological tests are shown in Chapter 35.

Rheumatoid factor

Rheumatoid factor (RF) is an antibody directed against the Fc fragment of human immunoglobulin. In routine clinical practice, immunoglobulin M (IgM) RF is usually measured. About 70% of patients with RA test positive for RF, but the specificity for RA is poor (Box 25.7). High RF titres in RA are associated with more severe disease and extra-articular features.

Anti-citrullinated peptide antibodies

Anti-citrullinated peptide antibodies (ACPAs) recognise peptides in which the amino acid arginine has been converted to citrulline by peptidylarginine deiminase, an enzyme abundant in inflamed synovium and in a variety of mucosal structures. Like RF, ACPA is positive in around 70% of people with RA, but specificity is higher (> 95%) and consequently ACPA has largely superseded RF in the diagnosis of RA. Like RF, ACPA positivity is associated with more severe disease and extra-articular features. It is important to emphasise that ACPA positivity does not equate to a diagnosis of RA since a proportion of people in the normal population are ACPA positive. These individuals are at increased risk of developing RA at some point in life but may never do so. The pathogenic role of ACPAs is still debated but they may amplify the synovial response to an inflammatory stimulus.

Antinuclear antibodies

Antinuclear antibodies (ANAs) are directed against one or more components of the cell nucleus, including nucleic acids and the proteins that process DNA or RNA. They occur in many inflammatory rheumatic diseases but are also found at low levels in normal individuals and in other diseases (Box 25.8). Serum ANAs are not associated with disease severity or activity. The most common indication for ANA testing is in patients suspected of having SLE or other autoimmune connective tissue diseases. ANA has high sensitivity for SLE (100%), but low specificity (10%–40%). A negative ANA virtually excludes SLE, but a positive result does not confirm it.

Anti-DNA antibodies bind to double-stranded DNA (dsDNA). They are useful in SLE monitoring as high levels are associated with more severe disease and an increase in antibody level may precede relapse. Most commonly, testing for anti-DNA antibodies is performed by enzyme-linked immunosorbent assay (ELISA), but immunofluorescent staining of DNA from the microorganism *Crithidia luciliae* is also used and has a much higher specificity than dsDNA ELISA for the diagnosis of SLE. It is primarily used in patients where the clinical suspicion of SLE is high but where standard dsDNA tests have yielded equivocal results.

It is also possible to screen for antibodies to various extractable nuclear antigens (ENA). These act as biomarkers for certain subtypes of autoimmune connective tissue diseases and some complications of SLE, but for most disorders their sensitivity and specificity are poor (Box 25.9).

Antiphospholipid antibodies

These antibodies can be detected in patients with SLE and in the antiphospholipid syndrome (see Box 24.73). In clinical practice the most commonly used tests are for antibodies to cardiolipin/beta-2-glycoprotein 1 (β_2GP1)

25.9 Conditions associated with antibodies to extractable nuclear antigens

Antibody (target/other name)	Disease association
Anti-centromere antibody	Localised cutaneous systemic sclerosis (sensitivity 60%, specificity 98%)
Anti-histone antibody	Drug-induced lupus (80%)
Anti-Jo-1 (anti-histidyl-tRNA synthetase)	Polymyositis, dermatomyositis or polymyositis–systemic sclerosis overlap (20%–30%) Particularly associated with interstitial lung disease
Anti-La antibody (anti-SS-B)	Sjögren syndrome (60%) SLE (20%–60%)
Anti-ribonucleoprotein antibody (anti-RNP)	Mixed connective tissue disease (100%) SLE (25%–50%), usually in conjunction with anti-Sm antibodies
Anti-Ro antibody (anti-SS-A)	SLE (35%–60%): associated with photosensitivity, thrombocytopenia and subacute cutaneous lupus Maternal anti-Ro antibodies associated with neonatal lupus and congenital heart block Sjögren syndrome (40%–80%)
Anti-RNA polymerase	Diffuse cutaneous systemic sclerosis (15%)
Anti Sm (anti-Smith antibody)	SLE (15%–30%); associated with renal disease
Anti-Scl-70 (anti-topoisomerase I antibody)	Diffuse cutaneous systemic sclerosis (15%); associated with more severe organ involvement, including pulmonary fibrosis

(SLE = systemic lupus erythematosus)

and the dilute Russell viper venom test, which is a functional assay for antibodies that interfere with the clotting mechanism in vitro.

Antineutrophil cytoplasm antibodies

Antineutrophil cytoplasm antibodies (ANCA) are IgG antibodies directed against the cytoplasmic constituents of neutrophils and are useful in the diagnosis and monitoring of systemic vasculitis. Two common patterns are described by immunofluorescence: cytoplasmic fluorescence (c-ANCA), which is caused by antibodies to proteinase-3 (PR3); and perinuclear fluorescence (p-ANCA), which is caused by antibodies to myeloperoxidase (MPO) and other proteins, such as lactoferrin and elastase. These antibodies are not specific for vasculitis and positive results may be found in autoimmune liver disease, malignancy, infection (bacterial and human immunodeficiency virus, HIV), inflammatory bowel disease (IBD), RA, SLE and pulmonary fibrosis.

Complement and complement component antibodies

Low complement C3 is an indicator of active SLE and some forms of vasculitis owing to consumption of complement by immune complexes (see Fig. 4.4). Low C4 is less specific for SLE activity. High C3 and functional measures of complement activation are non-specific features of inflammation. It is possible to screen for autoantibodies directed against a variety of other complement components. Some have clinical utility. For example, anti-C1q antibodies are associated with SLE, but also occur in hypocomplementemic urticarial vasculitis syndrome (HUVS).

Approach to autoantibody testing and interpretation

Testing for autoantibodies should only be performed to gain support for the diagnosis when clinical assessment suggests there may be an underlying autoimmune disease. They are not screening tests for the presence of autoimmune disease since they have limited sensitivity and specificity (see Box 25.9). Routine re-testing of autoantibody profiles is seldom helpful unless the clinical features of the disease change or evolve with time.

Tissue biopsy

Tissue biopsy is useful in confirming the diagnosis in certain musculoskeletal diseases.

Synovial biopsy is indicated in selected patients with chronic inflammatory monoarthritis or tenosynovitis to rule out chronic infectious causes, especially mycobacterial infections. Synovial biopsy can be obtained arthroscopically or by using ultrasound guidance under local anaesthetic.

Temporal artery biopsy can be of value in patients suspected of having giant cell arteritis.

Biopsies of affected tissues, such as skin, lung, nasopharynx, gut, kidney and muscle, may be of value in confirming a diagnosis of systemic vasculitis, whereas bone marrow biopsy can be helpful in the diagnosis of Vacuoles, E1 enzyme, X-linked, Autoinflammatory, Somatic (VEXAS) syndrome.

Muscle biopsy is important in the investigation of myopathy and inflammatory myositis. It is usually taken from the quadriceps or deltoid through a small skin incision under local anaesthetic. Since myositis can be patchy in nature, MRI is sometimes used to localise the best site for biopsy. Immunohistochemical staining, together with plain histology, gives information on primary and secondary muscle and neuromuscular disease. Repeat biopsies are sometimes used to monitor the response to treatment.

Bone biopsy is occasionally required in patients with infiltrative disorders of bone, renal bone disease, suspected chronic infection or malignancy and rarely to confirm or exclude the presence of osteomalacia. For focal lesions, the biopsy should be taken under X-ray guidance or at open surgery, from an affected site. If a systemic bone disease or disorder of mineralisation is suspected, biopsies are usually taken from the iliac crest using a large-diameter (8 mm) trephine needle under local anaesthetic and processed without demineralisation.

Electromyography

Electromyography is of value in the investigation of suspected myopathy and inflammatory myositis, when it shows the diagnostic triad of:

- spontaneous fibrillation
- short-duration action potentials in a polyphasic disorganised outline
- repetitive bouts of high-voltage oscillations on needle contact with diseased muscle.

Presenting problems in musculoskeletal disease

The pattern of joint involvement and time-course can often provide valuable clues to the underlying diagnosis. The most common clinical presentations of musculoskeletal disease are discussed in this section.

Monoarthritis

This refers to pain and swelling affecting a single joint. The most common causes are crystal arthritis, sepsis, reactive arthritis and oligoarticular juvenile idiopathic arthritis. Other potential causes are shown in Box 25.10.

Clinical assessment

The clinical history, pattern of joint involvement, speed of onset, and age and gender of the patient all give clues to the most likely diagnosis. A very rapid onset (6–12 hours) is suggestive of either gout or acute calcium pyrophosphate deposition (CPPD) arthritis, which is also known as pseudogout. Both may be triggered by an intercurrent illness, dehydration or surgery. Gout classically affects younger men and particularly targets the first metatarsophalangeal (MTP) joint, whereas pseudogout tends to affect older people, often with pre-existing OA or metabolic conditions

i 25.10 Causes of monoarthritis

Common

- Gout and pseudogout
- Septic arthritis
- Osteoarthritis
- Trauma
- Haemarthrosis
- Spondyloarthritis
- Psoriatic arthritis
- Reactive arthritis
- Enteropathic arthritis

Less common

- Rheumatoid arthritis
- Juvenile idiopathic arthritis
- Pigmented villonodular synovitis
- Foreign body reaction
- Tuberculosis
- Leukaemia*
- Gonococcal infection
- Osteomyelitis*

*In children, both leukaemia and osteomyelitis may present with monoarthritis.

that predispose to it. Reactive arthritis can also develop acutely and may be preceded by diarrheal illness or genital infection. Septic arthritis develops more slowly and continues to progress until treated. Haemarthrosis usually follows an injury and may be associated with a large effusion, in the absence of periarticular swelling or skin change. Pigmented villonodular synovitis also presents with synovial swelling and a large effusion, affecting a single joint but with a gradual onset. Rheumatoid arthritis seldom presents with monoarthritis, but psoriatic arthritis (PsA) can present this way, although the onset is usually more gradual in both conditions. Osteoarthritis can present with pain affecting a single joint, but the onset is gradual. Although there may be bony swelling of joints affected by OA, synovitis and effusions are uncommon.

Investigations

Aspiration of the affected joint is mandatory in patients with sudden onset of a hot swollen joint. The fluid should be sent for culture and Gram stain to seek the presence of organisms and should be checked by polarised light microscopy for crystals. Blood cultures should also be taken in patients suspected of having septic arthritis. CRP and ESR should be measured. Values are raised with both infection and inflammation, and serial measurements can be useful in assessing the response to treatment. Serum uric acid measurements are of limited value since urate is a negative acute phase reactant and values can fall to within the normal range in acute gout. If investigations suggest CPPD disease, elevations in serum calcium and PTH suggest primary hyperparathyroidism as the underlying cause (p. 719).

Management

If there is any suspicion of septic arthritis, intravenous antibiotics should be given promptly, pending the results of cultures (see Box 25.49). Patients with suspected crystal-induced arthritis or reactive arthritis may be given intra-articular glucocorticoid injections to help the pain and swelling, but only if Gram stain is negative and synovial fluid culture has been negative for 48 hours. Longer-term management should be directed towards the underlying cause.

Polyarthritis

This term is used to describe pain and swelling affecting five or more joints or joint groups. The possible causes are listed in Box 25.11 and extra-articular features are listed in Box 25.12.

Clinical assessment

The hallmarks of inflammatory polyarthritis are early-morning stiffness and worsening of symptoms with inactivity, along with synovial swelling and tenderness on examination.

The pattern of involvement can be helpful in reaching a diagnosis (Fig. 25.9). In RA there is typically symmetrical involvement targeting the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands and wrists as well as the ankles and metatarsophalangeal

i 25.11 Common causes of polyarthritis

Cause	Characteristics
Rheumatoid arthritis	Symmetrical, small and large joints, upper and lower limbs
Viral arthritis	Symmetrical, small joints; may be associated with rash and prodromal illness; self-limiting
Osteoarthritis	Symmetrical, targets PIP, DIP and first CMC joints in hands, knees, hips, back and neck; associated with Heberden and Bouchard nodes
Psoriatic arthritis	Tends to be asymmetrical, affecting PIP and DIP joints in the hands but large joints may also be affected; often associated with nail pitting/onycholysis, dactylitis, spondylitis and enthesitis
Axial spondyloarthritis and enteropathic arthritis	Tends to affect mid-size and large joints and entheses, lower more than upper limbs; history of inflammatory back pain
Systemic lupus erythematosus	Symmetrical, typically affecting small joints; clinical evidence of synovitis unusual
Juvenile idiopathic arthritis	Various patterns including: polyarticular, oligoarticular and systemic but also enthesitis-predominant
Chronic gout	Affects distal more than proximal joints; history of acute attacks
Chronic sarcoidosis	Small and large joints, often involves ankles
Poncet disease	Reactive arthritis often affecting large joints associated with tuberculosis
Calcium pyrophosphate arthritis	Chronic polyarthritis with involvement of wrists, ankles, knees and oligoarticular small hand joints

(CMC = carpometacarpal; DIP = distal interphalangeal; PIP = proximal interphalangeal)

i 25.12 Extra-articular features of inflammatory arthritis

Clinical feature	Disease association
Skin, nails and mucous membranes	
Psoriasis, nail pitting and dystrophy	Psoriatic arthritis
Raynaud phenomenon	Systemic sclerosis, antiphospholipid syndrome, SLE
Photosensitivity	SLE
Livedo reticularis	SLE, antiphospholipid syndrome
Splinter haemorrhages, nail-fold infarcts, purpuric lesions	Vasculitis
Urticaria and erythemas	SLE, adult-onset Still disease, systemic JIA, rheumatic fever
Oral ulcers	SLE, reactive arthritis, Behçet disease
Nodules	RA (mainly extensor surfaces), gout (tophi; eccentric, white deposits within), rheumatic fever
Xerostomia, dry skin, various rashes	Primary Sjögren disease
Eyes	
Uveitis	SpA, sarcoid, JIA, Behçet disease
Conjunctivitis	Reactive arthritis
Episcleritis, scleritis	RA, vasculitis
Heart, lungs	
Pleuro-pericarditis	SLE, RA, rheumatic fever
Aortic valve/root disease	HLA-B27-related SpA
Interstitial lung disease	RA, SLE, CTD
Abdominal organs	
Hepatosplenomegaly	RA, SLE
Haematuria, proteinuria	SLE, vasculitis, systemic sclerosis
Urethritis	Reactive arthritis and SpA (sterile)
Fever, lymphadenopathy	Infection, systemic JIA, rheumatic fever, SLE

(CTD = connective tissue disease; HLA = human leucocyte antigen; JIA = juvenile idiopathic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SpA = spondyloarthritis)

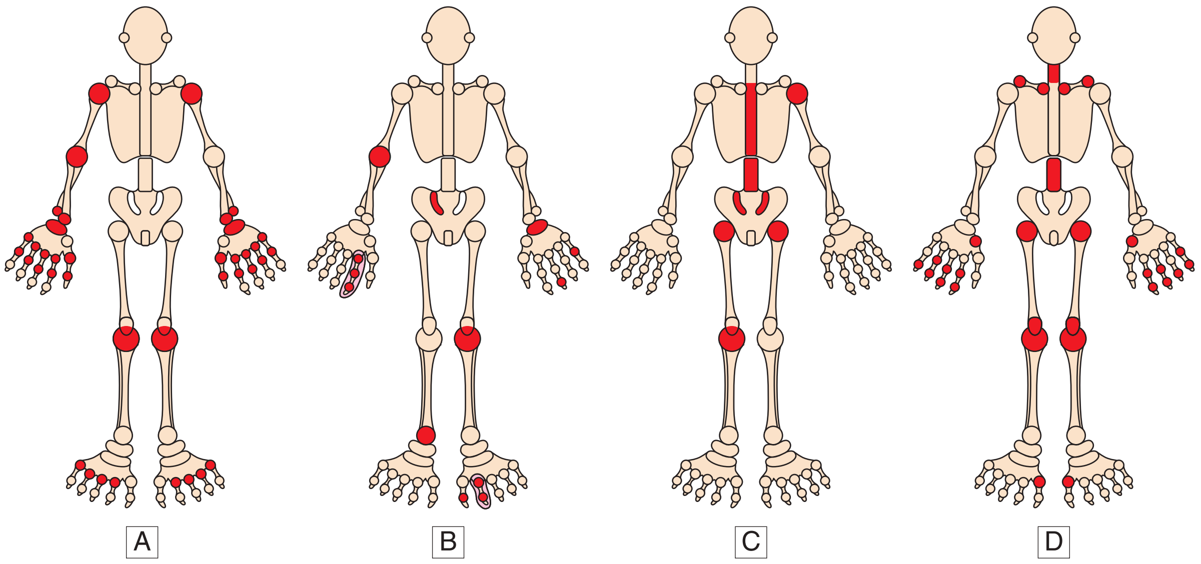


Fig. 25.9 **Patterns of joint involvement in different forms of polyarthritis.** A Rheumatoid arthritis typically targets the metacarpophalangeal and proximal interphalangeal joints of the hands and metatarsophalangeal joints of the feet, as well as other joints, in a symmetrical pattern. B Psoriatic arthritis targets proximal and distal interphalangeal joints of the hands, entheses and larger joints in an asymmetrical pattern. Sacroiliitis (often asymmetrical) may occur. C Axial spondyloarthritis/ankylosing spondylitis targets the spine, sacroiliac joints, entheses and large peripheral joints in an asymmetrical pattern. D Osteoarthritis targets the proximal and distal interphalangeal joints of the hands, first carpometacarpal joint at the base of the thumb, knees, hips, lumbar and cervical spine.

(MTP) and PIP joints of the feet. Other large joints may also be affected. In psoriatic arthritis (PsA), the PIP and distal interphalangeal (DIP) joints of the hands are usually affected, often in an asymmetrical pattern and accompanied by nail pitting or early onycholysis. Large joints may also be affected, and psoriasis may or may not be present. In SLE there may be polyarthritis, but this more usually causes polyarthralgia and tenosynovitis, mainly of distal limb joints and tendons. OA has a similar pattern of involvement to PsA in the hands but can usually be distinguished by the presence of Heberden and Bouchard nodes and lack of synovitis and other features of PsA.

Investigations

Blood samples should be taken for routine haematology, biochemistry, ESR, CRP, viral serology and an immunological screen, including ANA and ACPA (or RF). If there is clinical suspicion of an inflammatory arthritis, but clinical signs of synovitis are absent, ultrasound examination or MRI may be helpful in confirming the diagnosis.

Management

Management should be tailored to the underlying diagnosis. While investigations are in progress, non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics may be considered for symptom control. While glucocorticoids can be helpful in treating symptoms of inflammatory arthritis, they should generally be avoided until a definitive diagnosis has been made.

Fracture

Fractures are a common presenting symptom of osteoporosis, but they also occur in other bone diseases, in osteopenia and in some people with a normal skeleton where there has been a high trauma injury.

Clinical assessment

The presentation is with localised bone pain, which is worsened by movement of the affected limb or region. There is usually a history of trauma, but spontaneous fractures can occur in the absence of trauma in severe osteoporosis. Fractures can be divided into several subtypes, based on the precipitating event and presence or absence of an underlying disease (Box 25.13). The main differential diagnosis is soft tissue injury, but fracture should be suspected when there is marked pain and swelling, abnormal movement of the affected limb, crepitus or deformity. Femoral neck fractures typically produce a shortened, externally rotated leg that is painful to move. The pain from vertebral fracture is variable and a high index of suspicion is key to making the diagnosis by imaging, as discussed below.

25.13 Characteristics of different fracture types

Fracture type	Precipitation factor	Underlying disease
Fragility fracture	Fall from standing height or less	Osteoporosis Osteopenia
Vertebral fracture	Bending, lifting, falling	Osteoporosis Osteopenia
Stress fracture	Running, excessive training	None
High-energy fracture	Major trauma	None
Pathological fracture	Spontaneous, minimal trauma	Malignancy Paget disease of bone Osteomalacia

25.14 How to investigate a suspected fracture

- Order X-rays in two projections at right-angles to one another
- Include the whole bone and the joints at either end (this may reveal an additional unsuspected fracture)
- Check for evidence of displacement
- Check for a break in the cortex
- In suspected vertebral fracture, check for depression of the end plate
- If clinical suspicion is high but no fracture is seen, consider magnetic resonance imaging

Investigations

X-rays of the affected site should be taken in at least two planes and examined for discontinuity of the cortical outline (Box 25.14). In addition to demonstrating the fracture, X-rays may also show evidence of an underlying disorder, such as osteoporosis, Paget disease or osteomalacia. If the X-ray fails to show evidence of a fracture, but clinical suspicion remains high, MRI should be considered. In general, post-menopausal women and men >50 years, with low trauma fractures, should be referred for a DXA scan to screen for osteoporosis. DXA is also indicated in those under 50 years with strong clinical risk factors for osteoporosis.

Management

Management of fracture in the acute stage requires adequate pain relief, with opiates if necessary, reduction of the fracture to restore normal anatomy and immobilisation of the affected limb to promote healing. This can be achieved using an external cast or splint, or by internal fixation. Femoral neck fractures present a special management problem since non-union and osteonecrosis are common. This is especially true with intracapsular hip fractures, which should be treated by joint replacement surgery. Following the fracture, rehabilitation is required with physiotherapy and a supervised exercise programme. If the DXA scan shows evidence of osteoporosis or other metabolic bone disease, this should be treated appropriately as described later in this chapter.

Generalised musculoskeletal pain

Clinical assessment

There are a variety of causes of generalised pain, as summarised in Box 25.15. Relentlessly progressive pain occurring in association with weight loss suggests malignant disease with bone metastases. Generalised bone pain may also arise in osteomalacia, primary hyperparathyroidism and polyostotic Paget disease. An important common cause is fibromyalgia (FM) syndrome, which presents with generalised pain that particularly affects the trunk, back and neck. Accompanying features include fatigue, poor concentration and focal areas of hyperalgesia. Widespread pain may also occur in association with hypermobility Ehlers–Danlos syndrome (hEDS). Pain is a prominent feature in patients with polymyalgia rheumatica, but this tends to be localised to the pelvic and shoulder girdle. Similarly, pain is also a common feature of inflammatory arthritis and OA but tends to be localised to affected joints. Widespread pain can occur in PsA if there is extensive enthesitis.

Investigations

Bone scintigraphy is of value in patients with suspected bone metastases or Paget disease and can also reveal evidence of stress fractures in osteomalacia. FBC, ESR and CRP may be abnormal in the presence of inflammatory disease and myeloma. Plasma and urine protein electrophoresis should be performed to screen for myeloma, and if abnormalities are detected further imaging should be considered with X-ray, low-dose CT or MRI. Routine biochemistry, vitamin D and parathyroid hormone (PTH) should be measured if osteomalacia is suspected. In Paget disease, the typical picture is of an elevation in ALP with otherwise normal biochemistry. Investigations are unremarkable in patients with FM and hEDS.

Management

Management should be directed towards the underlying cause. Chronic pain of unknown cause and that associated with FM respond poorly to analgesics and NSAIDs, but may respond partially to antineuropathic agents, such as amitriptyline, duloxetine, gabapentin and pregabalin.

25.15 Causes of generalised pain

- Fibromyalgia
- Ehlers–Danlos syndrome, hypermobility type
- Metastatic cancer
- Osteomalacia
- Psoriatic arthritis (enthesopathic)

Muscle weakness

Muscle weakness can arise from a variety of causes, as shown in Box 25.16. It is important to distinguish between a subjective feeling of generalised weakness occurring with fatigue, and an objective weakness with loss of muscle power and function. The former is a non-specific manifestation of many systemic conditions.

Clinical assessment

Clinical examination should document the presence, pattern and severity of muscle weakness assessed using the Medical Research Council (MRC) scale (no power (0) to full power (5)). Proximal muscle weakness suggests the presence of a myopathy or myositis, which typically causes difficulty in standing from a seated position, walking up steps, squatting and lifting overhead. Worsening symptoms on exercise and post-exertional cramps suggest a metabolic myopathy, such as glycogen storage disease. A strong family history and onset in childhood or early adulthood suggest muscular dystrophy. Alcohol excess can cause inflammatory myositis and atrophy of type 2 muscle fibres. Proximal myopathy may be a complication of Cushing syndrome, glucocorticoid therapy and osteomalacia. Myopathy and myositis can also occur in association with many drugs (see Box 25.78) and viral infections, including HIV; in the latter case, it may be due to HIV itself or to treatment with zidovudine. Polymyositis and dermatomyositis in adults are frequently associated with occult malignancy, emphasising the importance of a thorough general examination of patients with this presentation.

Investigations

Investigations should include routine biochemistry and haematology, ESR, CRP, CK, serum 25(OH)-vitamin D, PTH, parvovirus, hepatitis B/C, HIV and streptococcus serology, serum and urine protein electrophoresis, serum angiotensin-converting enzyme (ACE), ANA, ENA, anti dsDNA, RF, complement and myositis-specific autoantibodies such as Jo-1. Open muscle biopsy (site-guided by MRI detection of abnormal muscle) and electromyography (EMG) are usually required to make the diagnosis. Genetic testing may be of value in patients where an inherited disorder is suspected. Patients suspected to have myositis should be screened for malignancy. Initially this involves a CT scan of the chest,

25.16 Causes of muscle weakness

Inflammatory

- Polymyositis
- Dermatomyositis
- Other autoimmune connective tissue disease
- Inclusion body myositis
- Sarcoid
- Myasthenia gravis

Endocrine

- Hypothyroidism
- Hyperthyroidism
- Cushing syndrome
- Addison disease

Metabolic

- Myophosphorylase deficiency
- Phosphofructokinase deficiency
- Hypokalaemia
- Carnitine deficiency
- Osteomalacia
- Hypercalcaemia

Genetic

- Muscular dystrophy
- Mitochondrial disease

Drugs/toxins

- Alcohol
- Cocaine
- Glucocorticoids
- Statins and fibrates
- TNF-α inhibitors
- Zidovudine

Infections (Ch. 14)

- Viral (HIV, cytomegalovirus, rubella, Epstein–Barr, echovirus)
- Parasitic (schistosomiasis, cysticercosis, toxoplasmosis)
- Bacterial (*Clostridium perfringens*, staphylococci, tuberculosis, *Mycoplasma*)

abdomen and pelvis followed by upper gastrointestinal endoscopy and colonoscopy if necessary.

Management

Management is determined by the underlying cause, but all patients with muscle disease should be referred for physiotherapy and graded exercises to maximise muscle function while specific treatment is introduced.

Regional musculoskeletal pain

Regional musculoskeletal pain is a common presenting complaint, usually occurring as the result of age-related degenerative disease of tendons and ligaments, OA and trauma.

Back pain

Back pain is a common symptom that affects 60%–80% of people at some time in their lives. Although the prevalence has not increased, reported disability from back pain has risen significantly in the last 30 years. In Western countries, back pain is the most common cause of sickness-related work absence. In the UK, 7% of adults consult their GP each year with back pain. Globally, low back pain is thought to affect about 9% of the population. The most important causes of low back pain are summarised in Box 25.17.

i 25.17 The main causes of low back pain

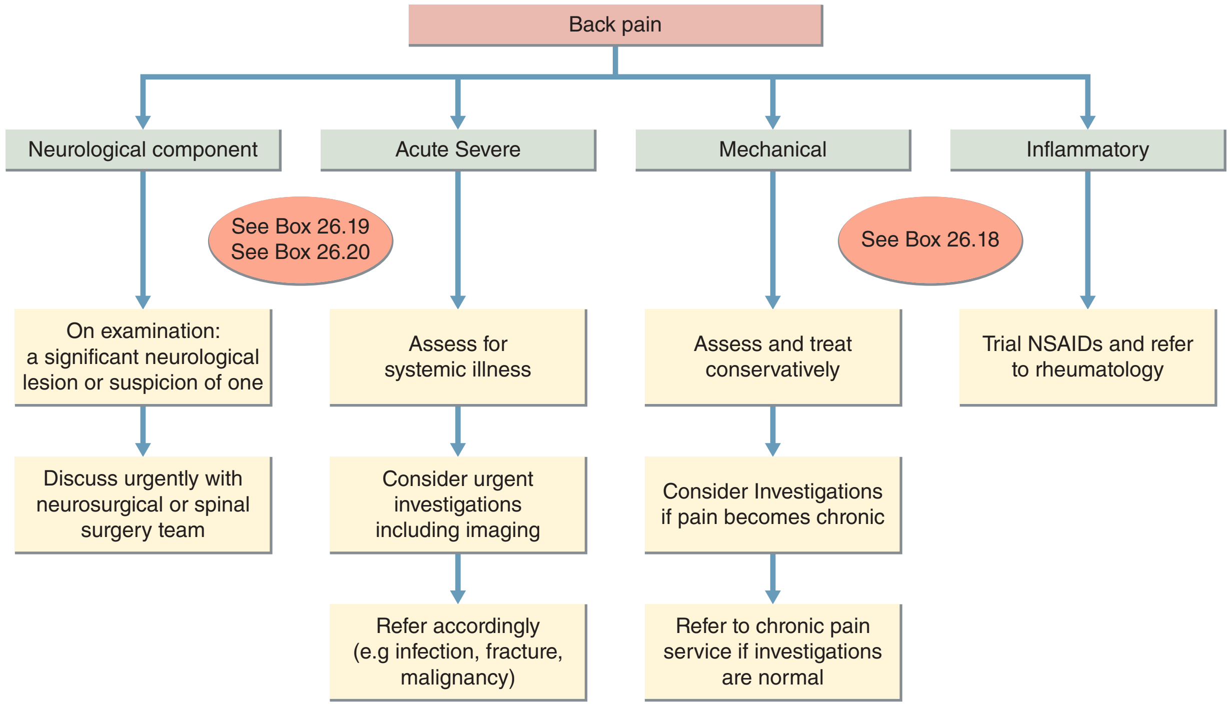
- Soft-tissue lesion, including myofacial back pain*
- Intervertebral disc disease (degenerative or annulus tear and prolapse)*
- Facet joint osteoarthritis*
- Vertebral fracture
- Paget disease
- Axial spondyloarthritis and axial psoriatic arthritis
- Discitis (infective or inflammatory ['spondylodiscitis'])
- Bone metastases
- Spondylolisthesis

*The main causes of 'mechanical' back pain.

Clinical assessment

The main purpose of clinical assessment is to differentiate the usually self-limiting disorder of mechanical back pain from more serious spinal pathology, as summarised in Figure 25.10. Mechanical back pain is the most common cause of acute back pain in people aged 20–55. This accounts for more than 90% of episodes, is usually acute and is associated with lifting or bending. It is exacerbated by activity and is generally relieved by rest (Box 25.18). It is usually confined to the lumbosacral region, buttock or thigh, is asymmetrical and does not radiate beyond the knee (which would imply nerve root irritation). On examination, there may be asymmetric local paraspinal muscle spasm and tenderness, with painful restriction of some, but not all, movements. Mechanical low back pain is more common in manual workers, particularly those in occupations that involve heavy lifting and twisting. The prognosis is generally good. After 2 days, 30% are better, and 90% have recovered by 6 weeks. Recurrences of pain may occur, and about 10%–15% of patients go on to develop chronic back pain that may be difficult to treat. Psychological elements, such as job dissatisfaction, depression and anxiety, are important risk factors for the transition to chronic pain and disability. By comparison, back pain secondary to inflammatory conditions (inflammatory back pain; IBP), such as axial spondyloarthritis (axSpA), axial psoriatic arthritis (axPsA) or axial CPPD disease, has different characteristics to mechanical back pain (see Box 25.18). Though less common in the population overall compared with mechanical pain, IBP typically presents for the first time in young adults (<40 years old) when due to axSpA or axPsA, though it can represent CPPD disease in adults in their late middle age and the elderly.

Back pain secondary to serious spinal pathology has important characteristics (Box 25.19). If there is clinical evidence of spinal cord or nerve root compression, or a cauda equina lesion, then urgent investigation is needed. Spinal stenosis presents insidiously with leg discomfort on walking that is relieved by rest, bending forwards or walking uphill. Patients may adopt a characteristic simian posture, with a forward stoop and slight flexion at hips and knees. The most common cause is the gradual development of coexisting contributing lesions such as facet joint arthritis, ligament flavum thickening or degenerative spondylolisthesis.



Back pain
Neurological component
Acute Severe
Mechanical
Inflammatory
See Box 26.19
See Box 26.20
See Box 26.18
On examination: a significant neurological lesion or suspicion of one
Assess for systemic illness
Assess and treat conservatively
Trial NSAIDs and refer to rheumatology
Discuss urgently with neurosurgical or spinal surgery team
Consider urgent investigations including imaging
Consider Investigations if pain becomes chronic
Refer accordingly (e.g infection, fracture, malignancy)
Refer to chronic pain service if investigations are normal

Fig. 25.10 Initial triage assessment of back pain.

25.18 Features of mechanical vs inflammatory back pain

Features of mechanical back pain	Features of inflammatory back pain
• Pain worse with physical activity and improved by rest • Most common site: lumbar area • Often precipitated by lifting or bending • Recurrent episodes • Site often low back referred to upper, outer part of leg • No clear-cut nerve root distribution • No systemic features • Self-limiting; recovery at 6 weeks in 90%	• Improvement with exercise, no improvement with rest, night pain, improved on getting up • Pain associated with stiffness • Pain and stiffness ease with movement • Site of pain can include posterior sacral area and posterior thigh (SIJs) • Responds well to NSAID • Recurrent episodes • Other features of axSpA may be present (see Box 25.59)

(axSpA = axial spondyloarthritis; NSAIDs = non-steroidal anti-inflammatory drugs; SIJs = sacroiliac joints)

25.19 Red flags for serious spinal pathology

History

- Age < 20 years or > 55 years at presentation
- Character: constant, progressive pain unrelieved by rest
- Location: thoracic pain
- Past medical history: carcinoma, tuberculosis, HIV, systemic glucocorticoid use, osteoporosis
- Constitutional: systemic upset, sweats, weight loss
- Major trauma

Examination

- Painful spinal deformity
- Severe/symmetrical spinal deformity
- Saddle anaesthesia
- Progressive neurological signs/muscle-wasting
- Multiple levels of root signs

25.20 Clinical features of radicular pain

Nerve root pain

- Unilateral leg pain worse than low back pain
- Pain radiates beyond knee
- Paraesthesia in same distribution
- Nerve irritation signs (reduced straight leg raising that reproduces leg pain)
- Motor, sensory or reflex signs (limited to one or adjacent nerve roots)
- Often self-limiting, with 50% recovery at 6 weeks

Cauda equina syndrome

- Difficulty with micturition
- Loss of anal sphincter tone or faecal incontinence
- Saddle anaesthesia
- Gait disturbance
- Pain, numbness or weakness affecting one or both legs

Degenerative disc disease and osteoarthritis is a common cause of chronic low back pain in middle-aged and older adults. Prolapse of an intervertebral disc presents when discs are still well hydrated (in young and early middle age) with nerve root pain, which can be accompanied by characteristic features such as sensory deficit, motor weakness and asymmetrical reflexes (Box 25.20). Examination may reveal a positive sciatic or femoral stretch test. About 70% of patients improve by 4 weeks. Spondylolisthesis may cause back pain that is typically aggravated by standing and walking. Occasionally, diffuse idiopathic skeletal hyperostosis (DISH) can cause back pain (p. 1089), but this is not a prominent feature. Arachnoiditis is a rare cause of chronic severe low back pain. It is caused by chronic inflammation of the nerve root sheaths in the spinal canal and can complicate meningitis, spinal surgery or myelography with oil-based contrast agents.

Investigations

Investigations are not required in patients with acute mechanical back pain. Those with persistent pain (> 6 weeks) or red flags (see Box 25.19) should undergo further investigation. MRI is the investigation of choice because it can demonstrate spinal stenosis, cord compression or nerve root compression, as well as inflammatory changes in axSpA, malignancy and sepsis. Plain X-rays can be of value in patients suspected of having vertebral compression fractures, OA and degenerative disc disease. If metastatic disease is suspected, bone scintigraphy or CT should be considered. Additional investigations that may be required include routine biochemistry and haematology, ESR and CRP (to screen for infection and inflammatory disease), protein and urine electrophoresis (for myeloma), human leucocyte antigen HLA-B27 for axSpA and prostate-specific antigen for prostate carcinoma. MRI is essential in investigating IBP as typical patterns of bone, disc and enthesis inflammation can be identified in axSpA, and MRI is an important part of making a firm diagnosis.

Management

Education is important in patients with mechanical back pain. It should emphasise the self-limiting nature of the condition and the fact that exercise is helpful rather than damaging. Regular analgesia and/or NSAIDs may be required to improve mobility and facilitate exercise. Return to work and normal activity should take place as soon as possible. Bed rest is not helpful and may increase the risk of chronic disability. Referral for physiotherapy should be considered if a return to normal activities has not been achieved by 6 weeks. Low-dose tricyclic antidepressant drugs may help pain, sleep and mood. With IBP, NSAIDs and physiotherapy are the mainstays of treatment. Glucocorticoids can help in severe acute bouts of IBP, but if IBP (due to axSpA or axPsA) is recurrent and/or severe and not responding to NSAIDs, biologic or tsDMARD treatment should be considered.

Other treatment modalities that are occasionally used include epidural and facet joint injection, traction and lumbar supports, though there is limited randomised controlled trial evidence to support their use. Malignant disease, osteoporosis and Paget disease require specific treatment of the underlying condition.

Surgery is required in less than 1% of patients with low back pain, but may be needed in progressive spinal stenosis, in spinal cord compression, severe spondylolisthesis, severe scoliosis and in some patients with nerve root compression.

Neck pain

Neck pain is a common symptom that can occur following an injury or falling asleep in an awkward position, as a result of stress or in association with OA of the spine. The causes are shown in Box 25.21. Most cases resolve spontaneously or with a short course of NSAIDs or analgesics and some exercise therapy. Patients with persistent pain that follows a nerve root distribution and those with upper or lower limb neurological signs should be investigated by X-rays plus MRI and, if necessary, referred for a neurosurgical opinion.

Shoulder pain

Shoulder pain is a common complaint over the age of 40 (Box 25.22). Varying pain patterns associated with common lesions are shown in Figure 25.11. For most shoulder lesions, general management is with analgesics, NSAIDs, local glucocorticoid injections and physiotherapy aimed at restoring normal movement and function. Surgery may be required in patients who have debilitating or persistent symptoms in association with rotator cuff lesions or severe acromioclavicular joint arthritis. If there is subacromial impingement, without evidence of a complete rotator cuff tear on MRI, subacromial glucocorticoid injection and

25.22 Clinical findings in shoulder pain

Rotator cuff and subacromial lesions

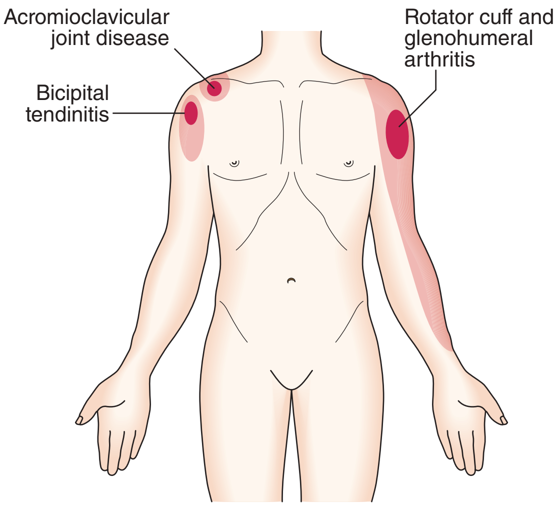
- Pain reproduced by resisted active movement:
  - Abduction: supraspinatus
  - External rotation: infraspinatus, teres minor
  - Internal rotation: subscapularis

Acromioclavicular joint

- Pain on full abduction and adduction (at 90° of forward elevation)

Bicipital (long head) tendinitis

- Tenderness over bicipital groove
- Pain reproduced by resisted active wrist supination or elbow flexion



Acromioclavicular joint disease
Bicipital tendinitis
Rotator cuff and glenohumeral arthritis

Fig. 25.11 Pain patterns around the shoulder. The dark shading indicates sites of maximum pain.

physiotherapy can be of value. Calcific supraspinatus tendinitis unresponsive to glucocorticoid injection can be treated with barbotage (needle disruption of deposit under ultrasound guidance). Complete rotator cuff tears in people under 40 years of age may respond well to surgical repair, but results are less good in older people. Adhesive capsulitis ('frozen shoulder') presents with pain associated with marked restriction of elevation and external rotation. Adhesive capsulitis is commonly associated with diabetes mellitus and neck/radicular lesions. Treatment in the early stage is with NSAID analgesia, a short course of oral prednisolone, intracapsular glucocorticoid injection, and regular 'pendulum' exercises of the arm to mobilise. Complete recovery sometimes takes up to 2 years. Hydrodilatation can be considered an option in the early 'frozen' stage. For severe or persistent symptoms, manipulation under anaesthesia is a surgical option.

25.23 Common local causes of elbow pain

Lesion	Pain	Examination findings
Lateral humeral epicondylitis (traumatic 'tennis elbow' or SpA-related enthesitis)	Lateral epicondyle Radiation to extensor forearm	Tenderness over epicondyle Pain reproduced by resisted active wrist extension
Medial humeral epicondylitis (traumatic 'golfer's elbow' or SpA-related enthesitis)	Medial epicondyle Radiation to flexor forearm	Tenderness over epicondyle Pain reproduced by resisted active wrist flexion
Olecranon bursitis (gout, rheumatoid arthritis or infection)	Olecranon	Tender swelling

(SpA = spondyloarthritis)

Elbow pain

The most common causes are repetitive trauma causing lateral epicondylitis (tennis elbow) and medial epicondylitis (golfer's elbow) (Box 25.23). SpAs, including psoriatic disease, can present with the same symptoms (tendon insertion enthesitis). Management is by rest, analgesics and topical or systemic NSAIDs. Local glucocorticoid injections may be required in resistant cases. Olecranon bursitis can also follow local repetitive trauma, but other causes include infections and gout.

Hand and wrist pain

Pain from hand or wrist joints is well localised to the affected joint, except for pain from the first carpometacarpal (CMC) joint, commonly targeted by OA or PsA; although maximal at the thumb base, the pain often radiates down the thumb and to the radial aspect of the wrist. Non-articular causes of hand pain include:

- *Tenosynovitis*: affects flexor or extensor digital tendons. Pain and tenderness are well localised to the tendon lesions. There is often early-morning 'claw-like' digit stiffness. De Quervain tenosynovitis involves the tendon sheaths of abductor pollicis longus and extensor pollicis brevis. It produces pain maximal over the radial aspect of the distal forearm and wrist and marked pain on forced ulnar deviation of the wrist with the thumb held across the patient's palm (Finkelstein sign). This test is not specific for this lesion alone.
- *Raynaud phenomenon*: digital vasospasm triggered mostly by cold.
- *C6, C7 or C8 radiculopathy*.
- *Carpal tunnel syndrome* (see also p. 1089): hand position–dependent and/or nocturnal pain, numbness and paraesthesia of thumb and second to fourth digits.

Hip pain

Pain from the hip joint is usually felt deep in the groin, with variable radiation to the buttock, anterolateral thigh or knee (Fig. 25.12). Symphysis pubis (SP) lesions, osteitis pubis and pubic ramus fracture can also present with groin pain. A lay person's description of their 'hip pain' will often locate the pain to the greater trochanter area. A common cause of 'true' hip joint pain in older people is OA. Paget disease can also enter into the differential diagnosis. Occasionally, inflammatory disease secondary to axSpA or PsA can present with groin (hip joint or SP), greater trochanter area or hip pain. Greater trochanter pain syndrome is usually due to either gluteus medius insertional tendinitis/enthesitis, trochanteric bursitis or referred pain (Box 25.24). Pain at this site may also be referred from the lumbosacral spine. Other less common causes of pain in the hip/groin area include inguinal hernia, adductor tendinitis and enthesitis of anterior superior/inferior iliac spines.

Knee pain

In middle and older age, the most common cause of knee pain is OA, the features of which are described later in this chapter. Pain that is associated with locking of the knee (sudden painful inability to extend fully) is usually due to a meniscal tear or osteochondritis dissecans. Referred pain from the hip may present at the knee and is reproduced by hip, not knee, movement. Pain from periarticular lesions is well localised to the involved structure (Box 25.25). Anterior knee pain may be due to patellar ligament or retinacular lesions (enthesitis, tendinitis, fat-pad syndrome) occurring typically from overuse and/or axSpA. Anterior knee pain is relatively common in adolescents and may be the result of patellar articular cartilage or ligament insertion osteochondritis.

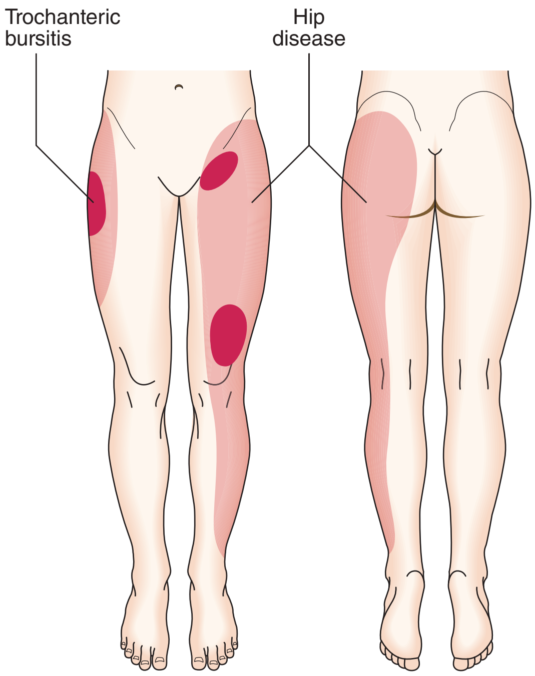


Fig. 25.12 Pain patterns of hip disease and trochanteric pain syndrome. The dark shading indicates sites of maximum pain.

Ankle and foot pain

Pain from the ankle (tibiotalar) joint due to OA or osteochondral defect is felt between the malleoli and is worse on weight-bearing. Pain from the subtalar joint (from the same lesions) is also worse on weight-bearing. Inflammatory arthritis of either of these joints may also occur and is associated with swelling and tenderness. These diagnoses can be associated with hindfoot tenosynovitis (peroneal or posterior tibial). Pain under the heel is typically due to plantar fasciitis. This can occur as the result of overuse, in which case it may respond to rest, padded footwear and local glucocorticoid injections, but can also arise in SpA as a manifestation of enthesitis. Pain affecting the back of the heel may be due to Achilles

25.25 Local causes of knee pain

Lesion	Pain	Examination findings
Osteoarthritis	Weight-bearing or on ascending and descending starts	Enlargement of knee joint, tenderness at joint margins, crepitus on flexion, small effusions, quadriceps wasting
Pre-patellar bursitis	Over patella	Tender fluctuant swelling in front of patella
Superficial and deep infrapatellar bursitis and fat-pad syndrome	Anterior knee, inferior to patella	Tenderness in front of (superficial) or behind (deep) patellar tendon with pain on full knee flexion
Anserine bursitis/ enthesitis	Upper medial tibia	Tenderness (± swelling) over upper medial tibia
Medial collateral ligament lesions (injury or enthesitis)	Upper medial tibia	Localised tenderness of upper medial tibia with pain reproduced by valgus stress on partly flexed knee
Popliteal cyst (Baker cyst)	Popliteal fossa	Tender swelling of popliteal fossa
Patellar ligament enthesopathy	Anterior upper tibia	Tenderness over tibial tubercle
Osteochondritis of patellar ligament (Osgood–Schlatter disease)	Anterior upper tibia	Pain on resisted active knee extension

25.24 Local causes of hip pain

Lesion	Pain	Examination findings
Osteoarthritis	Groin pain, worse on weight-bearing	Limited range of movement and/or pain on examination of hip
Gluteus medius enthesitis	Upper lateral thigh, worse on lying on that side at night	Tenderness over greater trochanter
Trochanteric bursitis	As above	As above
Adductor tendinitis (SpA-related enthesitis or sports-related trauma)	Upper inner thigh	Tenderness over adductor origin/tendon/muscle Pain reproduced by resisted active hip adduction
Ischiogluteal enthesitis/bursitis	Buttock, worse on sitting	Tenderness over ischial prominence
Pubic symphysitis (can mimic intra-articular hip lesions)	Medial groin pain, can radiate to inner or even outer upper thighs	Tenderness over symphysis joint. If pain is worse on trunk curl/rectus activation under symphysis-resting hand, it may be insertional rectus enthesitis (SpA)

(SpA = spondyloarthritis)

tendinitis or enthesitis. The MTP joints of the feet are commonly involved symmetrically in RA. The presentation is with pain on walking felt below the metatarsal heads, often described as 'walking on marbles'. Patients with active inflammation of the MTP joints have pain when the forefoot is squeezed. Involvement of the first MTP joint is common in OA or PsA and is associated, respectively, with hallux valgus and dactylitis. The hallux is also a classical target in acute gout. Morton neuroma is a neuropathy of an interdigital nerve and is usually located between the third and fourth metatarsal heads. Women are most commonly affected (tight shoes can be to blame). Local sensory loss and a palpable tender swelling between the metatarsal heads may be detected. Footwear adjustment often helps, with or without a local glucocorticoid injection, but surgical decompression may be required if symptoms persist. With many foot and ankle problems, where lesions and biomechanics affect walking, involvement of podiatric care, and optimising foot orthoses, is valuable.

Principles of management

The management of rheumatological disorders should be tailored to the underlying diagnosis. Certain aspects are common to many disorders, however, and the general principles are discussed here. The therapeutic aims are:

- to educate patients about their disease to enhance self-management
- to control pain, if it is present
- to optimise function
- to modify the disease process where this is possible
- to identify and treat comorbidity.

These aims are interrelated and success in one area often benefits others. Successful management depends on a thorough assessment. The management plan should be individualised and patient-centred, should involve relevant members of the multidisciplinary team, and should be agreed and understood by both the patient and all the practitioners that are involved. It must also take into account:

- the patient's activity requirements and occupational and recreational aspirations
- risk factors that may influence the disease
- the patient's perceptions and knowledge of the condition
- medications and coping strategies that have already been tried
- comorbid disease and its therapy
- the availability, costs and logistics of appropriate evidence-based interventions.

Generally, the simplest and safest interventions should be tried first. Symptoms and signs may change with time, so the management plan for most patients requires regular review and re-adjustment.

Core interventions that should be considered for everyone with a painful musculoskeletal condition are listed in Box 25.26. There are also other non-pharmacological and drug options, the choice of which depends on the nature and severity of the diagnosis.

Education and lifestyle interventions

Education

Patients must always be informed about the nature of their condition and its investigation, treatment and prognosis, since education can improve outcome. Information and therapist contact can reduce pain and disability, improve self-efficacy and reduce the health-care costs of many musculoskeletal conditions, including OA and RA. The mechanisms are unclear, but in part may result from improved adherence. Benefits are modest, but potentially long-lasting, safe and cost-effective. Education can be provided through one-to-one discussion, written literature, patient-led group education classes and interactive computer programs. The inclusion of the patient's partner or carer is often appropriate; this is essential for childhood conditions but also helps in many chronic adult conditions.

i **25.26 Interventions for patients with rheumatic diseases**

Core interventions

- Education
- Aerobic conditioning
- Muscle strengthening
- Simple analgesics
- Disease-modifying therapy
- Reduction of adverse mechanical factors
- Pacing of activities
- Appropriate footwear
- Weight reduction if obese

Other options

- Other analgesic drugs:
  - Oral non-steroidal anti-inflammatory drugs
  - Topical agents
  - Opioid analgesics
  - Amitriptyline
  - Gabapentin/pregabalin
- Local glucocorticoid injections
- Physical treatments:
  - Heat, cold, aids, appliances
- Surgery
- Coping strategies (see Box 25.27)

For children and adolescents with chronic diseases such as juvenile idiopathic arthritis (JIA), education and support of the whole family, schooling and psychological support are essential and best delivered through a multidisciplinary team.

Patient-run charitable organisations provide a wealth of information and support to patients (see 'Further information'). The detail of the educational materials and services that organisations can provide should be known to the multidisciplinary team, and organisation contact details should be made available to patients.

Exercise

Several types of exercise can be prescribed:

- *Aerobic fitness training* can produce long-term reduction in pain and disability. It improves well-being, encourages restorative sleep and benefits common comorbidity, such as obesity, diabetes, chronic heart failure and hypertension.
- *Local strengthening exercise* for muscles that act over compromised joints also reduces pain and disability, with improvements in the reduced muscle strength, proprioception, coordination and balance that associate with chronic arthritis. 'Small amounts often' of strengthening exercise are better than protracted sessions performed infrequently.
- *Weight-bearing exercise* is of value in osteoporosis, where it can result in modest increases in bone density and slow bone loss.

Joint protection

Excessive impact-loading and adverse repetitive use of a compromised joint or periarticular tissue can worsen symptoms in patients with arthritis. This can be mitigated by cessation of contact sports and by pacing of activities by dividing physical tasks into shorter segments with brief breaks in between. Other strategies include adaptations to machinery or tools at the workplace; the use of shock-absorbing footwear with thick, soft soles, which can reduce impact-loading through feet, knees, hips and back; and the use of a walking stick on the contralateral side to a painful hip, knee or foot.

Non-pharmacological interventions

Physical and occupational therapy

Local heat, ice packs, wax baths and other local external applications can induce muscle relaxation and provide temporary relief of symptoms in a range of rheumatic diseases.

Hydrotherapy and balneotherapy (immersion in a bath) induce muscle relaxation and facilitate movement in a warm, pain-relieving environment without the restraints of gravity and normal load-bearing. Various manipulative techniques may also help improve restricted movement.

Splints can give temporary rest and support for painful joints and periarticular tissues and can prevent harmful involuntary postures during sleep. Prolonged rest must be avoided. Orthoses are more permanent appliances used to reduce instability and excessive abnormal movement and provide support and comfort. They include working wrist splints, knee braces, iron and T-straps to control ankle instability and a multitude of (often custom-made) foot insole supports to offload painful or deformed foot structures. Orthoses are particularly suited to severely disabled patients in whom a surgical option is inappropriate and often need to be custom-made for the individual.

Aids and appliances can provide dignity and independence for patients with respect to activities of daily living. Common examples are a raised toilet seat, raised chair height, extended handles on taps, a shower instead of a bath, thick-handled cutlery and extended 'hands' to pull on tights and socks. Full assessment and advice from an occupational therapist maximise the benefits of these aids.

Self-help and coping strategies

These plans help patients to cope better with, and adjust to, chronic pain and disability. They may be useful at any stage but are particularly beneficial for patients with incurable problems who have tried all available treatment options. The aim is to increase self-management through self-assessment and problem-solving, so that patients can recognise negative, but potentially remediable, aspects of their mood (stress, frustration, anger or low self-esteem) and their situation (physical, social, financial). These may then be addressed by changes in attitude and health behaviour, as shown in Box 25.27.

Involvement of the spouse or partner in mutual goal setting can improve partnership adjustment. Such approaches are often an element of group education classes and pain clinics but may require more formal clinical psychological input.

Tailored multidisciplinary approaches are required for patients with JIA and other chronic childhood diseases, dependent on age and maturity. Adolescents and young adults have specific demands, different to those of young children and adults, which are influenced by many issues in their lives impinging on the disease process, its impact and their ability to cope with it.

Weight control

Obesity aggravates pain at most sites through increased mechanical strain and is a risk factor for progression of joint damage in patients with OA and other types of arthritis. Obesity contributes, through its metabolic and inflammatory effects, to amplifying symptoms of rheumatic disease and in certain scenarios has been linked with suboptimal responses to TNF-α inhibitors in PsA. This should be explained to obese patients and strategies offered on how to lose and maintain an appropriate weight, using pharmacological therapies if necessary (Ch. 5). By contrast, excessive weight loss is also detrimental and low weight (body mass index (BMI) $<20\,\text{kg/m}^2$) is associated with an increased risk of fractures. Patients should therefore be advised to maintain BMI within the 20–25 kg/m^2 range.

25.27 Self-help and coping strategies

- Yoga, Pilates and relaxation techniques to reduce stress
- Avoidance of negative situations or activities that produce stress and increase in pleasant activities that give satisfaction
- Information and discussion to alter beliefs about and perspectives on disease
- Reduction or avoidance of catastrophising and maladaptive pain behaviour
- Imagery and distraction techniques for pain
- Expansion of social contact and better use of social services

Surgery

A variety of surgical interventions can relieve pain and conserve or restore function in patients with bone, joint and periarticular disease (Box 25.28). Soft tissue release and tenosynovectomy can reduce inflammatory symptoms, improve function and prevent or retard tendon damage for variable periods, sometimes indefinitely. Synovectomy does not prevent disease progression, but may be indicated for pain relief when drugs, physical therapy and intra-articular injections have provided insufficient relief. The main approaches for damaged joints are osteotomy (cutting bone to alter joint mechanics and load transmission), excision arthroplasty (removing part or all of the joint), joint replacement (insertion of prosthesis in place of the excised joint) and arthrodesis (joint fusion).

25.28 Surgical procedures in rheumatological and bone diseases

Procedure	Indication
Soft tissue release	
Carpal tunnel	Median nerve compression
Tarsal tunnel	Posterior tibial nerve entrapment
Flexor tenosynovectomy	Relief of 'trigger' fingers
Ulnar nerve transposition	Ulnar nerve entrapment at elbow
Fasciotomy	Severe Dupuytren contracture
Tendon repairs and transfers	
Hand extensor tendons	Extensor tendon rupture
Thumb and finger flexor tendons	Flexor tendon rupture
Synovectomy	
Wrist and extensor tendon sheath (+ excision of radial head)	Pain relief and prevention of extensor tendon rupture in RA, resistant inflammatory synovitis
Knee synovectomy	Resistant inflammatory synovitis
Osteotomy	
Femoral osteotomy	Early OA of hip
Tibial osteotomy	Uni-compartmental knee OA
	Deformed tibia in OA or Paget disease
Excision arthroplasty	
First metatarsophalangeal joint (Keller procedure)	Painful hallux valgus
Radial head	Painful distal radio-ulnar joint
Lateral end of clavicle	Painful acromioclavicular joint
Metatarsal head	Painful subluxed metatarsophalangeal joints
Joint replacement arthroplasty	
Knee, hip, shoulder, elbow	Painful damaged joints in OA and RA
Arthrodesis	
Wrist	Damaged joint: pain relief, improvement of grip
Ankle/subtalar joints	Damaged joint: pain relief, stabilisation of hindfoot
Fracture repair	
Hip arthroplasty	Fractured neck of femur
External fixation	Multiple fractures, open fractures
Intramedullary nailing	Tibial and femur fractures
Screw, plating and wiring	Wrist and other fractures
Other procedures	
Facetectomy	Patello-femoral osteoarthritis
Nerve root decompression	Spinal stenosis, nerve entrapment
Vertebroplasty and kyphoplasty	Painful vertebral fracture (evidence base for efficacy poor)

(OA = osteoarthritis; RA = rheumatoid arthritis)

Surgical fixation of fractures is frequently required in patients with osteoporosis and other bone diseases.

The main aims of surgery are to provide pain relief and improve function and quality of life. If surgery is to be successful, the aims and consequences of each operation should be considered as part of an integrated programme of management and rehabilitation by multidisciplinary teams of surgeons, allied health professionals and physicians, and carefully explained to the patient. Assessment of motivation, social support and environment is no less important than careful consideration of patients' general health, their risks for major surgery, the extent of disease in other joints, and their ability to mobilise following surgery. For some severely compromised people, pain relief and functional independence are better served by provision of a suitable wheelchair, home adjustments and social services than by surgery that is technically successful but following which the patient cannot mobilise.

Pharmacological treatment

Analgesics

Paracetamol (1 g up to 4 times daily) is the oral analgesic of first choice for mild to moderate pain. It is thought to work by inhibiting prostaglandin synthesis in the brain while having little effect on peripheral prostaglandin production. It is well tolerated and has few adverse effects and drug interactions. An increased risk of gastrointestinal events and cardiovascular disease has been reported with chronic usage in observational studies, but this may be due to channeling of patients at higher risk of these events for treatment with paracetamol rather than an NSAID. Paracetamol can be combined with codeine (co-codamol) or dihydrocodeine (co-dydramol). These compound analgesics are more effective than paracetamol, but have more side-effects, including constipation, headache and delirium (especially in older adults). The centrally acting opioid analgesics tramadol and meptazinol may be useful for temporary control of severe pain unresponsive to other measures, but can cause nausea, bowel upset, dizziness and somnolence, and withdrawal symptoms after chronic use. The non-opioid analgesic nefopam (30–90 mg three times daily) can help moderate pain, though side-effects (nausea, anxiety, dry mouth) often limit its use. Patients with severe or intractable pain may require strong opioid analgesics, such as oxycodone or morphine.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) are among the most widely prescribed drugs for the treatment of pain, but their use has declined over recent years because long-term prescription is associated with an increased risk of cardiovascular disease. Oral NSAIDs are useful in the treatment of a range of rheumatic diseases with an inflammatory component. They inhibit the cyclo-oxygenase (COX) enzymes, which convert arachidonic acid, derived from membrane phospholipids, to prostaglandins (Fig. 25.13). There are two COX isoforms. COX-1 is constitutively expressed in gastric mucosa, platelets and kidneys, and production of prostaglandins at these sites protects against mucosal damage and regulates platelet aggregation and renal blood flow. The COX-2 enzyme is induced at sites of inflammation, producing prostaglandins that cause local pain and swelling. Inflammation also up-regulates COX-2 in the spinal cord, where it modulates pain perception. Ibuprofen, diclofenac and naproxen are non-selective drugs that inhibit both COX enzymes, whereas celecoxib and etoricoxib are selective inhibitors of COX-2. While NSAIDs have anti-inflammatory activity, they are not thought to have a disease-modifying effect in either OA or inflammatory rheumatic diseases.

Non-selective NSAIDs can damage the gastric and duodenal mucosal barrier and are associated with an increased risk of upper gastrointestinal ulceration, bleeding and perforation. The adjusted increased risk (odds ratio) of bleeding or perforation from non-selective NSAIDs is 4–5, though differences exist between NSAIDs (Box 25.29). Dyspepsia is a poor guide to the presence of NSAID-associated ulceration and bleeding, and the principal risk factors are shown in Box 25.30. Co-prescription of a proton pump inhibitor (PPI) or misoprostol (200 μg twice or 3 times daily) reduces the risk of NSAID-induced ulceration and bleeding, but H_2-antagonists in standard doses are ineffective. The COX-2 selective

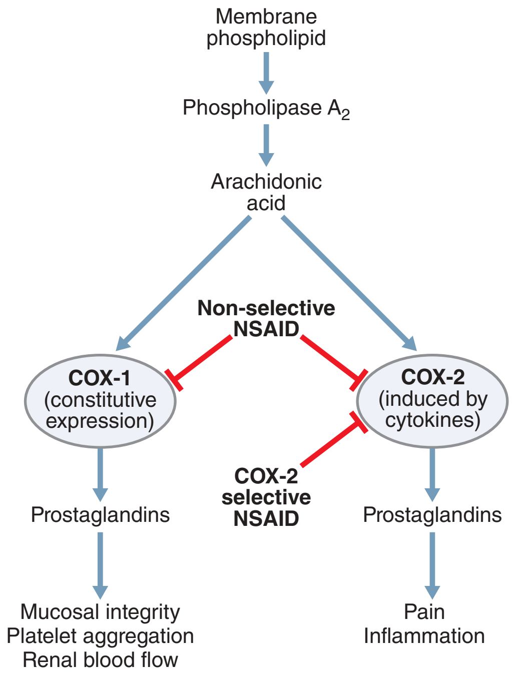

Fig. 25.13 **Mechanism of action of non-steroidal anti-inflammatory drugs.** (COX = cyclo-oxygenase)

25.29 Commonly used NSAIDs and their risk of gastrointestinal bleeding and perforation

Drug	Daily adult dose	Doses/day	Idiosyncratic side-effects, comments
Low risk			
Celecoxib	100–200 mg	1–2	Selective COX-2 inhibitor
Etoricoxib	60–120 mg	1	Selective COX-2 inhibitor
Medium risk			
Ibuprofen	1600–2400 mg	3–4	Gastrointestinal adverse effects more likely than with COX-2 inhibitors, even with PPI therapy
Naproxen	500–1000 mg	1–2	
Diclofenac	75–150 mg	2–3	
High risk			
Indomethacin	50–200 mg	1–2	High incidence of dyspepsia and CNS side-effects

(CNS = central nervous system; COX = cyclo-oxygenase; PPI = proton pump inhibitor)

25.30 Risk factors for NSAID-induced peptic ulcers

- Age > 60 years*
- Past history of peptic ulcer*
- Past history of adverse event with NSAID
- Concomitant glucocorticoid use
- High-dose or multiple NSAIDs
- High-risk NSAIDs (see Box 25.29)

*The most important risk factors.

NSAIDs are much less likely to cause gastrointestinal toxicity, but benefit is attenuated in patients on low-dose aspirin. The UK National Institute for Health and Care Excellence (NICE) guidelines advise that a PPI should be co-prescribed with all NSAIDs, including COX-2-selective NSAIDs, even though the risk of gastrointestinal events with these is low. Since chronic PPI therapy is associated with an increased risk of hip fracture, the merits of giving PPI therapy with a COX-2-selective drug need to be carefully considered.

Other side-effects of NSAIDs include fluid retention and renal impairment due to inhibition of renal prostaglandin production, non-ulcer-associated dyspepsia, abdominal pain, altered bowel habit and rashes. Interstitial nephritis, asthma and anaphylaxis can also occur but are rare. Recommendations for NSAID prescribing are summarised in Box 25.31. Because of the risk of adverse effects, NSAIDs should be used with great care in older patients (Box 25.32).

Topical agents

Topical NSAID creams and gels and capsaicin cream can help in the treatment of OA and superficial periarticular lesions affecting hands, elbows and knees. They may be used as monotherapy or as an adjunct to oral analgesics. Topical NSAIDs can penetrate superficial tissues and even reach the joint capsule, though intrasynovial levels mainly reflect blood-borne drug delivery. Capsaicin selectively binds to the protein transient receptor potential vanilloid type 1 (TRPV1), which is a heat-activated calcium channel on the surface of peripheral type C nociceptor fibres. Initial application causes a burning sensation, but continued use depletes presynaptic substance P, with subsequent pain reduction that is optimal after a period of 1–2 weeks. Lidocaine 5% medicated patches are licensed for the treatment of post-herpetic neuropathic pain but are also used off label for a variety of painful conditions including painful vertebral fractures, sometimes with good effects.

25.31 Recommendations for the use of NSAIDs

- Use the lowest dose for the shortest time possible to control symptoms
- Avoid NSAIDs in patients on warfarin
- Allow 2–3 weeks to assess efficacy. If response is inadequate, consider a trial of another NSAID
- Never prescribe more than one NSAID at a time
- Co-prescribe a proton pump inhibitor for patients with risk factors for gastrointestinal adverse effects (see Box 25.30)
- Avoid in patients with cardiovascular or cerebrovascular disease

25.32 Use of oral NSAIDs in old age

- **Gastrointestinal complications**: age is a strong risk factor for enteral bleeding and perforation, and for peptic ulceration. Older adults are more likely to die if they suffer NSAID-associated enteral bleeding or perforation.
- **Cardiovascular and cerebrovascular disease**: avoid NSAIDs in patients with cardiovascular and cerebrovascular disease. Therapy with NSAIDs may exacerbate hypertension and heart failure.
- **Renal disease**: use of NSAIDs may cause or worsen renal impairment.

Disease-modifying anti-rheumatic drugs

Disease-modifying anti-rheumatic drugs (DMARDs) comprise small-molecule inhibitors of the immune response, glucocorticoids and biologics. DMARDs not only improve symptoms but also favourably modify disease progression in a variety of inflammatory rheumatic diseases. Small-molecule inhibitors are either classical synthetic DMARDs (csDMARDs), which have relatively non-specific inhibitory effects on the immune response (Box 25.33), or targeted synthetic DMARDs (tsDMARDs), which are designed to inhibit the effects of a specific target molecule (Box 25.34). Biologics are monoclonal antibodies, fusion proteins or decoy receptors targeted towards specific cytokines, receptors and other cell-surface molecules regulating the immune response. They are collectively referred to as bDMARDs (Fig. 25.14). Most csDMARDs have the potential to cause bone marrow suppression or liver dysfunction and require regular blood monitoring, as summarised in Box 25.33. If toxicity occurs, treatment may need to be stopped temporarily and resumed at a lower dose or withdrawn completely if toxicity is severe.

Classical synthetic DMARDs

Methotrexate (MTX) is the principal csDMARD used in a range of inflammatory rheumatic diseases. It inhibits folic acid reductase, preventing formation of tetrahydrofolate, which is necessary for DNA synthesis in leucocytes and other cells. It can be given orally or subcutaneously using a variety of dose increment schedules, until benefit or toxicity occurs. Folic acid (5 mg/week) should be co-prescribed to be taken the day after MTX since it reduces adverse effects without impairing efficacy. Benefit is usually observed after 4–8 weeks, but treatment should continue for 3 months before reaching the conclusion that MTX has been ineffective. The most common adverse effects are nausea, vomiting and malaise, which usually occur 1–2 days after the weekly dose. There are drug interactions with sulfonamides and NSAIDs, both of which reduce renal clearance of MTX, but this is seldom an issue at the relatively low MTX doses prescribed for inflammatory rheumatic disease. Patients on MTX should avoid excess alcohol, which enhances MTX hepatotoxicity. Acute

25.33 Recommended monitoring of classical synthetic disease-modifying anti-rheumatic drugs (in line with British Society of Rheumatology guidelines)

		Monitoring*			
Drug	**Maintenance dose**	**FBC**	**LFTs**	**Other**	**Indications**
Methotrexate (MTX)	15–25 mg weekly orally or subcutaneously	✓	✓	Creatinine/eGFR	RA, PsA, JIA, SpA, CPPD disease
Sulfasalazine (SSZ)	2–4 g daily orally	✓	✓	Creatinine/eGFR	RA, PsA, SpA
Hydroxychloroquine (HCQ)	200–400 mg daily orally	–	–	Visual function	RA, SLE
Leflunomide (LEF)	10–20 mg daily orally	✓	✓	BP, creatinine/eGFR BP	RA, PsA
Azathioprine (AZA)	1–2.5 mg/kg daily orally	✓	✓	Creatinine/eGFR	SLE, SV
Cyclophosphamide	2 mg/kg daily orally or 15 mg/kg IV	✓	✓	Creatinine/eGFR	SLE, SV
Mycophenolate mofetil (MMF)	2–4 g daily orally	✓	✓	Creatinine/eGFR	SLE, SV
Ciclosporin A	3–5 mg/kg daily orally	–	–	BP, creatinine/eGFR	RA, PsA

*Monitoring tests are usually done every 2 weeks on initiation of treatment for 6 weeks, then monthly for 3 months, then 3-monthly.
(BP = blood pressure; CPP = calcium pyrophosphate; eGFR = estimated glomerular filtration rate; FBC = full blood count; IM = intramuscular; IV = intravenous; JIA = juvenile idiopathic arthritis; LFTs = liver function tests; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SpA = spondyloarthritis; SV = systemic vasculitis)

i 25.34 Targeted synthetic disease-modifying anti-rheumatic drugs

		Regular monitoring tests suggested			
Drug	**Maintenance dose**	**FBC**	**LFTs**	**Lipids***	**Indications**
Apremilast	30 mg twice daily orally	–	–	–	PsA
Tofacitinib	5 mg twice daily orally	✓	✓	✓	RA, PsA
Baricitinib	2–4 mg daily orally	✓	✓	✓	RA
Upadacitinib	15 mg daily orally	✓	✓	✓	RA, PsA, axSpA, GCA
Filgotinib	200 mg daily orally	✓	–	✓	RA
Avacopan	30 mg twice daily orally	✓	✓	–	ANCA-V

*Measured before and 3 months after starting targeted synthetic disease-modifying anti-rheumatic drug.

pulmonary toxicity (pneumonitis) is rare but can occur at any time during treatment, and patients should be warned to stop therapy and seek advice if they develop any new respiratory symptoms. If pneumonitis occurs, treatment should be withdrawn and high-dose glucocorticoids given. MTX must be co-prescribed with robust contraception in women of child-bearing potential, and treatment must be stopped for 3 months in advance of planning a pregnancy.

Sulfasalazine (SSZ) can be used alone or in combination with other drugs in the treatment of RA and PsA. Its mechanism of action is incompletely understood. Nausea and gastrointestinal intolerance are the main adverse effects, but leucopenia, abnormal liver function tests (LFTs) and rashes may occur. Benefit may be observed after 4–8 weeks, but treatment should be continued for 3 months before concluding that it has been ineffective. Orange staining of urine and contact lenses may occur. SSZ is generally considered to be safe during pregnancy.

Hydroxychloroquine (HCQ) can be used alone or in combination with other drugs in the treatment of RA and SLE. It acts by modulating lysosomal activity and autophagy causing inhibition of inflammatory responses. While a wide range of side-effects can theoretically occur, it is generally well tolerated in practice. An important adverse effect is ocular toxicity due to accumulation in the retina, which is dose and time dependent. Because of this it is recommended that optical coherence tomography (OCT) coupled with fundus autofluorescence (FAF) imaging should be performed after 5 years' treatment or annually in patients receiving more than 5 mg/kg/day, those taking tamoxifen and those with an eGFR of <60 mL/min. HCQ is generally considered to be safe during pregnancy.

Leflunomide (LEF) can be used alone or in combination with other drugs for the treatment of RA and PsA. It works by inhibiting dihydro-orotate dehydrogenase, an enzyme used by activated lymphocytes to synthesise pyrimidines necessary for DNA synthesis. It has low marrow toxicity, but may cause liver dysfunction, hypertension and increased hair loss. It must be co-prescribed with robust contraception in women of child-bearing potential. Treatment must be stopped for a period of 2 years in advance of planning a pregnancy, though should pregnancy be desired before this time, a washout procedure can be done with cholestyramine to remove the drug from the system.

Azathioprine (AZA) is most often used in vasculitis and SLE, often in combination with other drugs. It is metabolised to 6-mercaptopurine (6-MP), which blocks lymphocyte proliferation by inhibiting DNA synthesis. Bone marrow suppression is the most important side-effect, but nausea may also occur. Genetic polymorphisms in the enzyme thiopurine S-methyltransferase (TPMT) influence catabolism of 6-MP, and genetic testing for TPMT variants is often done to guide dosages. Allopurinol inhibits catabolism of azathioprine, necessitating a 75% reduction in azathioprine dose.

Cyclophosphamide is a cytotoxic alkylating agent that cross-links DNA and halts cell division, causing immunosuppression. It is mainly used to induce remission in ANCA-associated vasculitis and SLE with major organ involvement. It is usually given intravenously in pulses but can also be administered orally (see Box 25.33). Adverse effects include nausea, anorexia, vomiting, bone marrow suppression, cardiac toxicity, alopecia and haemorrhagic cystitis. The risk of cystitis can be mitigated by co-administration of mesna (2-mercaptoethane sulfonate), which binds its urotoxic metabolites, and a high fluid intake.

Mycophenolate mofetil (MMF) works by inhibiting inosine monophosphate dehydrogenase, a rate-limiting enzyme in the synthesis of guanosine nucleotides in lymphocytes. MMF is usually used in SLE, other connective tissue diseases and vasculitis. Haematological toxicity is the main adverse effect.

Ciclosporin A is a calcineurin inhibitor that inhibits lymphocyte activation. It is occasionally used in the treatment of RA and PsA.

Glucocorticoids have powerful anti-inflammatory and immunosuppressive effects and have been shown to have disease-modifying effects in various inflammatory rheumatic diseases. They can therefore be considered to be a type of csDMARD. Glucocorticoids promote apoptosis of many immune cells and inhibit a wide range of pro-inflammatory signalling pathways. They are used orally, intravenously, intramuscularly and by intra-articular injection in the treatment of a wide range of inflammatory rheumatic diseases, as well as by local injection in patients with soft tissue rheumatism.

Systemic glucocorticoids are widely used in moderate to high doses to induce remission in early RA, systemic and polyarticular JIA, giant cell arteritis, polymyalgia rheumatica, vasculitis and SLE. Many patients with SLE require low-dose maintenance therapy with glucocorticoids and this is sometimes also required in RA when other options are unsuitable. They are widely used in the short-term treatment of flares in many inflammatory rheumatic diseases. Glucocorticoids should be used with caution in PsA because of a rebound increase in activity of psoriasis when the effects wear off.

Intra-articular glucocorticoids are employed in the treatment of a wide range of inflammatory diseases and are primarily indicated when there are one or two problem joints with persistent synovitis despite good general control of the disease. Methylprednisolone is one of the most widely used, typically in doses of 40–80 mg.

Intramuscular methylprednisolone (80–120 mg) is a useful way of controlling inflammatory arthritis while waiting for the effects of newly introduced drugs to take effect. It can also be helpful in patients with stable disease who have a flare in disease activity.

Targeted synthetic DMARDs

Targeted synthetic DMARDs (tsDMARD) are small molecules targeted at specific intracellular targets involved in regulating the immune response. These drugs are generally used as second-line agents in patients who have responded inadequately to, or who have developed adverse effects with csDMARDs. The targets and mechanism of action for selected tsDMARDs are shown in Figure 25.14. Available tsDMARDs and recommended doses are shown in Box 25.34.

Janus-activated kinase (JAK) inhibitors (JAKi) work by inhibiting JAK enzymes, which are a family of intracellular signalling molecules that play a key role in transducing the effects of several pro-inflammatory cytokines. People taking JAKi are an increased risk of infections, and because of this, it is customary to screen patients for evidence of occult infection with HIV, hepatitis C, hepatitis B and previous tuberculosis before commencing therapy. Other adverse effects include an increased risk of DVT, an increased risk of cardiovascular disease and increased risk of malignancy. Because of these adverse effects, JAKi should be avoided in those over the age of 65 unless other bDMARDs are unsuitable. Currently, there are four drugs in this class, most often in combination with MTX or other csDMARDs. Tofacitinib is indicated for adults with RA and PsA; baricitinib and filgotinib are both indicated for RA. Upadacitinib is indicated as for RA, PsA, axSpA and GCA. Tofacitinib requires long-term blood monitoring for marrow and liver toxicity, but this is not required with the other JAKi once the first 3 months of therapy have been completed.

Apremilast is used in the treatment of PsA. It is a small molecule inhibitor of phosphodiesterase 4, an enzyme that breaks down cyclic adenosine monophosphate (cAMP). The resulting elevation in cAMP intracellularly suppresses production of pro-inflammatory cytokines, thereby reducing inflammation. The main adverse effects are gastrointestinal upset, weight loss and an increased risk of depression.

Avacopan is a small molecule inhibitor of the complement 5a receptor (C5aR1), which is used as an adjunct to immunosuppressive therapy with cyclophosphamide and/or rituximab as a steroid-sparing therapy in ANCA-associated vasculitis. The main adverse effects are an increased risk of infection and abnormal LFTs.

Biologic DMARDs

Biologic disease-modifying drugs (bDMARDs) is the term used to describe monoclonal antibodies, fusion proteins or decoy receptors used in the treatment of a range of inflammatory rheumatic diseases. The targets of bDMARDs are summarised in Figure 25.14B. They are most often given as self-administered subcutaneous injections every 1–4 weeks or as intermittent infusions. The main adverse effect of biologics is an increased risk of infections, and screening for occult infections is generally performed before commencing therapy as described for JAKi. Biologics are not carcinogenic, but patients who develop cancer while on treatment may exhibit accelerated progression of the tumour due to suppression of the immune response. If this occurs, treatment should be stopped. Treatment costs are higher than with csDMARDs but have reduced considerably over recent years due to the emergence of biosimilars. Many countries have set guidelines and funding restrictions that limit their use to patients that have responded inadequately or developed adverse effects with csDMARDs. Their mechanisms of action, dosages and indications are summarised in Box 25.35.

TNF-α inhibitors. Most drugs in this class are monoclonal antibodies that bind to and neutralise TNF-α, but etanercept is a decoy receptor that prevents TNF-α binding to its receptor. Anti-TNF-α therapy is frequently used as the first-line biologic in RA, JIA and PsA when csDMARD therapy has been incompletely effective, and as first-line biologic in axSpA in patients who have failed to respond adequately to NSAID therapy. These medicines are contraindicated in patients with active infections and those with in-dwelling catheters. Other contraindications are heart failure (New York Heart Association grade 3 or 4) and multiple sclerosis, both of which may be worsened by treatment. Anti-TNF-α therapies can be used during pregnancy but should be stopped in the third trimester since they cross the placenta and can cause immunosuppression in the neonate. An exception is certolizumab, which does not cross the placenta and can be used safely throughout pregnancy.

Rituximab is an antibody directed against the CD20 receptor, which is expressed on B lymphocytes and immature plasma cells. Rituximab

i 25.35 Biologic disease-modifying drugs

Drug	Maintenance dose	Mechanism of action	Indications
Etanercept	50 mg weekly SC	Decoy receptor for TNF-α	RA, PsA, axSpA, JIA
Infliximab	3–5 mg/kg 8-weekly IV or 120 mg 2-weekly SC	Anti TNF-α antibody	RA, PsA, axSpA, JIA
Adalimumab	40 mg 2-weekly SC		
Certolizumab	200 mg 2-weekly SC		
Golimumab	50 mg 4-weekly SC		
Rituximab	1000 mg IV every 6–12 months (RA) 1000 mg IV every 6–12 months (ANCA-V)	Anti-CD20 antibody; destroys B cells	RA, ANCA-V, SLE
Belimumab	200 mg weekly SC	Anti BAFF antibody; inhibits B-cell activation	SLE
Abatacept	125 mg weekly SC or 10 mg/kg 4-weekly IV	Fusion protein of CTLA4 and IgG. Decoy receptor for CD80 and CD86. Inhibits T-cell co-stimulation	RA, PsA, JIA
Tocilizumab	162 mg weekly SC or 8 mg/kg 4-weekly IV	Anti-IL-6 receptor antibody	RA, JIA, GCA
Sarilumab	200 mg 2-weekly SC	Anti-IL-6 receptor antibody	RA
Mepolizumab	300 mg 4-weekly SC	Anti IL-5 antibody	EGPA
Benralizumab	30 mg 4-weekly SC	Anti IL-5 receptor antibody	EGPA
Ustekinumab	45 mg 12-weekly SC	Anti IL-12 and IL-23 antibody	PsA
Secukinumab	150–300 mg 4-weekly SC	Anti IL-17A antibody	PsA, axSpA
Ixekizumab	80 mg 4-weekly SC	Anti IL-17A antibody	PsA and axSpA
Bimekizumab	160 mg 4-weekly SC	Anti IL-17A/F antibody	PsA and axSpA
Anakinra	100 mg daily SC	Decoy receptor for IL-1	RA, CAPS, AOSD, gout
Canakinumab	150 mg or 2 mg/kg 8-weekly SC	Anti IL-1β antibody	CAPS, sJIA, AOSD, gout
Guselkumab	100 mg 8-weekly SC	Anti IL-23 antibody	PsA
Risankizumab	150 mg 12-weekly SC		

(ANCA-V = ANCA-associated vasculitis; AOSD = adult-onset Still disease; axSpA = axial spondyloarthritis; BAFF = B cell–activating factor of the TNF family; CAPS = cryopyrin-associated periodic syndromes; CD = cluster of differentiation; EGPA = eosinophilic granulomatosis with polyangiitis; GCA = giant cell arteritis; IL = interleukin; IV = intravenous; JIA = juvenile idiopathic arthritis; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SC = subcutaneous; sJIA = systemic juvenile idiopathic arthritis; SLE = systemic lupus erythematosus; TNF-α = tumour necrosis factor alpha)

causes profound B-cell lymphopenia for several months due to complement-mediated lysis of cells that express CD20. Rituximab is indicated in RA where the response to csDMARDs has been inadequate and to induce remission in adults and children with ANCA-associated vasculitis. It is also used off label in SLE and myositis, but the evidence for benefit is weak. In RA, treatment can be repeated when signs of improvement are wearing off (6–12 months or longer). In ANCA-associated vasculitis, repeated courses of treatment are recommended every 6 months to maintain remission. Adverse effects include hypogammaglobulinaemia, infusion reactions, an increased risk of infections and, rarely, progressive multifocal leucoencephalopathy (PML), a serious and potentially fatal infection of the central nervous system caused by reactivation of JC virus.

Belimumab is a monoclonal antibody that blocks the effects of the cytokine B cell–activating factor of the TNF family (BAFF), which is required for B-cell survival and function. It is indicated in juvenile and adult patients with SLE who have had an inadequate response to csDMARDs. The main adverse effects are an increased risk of infection, leucopenia and hypersensitivity reactions following infusion.

Abatacept is a fusion protein in which the Fc domain of IgG has been combined with the extracellular domain of CTLA4, which blocks T-cell activation by acting as a decoy for CD28, a co-stimulatory molecule necessary for T-cell activation. It is indicated for RA and PsA and polyarticular onset JIA where the response to csDMARDs is inadequate. The main adverse effect is an increased risk of infections.

IL-1 inhibitors. There are two drugs in this class. Anakinra is a human IL-1 receptor antagonist, which neutralises the effects of interleukin-1α (IL-1α) and interleukin-1β (IL-1β) by inhibiting binding to interleukin-1 type I receptor (IL-1RI). Its most frequent use is for the treatment of adult-onset Still disease and for periodic fever syndromes (p. 74). It has some efficacy in RA but is seldom used since other drugs are more effective. Other indications include acute gout, although it is not licensed for this condition, and chronic non-infectious osteomyelitis (see p. 1090). Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia. Canakinumab is a monoclonal antibody directed against IL-1β, which is indicated for the treatment of systemic JIA (Still disease), adult-onset Still disease and acute flares of gout resistant to other treatments. The usual maintenance dose in adults is 150–300 mg every 8 weeks. Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia.

IL-5 inhibitors. Mepolizumab is a monoclonal antibody directed against IL-5, which is a cytokine that regulates the differentiation and activation of eosinophils. Benralizumab is a monoclonal antibody directed against the IL-5 receptor. Both are approved for the treatment of eosinophilic granulomatosis with polyangiitis (EGPA) and are used as adjunctive therapy as a steroid-sparing medicine in patients who have not responded to therapy with rituximab or cyclophosphamide. Adverse effects include headache and an increased risk of helminthic infections.

IL-6 inhibitors. Tocilizumab is a monoclonal antibody that competes with IL-6 for binding to the IL-6 receptor, thereby inhibiting IL-6 signalling. It is indicated in RA with or without MTX after inadequate response to csDMARDs and in patients 12 years of age and older with systemic JIA, who have responded inadequately to therapy with NSAIDs and systemic glucocorticoids. It is also indicated as a steroid-sparing agent in GCA. Sarilumab is a monoclonal antibody (IgG1) that works in a similar way to tocilizumab, which is licensed for treating adult RA where there has been an inadequate response to csDMARDs. Adverse effects of both agents include leucopenia, abnormal LFTs, hypercholesterolaemia and hypersensitivity reactions. Both drugs should be avoided during pregnancy if possible.

Combined IL-12/IL-23 inhibitors. Ustekinumab is the only drug in this class. It is an antibody to p40, which is a subunit shared by the cytokines IL-23 and IL-12. It acts as an inhibitor of both IL-12 and IL-23 signalling and is indicated in adults with PsA who have not responded adequately to csDMARDs. It can be used as monotherapy or in combination with MTX. Adverse effects include an increased risk of infections, hypersensitivity reactions and an exfoliative dermatitis.

IL-23 inhibitors. Guselkumab and risankizumab are antibodies directed against the p19 protein of IL-23. They are specific inhibitors of IL-23 signalling and are effective in the treatment of PsA and the accompanying psoriasis. They can be used alone or in combination with MTX or another csDMARD. The main adverse effect is an increased risk of infections.

IL-17 inhibitors. Three drugs in this class are used for the treatment of inflammatory rheumatic disease; secukinumab and ixekizumab are monoclonal antibodies to IL-17A, whereas bimekizumab neutralises both IL-17A and IL-17F. The IL-17A and IL-17A/F inhibitors are indicated in adults with PsA and axSpA who have not responded adequately to csDMARDs and/or anti-TNF-α. Adverse effects include an increased risk of triggering flares in IBD, infections, nasopharyngitis and headache. Clinical experience indicates that these drugs are probably safe during pregnancy, but information is limited.

Osteoarthritis

Osteoarthritis (OA) is by far the most common form of arthritis and is a major cause of pain and disability in older people. It is characterised by focal loss of articular cartilage, subchondral osteosclerosis, osteophyte formation at the joint margin and remodelling of joint contour with enlargement of affected joints.

Epidemiology

The prevalence rises progressively with age, and it has been estimated that 45% of all people develop knee OA and 25% hip OA at some point during life. Although some are asymptomatic, the lifetime risk of having a total hip or knee replacement for OA in someone aged 50 is about 11% for women and 8% for men in the UK. There are major ethnic differences in susceptibility: the prevalence of hip OA is lower in Africa, China, Japan and South Asia than in European countries, while that of knee OA is higher.

Pathophysiology

OA is a complex disorder, with both genetic and environmental components (Box 25.36). Family-based studies have estimated that the heritability of OA ranges from about 43% at the knee to between 60% and 65% at the hip and hand, respectively. In most cases, the inheritance is polygenic and mediated by several genetic variants of small effect. OA can be a component of multiple epiphyseal dysplasias, which are caused by pathogenic variants in genes that encode components of cartilage matrix. Structural abnormalities, such as slipped femoral epiphysis and developmental dysplasia of the hip, are also associated with a high risk of OA, presumably due to abnormal load distribution across the joint. Similar mechanisms probably explain the increased risk of OA in patients with limb deformity secondary to Paget disease of bone.

Biomechanical factors play an important role in OA related to certain occupations, such as farmers (hip OA), miners (knee OA) and elite or professional athletes (knee and ankle OA). It has been speculated that the higher prevalence of knee OA in South and East Asia might be accounted for by squatting. There is also a high risk of knee OA in people who have had destabilising injuries, such as cruciate ligament rupture, and those who have had meniscectomy. For most individuals, however, participation in recreational sport does not appear to increase the risk significantly. There is a strong association between obesity and OA, particularly of the hip and knee. This is thought to be due partly to biomechanical factors, but it has also been speculated that cytokines released from adipose tissue may play a role. Oestrogen appears important; lower rates of joint replacements for OA have been observed in women who use hormone replacement therapy (HRT), while women who receive aromatase inhibitor therapy for breast cancer often experience a flare in symptoms of OA.

Degeneration of articular cartilage is the defining feature of OA. Under normal circumstances, chondrocytes are terminally differentiated cells, but in OA they start dividing to produce nests of metabolically active cells (Fig. 25.15A). Initially, matrix components are produced by these cells at an increased rate, but at the same time there is accelerated degradation of the major structural components of cartilage matrix, including aggrecan and type II collagen (see Fig. 25.4). Eventually, the concentration of aggrecan in cartilage matrix falls and makes the cartilage vulnerable to load-bearing injury. Fissuring of the cartilage surface ('fibrillation') then occurs, leading to the development of deep vertical clefts (Fig. 25.15B), localised chondrocyte death and decreased cartilage thickness. This is initially focal, mainly targeting the maximum load-bearing part of the joint, but eventually large parts of the cartilage surface are damaged. Calcium pyrophosphate (CPP) and basic calcium phosphate (BCP) crystals often become deposited in the abnormal cartilage.

OA is also accompanied by abnormalities in subchondral bone, which becomes sclerotic and the site of subchondral cysts. Fibrocartilage is produced at the joint margin, which undergoes endochondral ossification to form osteophytes. Bone remodelling and cartilage thinning slowly

i 25.36 Risk factors for osteoarthritis

Genetics
- Skeletal dysplasias
- Polygenic inheritance

Developmental abnormalities
- Developmental dysplasia of the hip
- Slipped femoral epiphysis

Repetitive loading
- Farmers
- Miners
- Elite athletes

Adverse biomechanics
- Meniscectomy
- Ligament rupture
- Paget disease

Obesity

Trauma

Hormonal
- Oestrogen deficiency
- Aromatase inhibitors

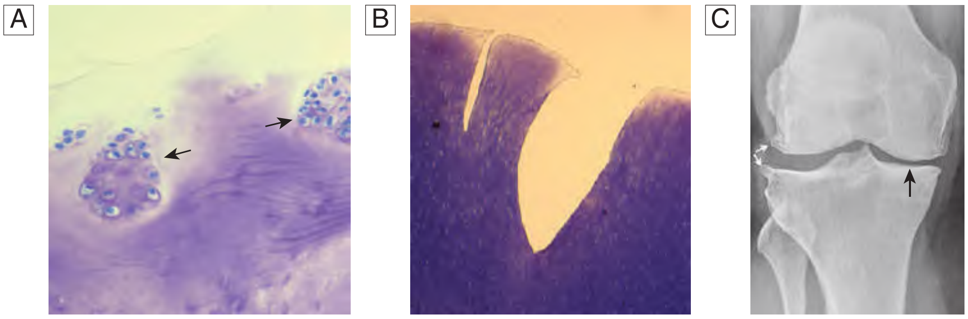

Fig. 25.15 Pathological changes in osteoarthritis. A Abnormal nests of proliferating chondrocytes (arrows) interspersed with matrix devoid of normal chondrocytes. B Fibrillation of cartilage in osteoarthritis (OA). C X-ray of knee joint affected by OA, showing osteophytes at joint margin (white arrows) and loss of joint space affecting the medial tibiofemoral compartment (black arrow).

alter the shape of the OA joint, increasing its surface area. It is almost as though there is a homeostatic mechanism operative in OA that causes enlargement of the failing joint to spread the mechanical load over a greater surface area.

Patients with OA also have higher BMD values at sites distant from the joint and this is particularly associated with osteophyte formation. This is in keeping with observations made in epidemiological studies that show that patients with OA are partially protected from developing osteoporosis and vice versa. This is likely to be due to genetic factors that predispose to osteoporosis, which might be protective for OA.

The synovium in OA is often hyperplastic and may be the site of inflammatory change, but to a much lesser extent than in RA and other inflammatory arthropathies. Osteochondral bodies commonly occur within the synovium, reflecting chondroid metaplasia or secondary uptake and growth of damaged cartilage fragments. The outer capsule also thickens and contracts, usually retaining the stability of the remodelling joint. The muscles surrounding affected joints commonly show evidence of wasting and non-specific type II fibre atrophy.

Clinical features

Osteoarthritis has a characteristic distribution, mainly targeting the hips, knees, PIP and DIP joints of the hands, neck and lumbar spine (see Fig. 25.9). The main presenting symptoms are pain and functional restriction. The causes of pain in OA are not completely understood but may relate to increased pressure in subchondral bone (mainly causing night pain), trabecular microfractures, capsular distension and low-grade synovitis. Pain may also result from bursitis and enthesopathy secondary to altered joint mechanics. Typical OA pain has the characteristics listed in Box 25.37. For many people, functional restriction of the hands, knees or hips is an equal, if not greater, problem than pain. The clinical findings vary according to severity but are principally those of joint damage.

The correlation between the presence of structural change, as assessed by imaging, and symptoms such as pain and disability varies markedly according to site. It is stronger at the hip than at the knee and weak at most small joints. This suggests that the risk factors for pain and disability may differ from those for structural change. At the knee, for example, reduced quadriceps muscle strength and adverse psychosocial factors (anxiety, depression) correlate more strongly with pain and disability than the degree of radiographic change.

Radiological evidence of OA is very common in middle-aged and older people, and the disease may coexist with other conditions, so it is important to remember that pain in a patient with OA may be due to another cause.

Generalised nodal OA

Characteristics of this common form of OA are shown in Box 25.38. Some patients are asymptomatic whereas others develop pain, stiffness and swelling of one or more PIP and DIP joints of the hands from the age of about 40 years onwards. Gradually, these develop posterolateral swellings on each side of the extensor tendon, which slowly enlarge and harden to become Heberden (DIP) and Bouchard (PIP) nodes (Fig. 25.16). Typically, each joint goes through a phase of episodic symptoms (1–5 years) while the node evolves, and OA develops. Once OA is fully established, symptoms may subside, and hand function often remains good. Affected joints are enlarged because of osteophyte formation and often show characteristic deformities with lateral deviation of the affected DIP joints (Fig. 25.16). Involvement of the first carpometacarpal (CMC) joint is also common, leading to pain on trying to open bottles

i 25.37 Symptoms and signs of osteoarthritis

Pain

- Insidious onset over months or years
- Variable or intermittent nature over time (‘good days, bad days’)
- Mainly related to movement and weight-bearing, relieved by rest
- Mild morning stiffness (< 15 mins) and inactivity gelling (< 5 mins) after rest
- Usually only one or a few joints painful

Clinical signs

- Restricted movement due to capsular thickening or blocking by osteophyte
- Palpable, sometimes audible, coarse crepitus due to rough articular surfaces
- Bony swelling around joint margins
- Deformity, usually without instability
- Joint-line or periarticular tenderness
- Muscle weakness and wasting
- Mild or absent synovitis

i 25.38 Characteristics of generalised nodal osteoarthritis

- Polyarticular finger interphalangeal joint osteoarthritis
- Heberden and Bouchard nodes
- Marked female preponderance
- Peak onset in middle age
- Good functional outcome for hands
- Predisposition to osteoarthritis at other joints, especially knees
- Strong genetic predisposition

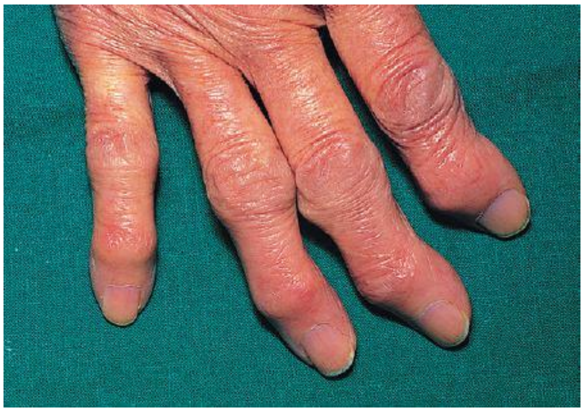

Fig. 25.16 Nodal osteoarthritis. Heberden nodes and lateral (ulnar to radial) deviation of distal interphalangeal joints, with mild Bouchard nodes at the proximal interphalangeal joints.

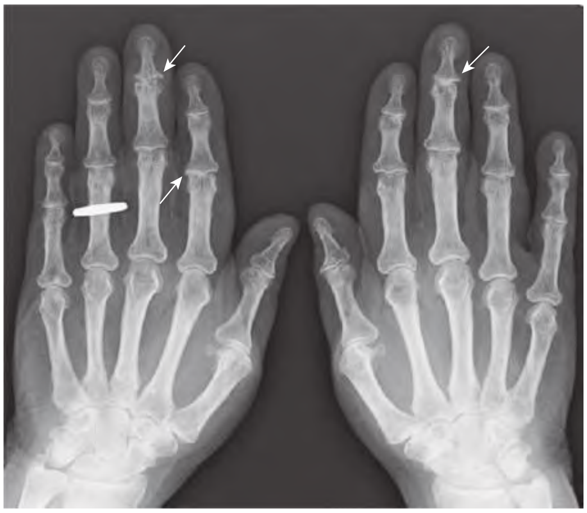

Fig. 25.17 X-ray appearances in hand osteoarthritis. There is joint space narrowing affecting the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints in both hands. There are typical articular subchondral and ‘gull wing’ appearances to some osteoarthritis-affected joints, as well as osteophyte formation that is most marked at the second DIP joints bilaterally and the first PIP joint on the right hand (arrows).

and jars, and functional impairment. Clinically, it may be detected by the presence of crepitus on joint movement and squaring of the thumb base.

Generalised nodal OA has a very strong genetic component: the daughter of an affected mother has a 1 in 3 chance of developing nodal OA herself. People with nodal OA are also at increased risk of OA at other sites, especially the knee.

Knee OA

At the knee, OA principally targets the patello-femoral and medial tibiofemoral compartments, but eventually can affect the whole joint (Fig. 25.18). It may be isolated or occur as part of generalised nodal OA. Most patients have bilateral and symmetrical involvement. In men, trauma is often a more important risk factor and may result in unilateral OA.

The pain is usually localised to the anterior or medial aspect of the knee and upper tibia. Patello-femoral pain is usually worse going up and down stairs or inclines. Posterior knee pain suggests the presence of a complicating popliteal cyst (Baker cyst). Prolonged walking, rising from a chair, getting in or out of a car, or bending to put on shoes and socks may be difficult. Local examination findings may include:

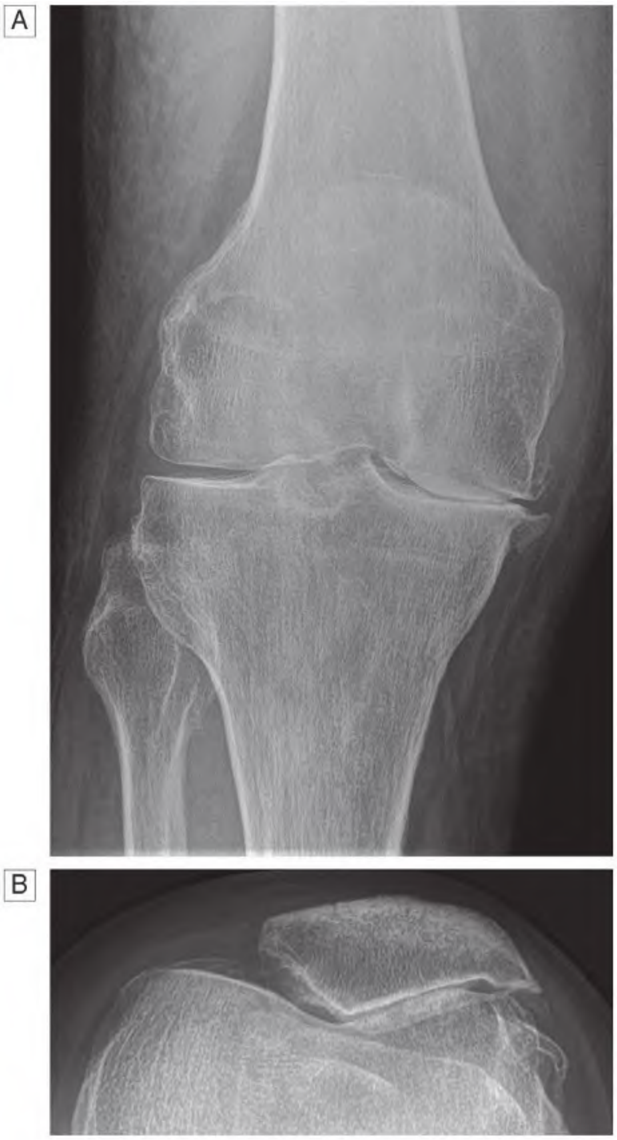

Fig. 25.18 **X-ray appearances in advanced right knee osteoarthritis.** A Severe loss of both medial and lateral tibiofemoral compartment joint spaces. Medial side is more severe, where there are also marginal joint osteophytes. B Skyline view of the patello-femoral joint showing severe medial joint space loss and medial patella displacement in the patello-femoral groove.

- a jerky, asymmetric (antalgic) gait with less time weight-bearing on the painful side
- a varus (Fig. 25.19) or, less commonly, valgus and/or a fixed flexion deformity
- joint-line and/or periarticular tenderness (secondary anserine bursitis and medial ligament enthesopathy (see Box 25.25), causing tenderness of the upper medial tibia)
- weakness and wasting of the quadriceps muscle
- restricted flexion and extension with crepitus
- bony swelling around the joint line.

CPP crystal deposition in association with OA is common at the knee. This may result in a more overt inflammatory component (stiffness, effusions) and super-added acute attacks of synovitis (acute CPP crystal arthritis), which may be associated with more rapid radiographic and clinical progression.

Hip OA

Hip OA most commonly targets the superior aspect of the joint (Fig. 25.20). It is often unilateral at presentation, frequently progresses with superolateral migration of the femoral head and has a poor prognosis. The less common central (medial) OA shows more central cartilage loss and is largely confined to women. It is often bilateral at presentation and can be associated with generalised nodal OA. It has a better prognosis than superior hip OA and progression to axial migration of the femoral head is uncommon.

The best correlation between symptoms and radiographic change is observed in people with hip OA. Hip pain is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin. Lateral hip pain, worse on lying on that side with tenderness over the greater trochanter, suggests secondary trochanteric bursitis. Common functional difficulties are the same as for knee OA; in addition, restricted hip abduction in women may cause pain during sexual intercourse. Examination may reveal:

- an antalgic gait
- weakness and wasting of quadriceps and gluteal muscles
- pain and restriction of internal rotation with the hip flexed, and/or joint extension – the earliest and most sensitive sign of hip OA
- anterior groin tenderness just lateral to the femoral pulse
- fixed flexion, external rotation deformity of the hip
- ipsilateral leg shortening with severe joint attrition and superior femoral migration.

Obesity is associated with more rapid progression of hip OA.

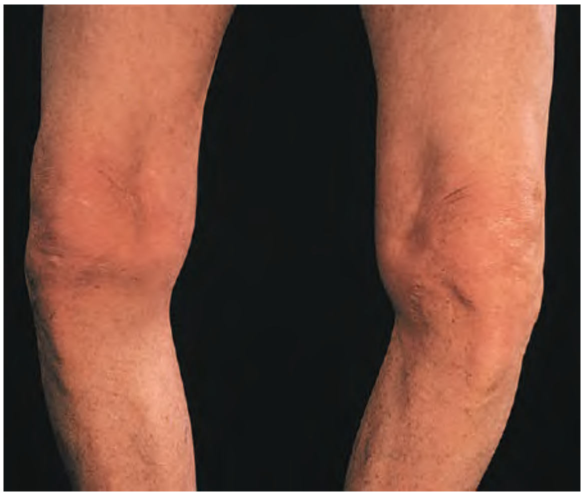

Fig. 25.19 **Typical varus knee deformity resulting from marked medial tibiofemoral osteoarthritis.**

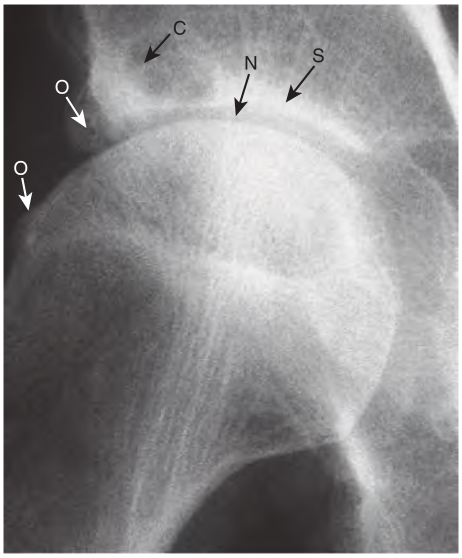

Fig. 25.20 **X-ray of hip showing changes of osteoarthritis.** Note the superior joint space narrowing (N), subchondral sclerosis (S), marginal osteophytes (O) and cysts (C).

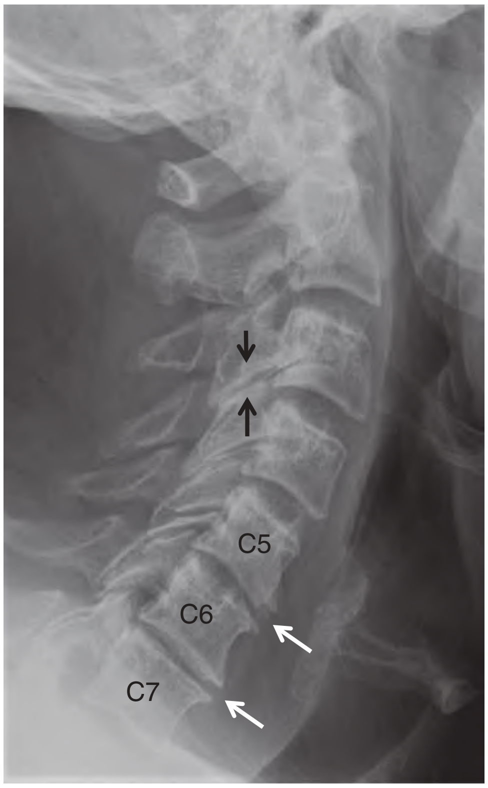

Fig. 25.21 **Cervical spine X-ray showing typical changes of osteoarthritis.** Intervertebral disc space narrowing at C5/6 and C6/7, anterior vertebral body osteophytes (white arrows) and osteosclerosis of a C3/4 facet joint (black arrows).

Spine OA

The cervical and lumbar spine facet joints and intervertebral disc–vertebral endplates are the sites most often affected by an OA process, where the disease complex is referred to as cervical and lumbar spondylosis, respectively (Fig. 25.21). Spine OA may occur in isolation or as part of generalised OA. The typical presentation is with pain localised to the low back region or the neck, although radiation of pain to the arms, buttocks and legs may also occur due to segmental nerve irritation and nerve root compression. Pain is typically relieved by rest and worse on movement. On physical examination, the range of movement may be limited, and loss of lumbar lordosis is typical. The straight leg-raising test or femoral stretch test may be positive, and neurological signs may be seen in the legs where there is complicating spinal stenosis or nerve root compression.

i **25.39 Causes of early-onset osteoarthritis**

Monoarticular

- Previous trauma, localised instability

Pauciarticular or polyarticular

- Juvenile idiopathic arthritis
- Metabolic or endocrine disease:
  Haemochromatosis
  Ochronosis
  Acromegaly
  Alkaptonuria
- Spondylo-epiphyseal dysplasia
- Late osteonecrosis
- Neuropathic joint
- Kashin–Beck disease

Early-onset OA

Rarely, OA may present before the age of 45. In most cases, a single joint is affected and there is a clear history of previous trauma. However, specific causes of OA need to be considered in people with early-onset disease affecting several joints, especially those not normally targeted by OA, in which case rare causes need to be considered (Box 25.39). Kashin–Beck disease is a rare form of OA that occurs in children, typically between the ages of 7 and 13, in some regions of China. The cause is unknown, but suggested predisposing factors are selenium deficiency and contamination of cereals with mycotoxin-producing fungi.

Erosive OA

This term is used to describe an unusual group of patients with hand OA who have a more prolonged symptom phase, more overt inflammation, more disability and worse outcome than those with nodal OA. Distinguishing features include preferential targeting of PIP joints, subchondral erosions on X-rays, occasional ankylosis of affected joints and lack of association with OA elsewhere. It is unclear whether erosive OA is part of the spectrum of hand OA or a discrete subset.

Investigations

A plain X-ray of the affected joints should be performed and often will show one or more of the typical features of OA (see Figs. 25.17, 25.18, 25.20). In addition to providing diagnostic information, X-rays are of value in assessing the severity of structural change, which is helpful if joint replacement surgery is being considered. Non-weight-bearing postero-anterior views of the pelvis are adequate for assessing hip OA. Patients with suspected knee OA should have standing anteroposterior X-rays taken to assess tibio-femoral cartilage loss and a flexed skyline view to assess patello-femoral involvement. Spine OA can often be diagnosed with X-ray, which typically shows evidence of disc space narrowing and osteophytes. Facet joint OA can be difficult to grade without oblique X-ray views. If nerve root compression or spinal stenosis is suspected, MRI should be performed.

Routine biochemistry, haematology and autoantibody tests are usually normal, though inflammatory OA can be associated with a mild acute phase response. Synovial fluid aspirated from an affected joint is viscous, with a low cell count.

Unexplained early-onset OA requires additional investigation, guided by the suspected underlying condition. X-rays may show typical features of dysplasia or osteonecrosis, widening of joint spaces in acromegaly,

25.40 Osteoarthritis in old age

- **Pain and disability**: osteoarthritis is the principal cause in old age.
- **Calcium pyrophosphate deposition disease**: may cause acute attacks of synovitis (pseudogout) on a background of chronic osteoarthritis.
- **Falls**: reduced muscle strength and pain associated with lower limb osteoarthritis increase the risk.
- **Muscle-strengthening exercises**: safely reduce the pain and disability of knee osteoarthritis with accompanying improvements in balance and reduced tendency to fall.
- **Oral paracetamol and topical non-steroidal anti-inflammatory drugs**: safe in older people, with no important drug interactions or contraindications.
- **Intra-articular injection of glucocorticoid**: a very safe and often effective treatment, particularly useful for tiding a patient over a special event.
- **Total joint replacement**: an excellent cost-effective treatment for severe disabling knee or hip osteoarthritis in older people. There is no age limit for joint replacement surgery.

multiple cysts, chondrocalcinosis and MCP joint involvement in haemochromatosis or disorganised architecture in neuropathic joints.

Management

Treatment follows the general principles outlined earlier in this chapter. Measures that are pertinent in older people are summarised in Box 25.40.

Education

It is important to explain the nature of the condition fully, outlining the role of relevant risk factors such as obesity, heredity and trauma. The patient should be informed that established structural changes are permanent and that, although a cure is not possible, pain and function can often be improved. The prognosis should also be discussed, mentioning that it is generally good for nodal hand OA and better for knee than hip OA.

Lifestyle advice

Weight loss has a substantial beneficial effect on symptoms if the patient is obese and is probably one of the most effective treatments available for OA of the lower limbs. Strengthening and aerobic exercises also have beneficial effects in OA and should be advised, preferably with reinforcement by a physiotherapist. Quadriceps strengthening exercises are particularly beneficial in knee OA. Shock-absorbing footwear, pacing of activities, use of a walking stick for painful knee or hip OA, and provision of built-up shoes to equalise leg lengths can all improve symptoms.

Non-pharmacological therapy

Acupuncture and transcutaneous electrical nerve stimulation (TENS) can be effective in knee OA. Local physical therapies, such as heat or cold, can sometimes give temporary relief.

Pharmacological therapy

If symptoms do not respond to non-pharmacological measures, paracetamol should be tried. The addition of a topical NSAID and then capsaicin for knee and hand OA can also be helpful. Oral NSAIDs should be considered in patients who remain symptomatic. These drugs are significantly more effective than paracetamol and can be successfully combined with paracetamol or compound analgesics if the pain is severe. Strong opiates may occasionally be required. Antineuropathic drugs, such as amitriptyline, gabapentin and pregabalin, are sometimes used in patients with symptoms that are difficult to control, but the evidence base for their use is poor. Recently the GLP1 agonist semaglutide has been shown to be more effective than lifestyle modifications in helping obese patients with knee OA to lose weight, with accompanying improvements in pain and quality of life.

Intra-articular injections

Intra-articular (IA) glucocorticoid injections are effective in the treatment of knee OA and are also used for symptomatic relief in the treatment of OA at the first CMC joint. The duration of effect is usually short, but trials of serial IA glucocorticoid every 3 months in knee OA have shown efficacy for up to 1 year. Intra-articular injections of hyaluronic acid (HA) can help for early-stage knee OA and are comparable in efficacy to some other forms of therapies. With HA injections there are beneficial effects on pain and function 5–13 weeks post injection. Injected HA was not recommended for the treatment of knee OA in the 2022 NICE guidance.

Neutraceuticals

Chondroitin sulphate and glucosamine sulphate have been used alone and in combination for the treatment of knee OA. There is evidence from randomised controlled trials that these agents can improve knee pain to a small extent (3%–5%) compared with placebo.

Surgery

Surgery should be considered for patients with OA whose symptoms and functional impairment impact significantly on their quality of life despite optimal medical therapy and lifestyle advice. Total joint replacement surgery is by far the most common surgical procedure for patients with OA. It can transform the quality of life for people with severe knee or hip OA and is indicated when there is significant structural damage on X-ray. Although surgery should not be undertaken at an early stage during the development of OA, it is important to consider it before functional limitation has become advanced since this may compromise outcome. Patient-specific factors, such as age, gender, smoking and presence of obesity, are not barriers to referral for joint replacement.

Only a small proportion of patients with OA progress to the extent that total joint replacement is required, but OA is by far the most frequent indication for this. Over 95% of joint replacements continue to function well into the second decade after surgery and most provide life-long, pain-free function. Up to 20% of patients are not satisfied with the outcome, however, and a few experience little or no improvement in pain. Other surgical procedures are performed much less frequently. Resurfacing of the femoral head can be considered for younger patients with hip OA (age < 60) as an alternative to total joint replacement. Tibial osteotomy represents an alternative to total joint replacement in younger patients with knee OA and can be effective at improving pain by altering alignment of the lower leg. Cartilage repair is sometimes performed to treat focal cartilage defects resulting from joint injury.

Crystal-induced arthritis/disease

A variety of crystals can deposit in and around joints and structures in the spine and cause an acute inflammatory or even chronic inflammatory arthritis or disease (Box 25.41). Several factors influence crystal formation (Fig. 25.22). There must be sufficient concentration of the chemical components (ionic product), but whether a crystal then forms depends on the balance of tissue factors that promote and inhibit crystal nucleation and growth. The inflammatory potential of crystals resides in their physical irregularity and high negative surface charge, which can induce inflammation and damage cell membranes. Crystals may also cause mechanical damage to tissues and act as wear particles at the joint surface. They can reside in cartilage or tendon for years without causing inflammation or symptoms and it is only when they are released that they trigger inflammation. This may occur spontaneously but can also result from local trauma, rapid changes in the concentration of the components that form crystals, or in association with an acute phase response triggered by intercurrent illness or surgery. In the longer term, a reduction in concentrations of the solutes that form crystals causes dissolution of crystals and remission of the arthritis.

25.41 Crystal-associated arthritis and deposition in connective tissue

Crystal	Disease
Common	
Monosodium urate monohydrate	Acute or chronic tophaceous gout
Calcium pyrophosphate (CPP)	CPP deposition (CPPD) disease Acute CPP crystal arthritis Chronic CPP crystal arthritis Chondrocalcinosis Axial CPPD disease (crowned dens syndrome)
Basic calcium phosphate (BCP)	Calcific periarthritis Calcinosis
Uncommon	
Cholesterol	Chronic effusions in rheumatoid arthritis
Calcium oxalate	Acute arthritis in dialysis patients
Extrinsic crystals/semi-crystalline particles:	
• Synthetic crystals	Acute synovitis
• Plant thorns/sea urchin spines	Chronic monoarthritis, tenosynovitis

Gout

Gout is the most common inflammatory arthritis in men and is not uncommon in older women, though comparative robust epidemiological data on the prevalence of gout versus calcium crystal arthritis/disease in older people are lacking. Gout is caused by deposition of monosodium urate monohydrate crystals in and around synovial joints.

Epidemiology

The prevalence of gout is approximately 1%–2%, with a greater than 5:1 male preponderance. Gout has become progressively more common over recent years in affluent societies due to the increased prevalence of obesity and metabolic syndrome, of which hyperuricaemia is an integral component. The risk of developing gout increases with age and with serum uric acid (SUA) levels. These are normally distributed in the general population, and hyperuricaemia is defined as an SUA of more than 2 standard deviations above the mean for the population. SUA levels are higher in men, increase with age and are positively associated with body weight. Levels are higher in some ethnic groups (such as Maoris and Pacific Islanders). Although hyperuricaemia is a strong risk factor for gout, only a minority of hyperuricaemic individuals actually develop gout.

Pathophysiology

About one-third of the body uric acid pool is derived from dietary sources and two-thirds from endogenous purine metabolism (Fig. 25.23). The concentration of uric acid in body fluids depends on the balance between endogenous synthesis and elimination by the kidneys (two-thirds) and gut (one-third). Purine nucleotide synthesis and degradation are regulated by a network of enzyme pathways, but xanthine oxidase plays a pivotal role in catalysing the conversion of hypoxanthine to xanthine and xanthine to uric acid.

The causes of hyperuricaemia are shown in Box 25.42. In over 90% of patients, the main abnormality is reduced uric acid excretion by the kidney, which is genetically determined. Impaired renal excretion of urate also accounts for the occurrence of hyperuricaemia in chronic renal failure and for hyperuricaemia associated with thiazide diuretic therapy.

Other risk factors for gout include metabolic syndrome, high alcohol intake (predominantly beer, which contains guanosine), generalised OA and a diet relatively high in game, offal, seafood, red meat and fructose, or low in vitamin C. Lead poisoning may cause gout (saturnine gout). The association between OA and gout is thought to be due to a reduction in levels of proteoglycan and other inhibitors of crystal formation in osteoarthritic cartilage, predisposing to crystal formation.

Some patients develop gout because they over-produce uric acid. The mechanisms are poorly understood, except in the case of a few single gene disorders where there are pathogenic variants in genes that regulate purine metabolism (see Box 25.42). Lesch–Nyhan syndrome is an X-linked recessive form of gout that is also associated with

25.42 The main causes of hyperuricaemia and gout

Diminished renal excretion

- Increased renal tubular reabsorption*
- Renal failure
- Lead toxicity
- Lactic acidosis
- Alcohol
- Drugs:
  Thiazide and loop diuretics
  Low-dose aspirin
  Ciclosporin
- Pyrazinamide
- Cancer chemotherapy
- ACE inhibitors

Increased intake

- Game
- Shellfish
- Offal
- Red meat

Increased production

- Myeloproliferative and lymphoproliferative disease
- Psoriasis
- High fructose intake
- Glycogen storage disease
- Inherited disorders:
  Lesch–Nyhan syndrome (pathogenic variants in *HPRT*)

*Usually genetically determined (see text).
(ACE = angiotensin-converting enzyme; HPRT = hypoxanthine guanine phosphoribosyl transferase)

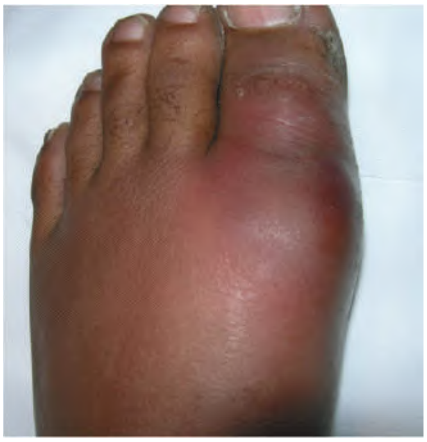

Fig. 25.24 Acute gout. Swelling, erythema, extreme pain and tenderness of the first metatarsophalangeal joint. *From Goldman L, Shafer AI. Goldman-Cecil medicine. 26th ed. Philadelphia: Elsevier; 2020.*

mental retardation, self-mutilation and choreoathetosis. An inherited cause should be suspected if other clinical features are present or there is an early age at onset with a positive family history. Severe hyperuricaemia can also occur in patients with haematological and other cancers who are undergoing chemotherapy due to increased purine turnover (tumour lysis syndrome). This acute rise in urate seldom, if ever, causes gout but can cause acute kidney injury.

Clinical features

The classical presentation is with acute monoarthritis, which affects the first MTP joint in over 50% of cases (Fig. 25.24). Other common sites are the ankle, midfoot, knee, small joints of hands, wrist and elbow. The axial skeleton and large proximal joints are rarely involved. Typical features of the acute form of gout include:

- rapid onset, reaching maximum severity in 2–6 hours, worse in the early morning
- severe pain, often described as the 'worst pain ever'
- extreme tenderness, so the patient is unable to wear a sock or to let bedding rest on the joint
- marked swelling with overlying red, shiny skin
- self-limiting over 5–14 days, with complete resolution.

25.43 Gout in old age

- **Aetiology**: a higher proportion of older patients have gout secondary to diuretic use and chronic kidney disease. Gout is often associated with osteoarthritis.
- **Presentation**: may be atypical, with painful tophi and chronic symptoms, rather than acute attacks. Joints of the upper limbs are more frequently affected.
- **Management**: acute attacks are best treated by aspiration and intra-articular injection of glucocorticoids, followed by early mobilisation. Non-steroidal anti-inflammatory drugs and colchicine should be used with caution because of increased risk of toxicity. Low doses of allopurinol (50 mg/day) should be given and increased gradually to avoid toxicity.

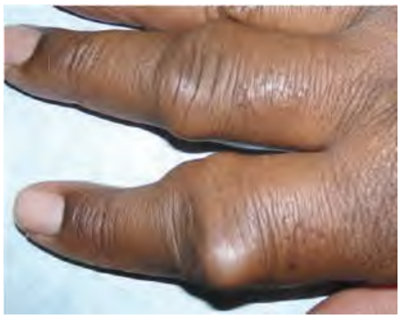

Fig. 25.25 Tophi over the proximal interphalangeal joints of the hands. *From Goldman L, Shafer AI. Goldman-Cecil medicine. 25th ed. Elsevier; 2016.*

During the attack, the joint shows signs of marked synovitis, swelling and erythema. There may be accompanying fever, malaise and even delirium, especially if a large joint such as the knee is involved. As the attack subsides, pruritus and desquamation of overlying skin are common. The main differential diagnosis is septic arthritis, cellulitis and reactive arthritis. Acute attacks may also manifest as bursitis, or tenosynovitis. Sometimes an acute attack will be followed by further attacks in other joints a few days later (cluster attacks), the first possibly acting as a trigger. Simultaneous polyarticular attacks are unusual.

Some people never have a second episode and in others several years may elapse before a second attack occurs. Patients with repeated attacks may progress to chronic gout, with chronic pain, joint damage, deformity and functional impairment. Patients with uncontrolled hyperuricaemia who suffer multiple attacks of acute gout may also progress to chronic gout. Gout may present as polyarticular in older women, and ultimately in men who have had repeated acute attacks of gout. In women polyarticular gout may not be preceded by acute symptoms, and it can be misdiagnosed as other types of polyarthritis. The presentation of gout in old age may be atypical, with chronic symptoms rather than acute attacks (Box 25.43).

Crystals may be deposited in the joints and soft tissues to produce irregular firm nodules called tophi. These have predilection for the extensor surfaces of fingers (Fig. 25.25), hands, forearm, elbows, Achilles tendons and sometimes the helix of the ear. Tophi have a white colour, differentiating them from rheumatoid nodules. Tophi can ulcerate, discharging white gritty material, become infected or induce a local inflammatory response, with erythema and pus in the absence of secondary infection. They are usually a feature of long-standing gout but can sometimes develop within 12 months in patients with chronic renal failure. Occasionally, tophi may develop in the absence of previous acute attacks, especially in patients on thiazide therapy who have coexisting OA.

In addition to causing musculoskeletal disease, chronic hyperuricaemia may be complicated by renal stone formation and, if severe, renal impairment due to the development of interstitial nephritis as a result of urate deposition in the kidney. This is particularly common in patients with chronic tophaceous gout who are on diuretic therapy.

Investigations

The diagnosis of gout can be confirmed by the identification of urate crystals in the aspirate from a joint, bursa or tophus (see Fig. 25.5A). In acute gout, the synovial fluid may be turbid due to an elevated neutrophil count. In chronic gout, the appearance is more variable, but occasionally the fluid appears white due to the presence of urate crystals. Between attacks, aspiration of an asymptomatic joint may still reveal crystals.

A biochemical screen, including renal function, uric acid, glucose and lipid profile, should be performed because of the association with metabolic syndrome. Hyperuricaemia is usually present in gout, but levels may be normal during an attack because serum urate falls during inflammation. Acute gout is characterised by an elevated ESR and CRP and with neutrophilia, all of which return to normal as the attack subsides. Tophaceous gout may be accompanied by a modest but chronic elevation in ESR and CRP.

X-rays are usually normal in acute gout, but well-demarcated erosions may be seen in patients with chronic or tophaceous gout (Fig. 25.26). Tophi may also be visible on X-rays as soft tissue swellings. In late disease, destructive changes may occur that are similar to those in other forms of advanced inflammatory arthritis.

Management

Management should focus on first dealing with the acute attack and then giving prophylaxis to lower SUA and prevent further attacks.

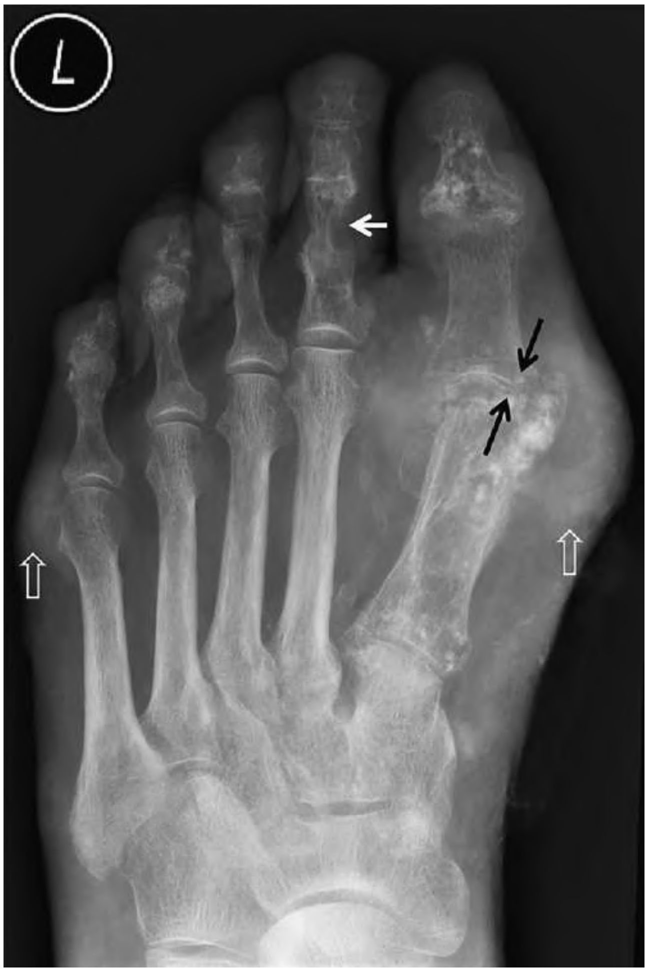

Fig. 25.26 Erosive arthritis in chronic gout. Erosive arthritis in the left foot secondary to chronic tophaceous gout. Punched-out ('Lulworth Cove') erosion of proximal phalanx of the second toe (white arrow), destructive arthritis of the first metatarsal phalangeal joint (black arrows) and partially calcified tophi (open arrows).

Acute gout

Simple measures such as elevating the affected joint and applying ice can be helpful. Oral colchicine given in doses of 0.5 mg 2–4 times daily is the treatment of first choice in acute gout. It works by inhibiting the inflammasome (see Fig. 4.2), which reduces IL-1β production by macrophages. The most common adverse effects are nausea, vomiting and diarrhoea. Oral NSAIDs are also effective but are used less commonly since many patients affected by acute gout have coexisting cardiovascular, cerebrovascular or chronic kidney disease. Oral prednisolone (15–20 mg daily for 2–3 days) or intramuscular methylprednisolone (80–120 mg daily) are highly effective and are a good choice in older adults where there is an increased risk of toxicity with colchicine and NSAIDs (see Box 25.43). IL-1 inhibition with anakinra or canakinumab (see Box 25.35) is effective but both treatments are expensive and are only given when first-line treatments are ineffective. Patients with recurrent episodes can keep a supply of an NSAID, colchicine or prednisolone and take it as soon as the first symptoms occur, continuing until the attack resolves. Joint aspiration can give pain relief, particularly if a large joint is affected, and may be combined with an intra-articular glucocorticoid injection if the diagnosis is clear and infection has been excluded.

Prophylaxis

Patients who have had a single attack of gout do not necessarily need to be given urate-lowering therapy, but it should be offered to individuals who have more than one acute attack within 12 months and those with complications such as tophi or erosions (Box 25.44). The long-term therapeutic aim is to prevent attacks occurring by bringing SUA below the level at which monosodium urate monohydrate crystals form. A therapeutic target of $<300\,\mu$mol/L (5 mg/dL) is recommended in the British Society of Rheumatology guidelines, whereas the European League Against Rheumatism guidelines recommend a threshold of $<360\,\mu$mol/L (6 mg/dL) or $<300\,\mu$mol/L (5 mg/dL) in those with severe gout.

Allopurinol is the drug of first choice. It inhibits xanthine oxidase, which reduces the conversion of hypoxanthine and xanthine to uric acid. The recommended starting dose is 100 mg daily, or 50 mg in older patients and in renal impairment. The dose of allopurinol should be increased by 100 mg every 4 weeks (50 mg in older patients and those with renal impairment) until the target uric acid level is achieved, side-effects occur, or the maximum recommended dose is reached (900 mg/day). Acute flares of gout often follow initiation of urate-lowering therapy. The patient should be warned about this and told to continue therapy, even if an attack occurs. The risk of flares can be reduced by prophylaxis with oral colchicine (0.5–1 mg daily) or an NSAID for the first few months. Alternatively, patients can be given a supply of colchicine, an NSAID or prednisolone to be taken at the first sign of an acute attack. In the longer term, annual monitoring of uric acid levels is recommended. In most patients, urate-lowering therapy needs to be continued indefinitely.

Febuxostat also inhibits xanthine oxidase. It is typically used in patients with an inadequate response to allopurinol and when allopurinol is contraindicated or causes adverse effects. Febuxostat undergoes hepatic metabolism, and no dose adjustment is required for renal impairment. It is more effective than allopurinol, but commonly provokes acute attacks when therapy is initiated. The usual starting dose is 40–80 mg daily, increasing to 120 mg daily in patients with an inadequate response. Prophylaxis against acute attacks should be given on initiating therapy, as described for allopurinol.

25.44 Indications for urate-lowering drugs

- Recurrent attacks of acute gout
- Evidence of bone or joint damage
- Tophi
- Renal impairment
- Nephrolithiasis
- Chemotherapy-related hyperuricemia

Uricosuric drugs, such as probenecid, sulfinpyrazone and benzbromarone, lower urate levels but are used much less commonly than xanthine oxidase inhibitors. Uricosuric drugs are contraindicated in urate over-producers and those with renal impairment or urolithiasis and require patients to maintain a high fluid intake to avoid uric acid crystallisation in the renal tubules. Notably, benzbromarone is approved in parts of Europe and Asia (50–200 mg daily), and has equivalent urate lowering ability to allopurinol but is superior to probenecid. It is associated with a low rate of liver toxicity. Probenecid is a relatively weak but well-established and relatively safe uricosuric drug. Pegloticase and rasburicase are recombinant uricases. The 2020 ACR guidelines recommend pegloticase, given as intravenous (IV) infusion (typically 8 mg) every 2 weeks, for patients who continue to have frequent gout flares or non-resolving tophi despite compliance with maximally tolerated xanthine oxidase inhibitors, uricosurics, combination therapy, and other interventions. Rasburicase is licensed for hyperuricaemia and gout from tumour lysis syndrome and is given IV daily for 1–5 days based on clinical response. Both drugs can cause anaphylaxis, are expensive and are immunogenic. A limiting factor for longer-term treatment is the development of anti-drug antibodies, which are associated with an impaired therapeutic response.

Lifestyle measures are as important as drug therapy in treatment of gout. Patients should be advised to lose weight if appropriate and reduce excessive alcohol intake, especially beer. Several antihypertensive drugs, including thiazides, β-adrenoceptor antagonists (β-blockers) and ACE inhibitors, increase uric acid levels, whereas losartan has a uricosuric effect and should be substituted for other drugs if possible. Patients should avoid large amounts of seafood and offal, which have a high purine content, but a highly restrictive diet is not necessary.

Calcium pyrophosphate deposition disease

Calcium pyrophosphate deposition (CPPD) disease encompasses a range of clinical presentations. CPP crystals can deposit in articular cartilage, synovium, entheses, tendons and ligaments – both axial and peripheral skeletal sites. The acute form of CPPD disease is acute CPP crystal arthritis ('pseudogout'). Acute CPP crystal arthritis is rare under the age of 55 years but occurs in 10%–15% of people between 65 and 75 years and 30%–60% of those over 85 years. It typically involves the knee, wrist, ankle, shoulder and hip. Acute CPP inflammation can also affect axial skeletal structures. Risk factors for CPPD disease are shown in Box 25.45. Frequently, patients with CPPD disease have multiple joint chondrocalcinosis and a proportion present with chronic CPP crystal arthritis without a history of previous acute CPP crystal arthritis. The picture is typically an inflammatory polyarthritis superimposed on a background of OA – typically of the wrist, shoulder or knee (Fig. 25.27). Chronic CPP crystal arthritis can be mistaken for RA by the unwary, as MCP joints can be affected (usually just 2nd and 3rd, sparing the 4th and 5th) and low titre RF is a common incidental finding in old age. The prevalence of CPPD disease affecting the axial skeletal is unknown.

i 25.45 The main risk factors for calcium pyrophosphate deposition disease

Common

- Older age
- Osteoarthritis[1]
- Hyperparathyroidism (both primary and secondary)
- Hypovitaminosis-D (by causing secondary hyperparathyroidism)

Rare

- Familial CPPD[1,2]
- Haemochromatosis[1]
- Hypophosphatasia
- Hypomagnesaemia
- Hypoparathyroidism
- Wilson disease

[1] May be associated with structural damage to affected joints.

[2] Most commonly caused by pathogenic variants in *ANKH.*

Pathophysiology

The underlying mechanisms of crystal deposition are poorly understood. Clinical studies have shown that CPP levels are raised in patients with CPPD disease, possibly due to over-production, but why this happens is unclear. In hypophosphatasia (see Box 25.74), the predisposing factor is thought to impair degradation of CPP due to deficiency of ALP. In OA, it is thought that a reduction in the amounts of proteoglycan and other natural inhibitors of crystal formation in the abnormal cartilage predisposes to crystal deposition (see Fig. 25.22).

Clinical features

The typical acute CPP crystal arthritis presentation is with a swollen tender joint that is warm and erythematous with a large effusion. Fever is common and the patient may appear confused and ill. The knee is most commonly affected, followed by the wrist, shoulder, ankle and elbow. Trigger factors include trauma, intercurrent illness, dehydration and surgery. Septic arthritis and gout are the main differential diagnoses.

Chronic CPP crystal arthritis can mimic RA, though joint involvement patterns are generally different (in chronic CPP crystal arthritis: wrists, MCP joints 2 and 3, ankles, shoulders). Affected joints usually show features of OA, with varying degrees of synovitis. Effusion and synovial thickening are usually most apparent at knees and wrists. Wrist involvement may result in carpal tunnel syndrome. Inflammatory changes can occur at entheses such as the gluteal tendon insertions at the greater trochanters and may involve tendons and the ligamentum flavum. Inflammation around the odontoid may occur secondary to CPP crystal deposition, leading to crowned dens syndrome; this presents clinically with upper neck and occipital head pains (with neck rotation being the most severely affected movement). Severe damage and instability of knees, hips or shoulders can mimic a neuropathic joint.

Investigations

The pivotal investigation in diagnosing acute CPP crystal arthritis is joint aspiration, followed by examination of synovial fluid using compensated

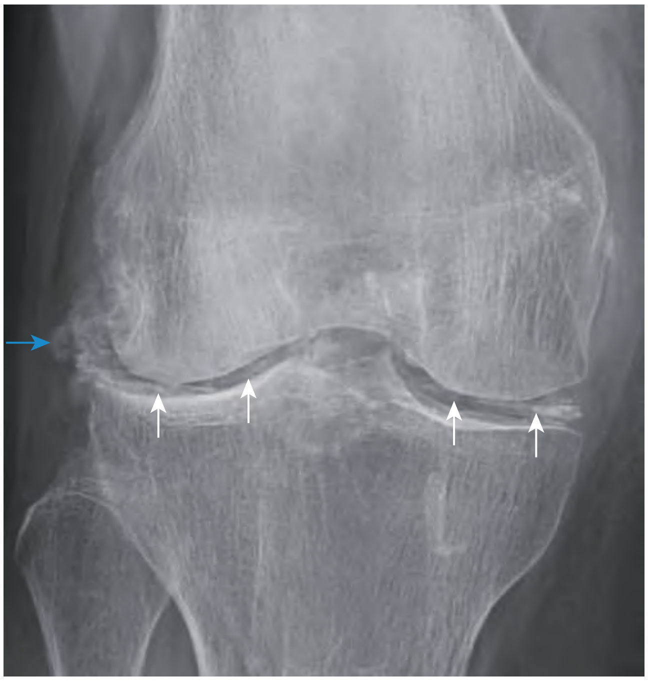

Fig. 25.27 Chondrocalcinosis of the knee. Chondrocalcinosis of the medial and lateral tibiofemoral menisci of the right knee (white arrows) in a patient with chronic calcium pyrophosphate (CPP) crystal arthritis. There is joint space narrowing of both tibiofemoral compartments and synovial calcification in the lateral joint compartment.

polarised microscopy to demonstrate CPP crystals (see Fig. 25.5B). The aspirated fluid is often turbid and may be uniformly blood-stained, reflecting the severity of inflammation. Since sepsis and acute CPP crystal arthritis can coexist, Gram stain and culture of the fluid should be performed to exclude infection, even if CPP crystals are identified in synovial fluid.

For diagnosing chronic CPP crystal arthritis and CPP axial skeletal disease, X-rays of the affected joints, carefully reviewed, may show evidence of calcification in hyaline cartilage and/or fibrocartilage or in peri-articular entheses. Reviewing CT images, if available (and windowed for bone), is often helpful in revealing CPP deposition in pelvic and spine structures. Screening for secondary causes (see Box 25.45) and metabolic risk factors should be undertaken in all cases of CPPD disease and abnormalities treated.

Management

In acute CPP crystal arthritis, ice packs, joint elevation and joint aspiration provides symptomatic relief. Once infection is excluded, intra-articular glucocorticoid can be injected. NSAIDs and colchicine (0.5–2 mg daily) are helpful but must be used with caution in older patients. Chronic CPP crystal arthritis can respond to low-dose oral glucocorticoids, and methotrexate. Colchicine long-term (0.5–1 mg daily) may play a role in preventing acute CPP inflammatory flare-ups. Little is known about the optimum drug management of chronic CPPD disease in the axial skeletal.

Basic calcium phosphate deposition disease

Basic calcium phosphate (BCP) deposition disease is caused by the deposition of hydroxyapatite or apatite crystals and other basic calcium phosphate salts (octacalcium phosphate, tricalcium phosphate) in soft tissues. The main affected sites are tendons, ligaments and hyaline cartilage in patients with degenerative disease, and skeletal muscle and subcutaneous tissues in connective tissue diseases.

Pathophysiology

Under normal circumstances, inhibitors of mineralisation, such as pyrophosphate and proteoglycans, prevent calcification of soft tissues. When these protective mechanisms break down, abnormal calcification occurs. There are many causes (Box 25.46). Consequences of the soft-tissue calcification can include local tissue reaction/inflammation in some instances and may lead to pure bone formation in other disease contexts, depending on pathogenic genetic influences, local tissue factors, and/or systemic metabolic and inflammatory pathology.

Calcific periarthritis

This occurs as the result of deposition of BCP in tendons, which provokes an acute inflammatory response. Commonly the supraspinatus tendon is affected (Fig. 25.28), but other sites may also be involved, including the tendons around the hip, feet and hands. The presentation is with acute pain, swelling and local tenderness that develops rapidly over 4–6 hours. The overlying skin may be hot and red, raising the possibility of infection. Attacks sometimes occur spontaneously but can also be triggered by trauma. Modest systemic upset and fever are common. Tendon calcification may be seen on X-ray. If the affected joint or bursa is aspirated, inflammatory fluid containing many calcium-staining (alizarin red S) aggregates may be obtained. During an acute attack, there may be neutrophilia with an elevation in ESR and CRP. Routine biochemistry is normal. Treatment is with analgesics and NSAIDs, and if the condition does not resolve over a few weeks, barbotage (dry needling under US scan guidance) and/or local injection of glucocorticoid can be considered. Large deposits sometimes accumulate, causing limitation of joint movement, and may require surgical removal.

i 25.46 Rheumatic diseases associated with basic calcium phosphate deposition

Disease	Site of calcification
Calcific periarthritis	Tendons and ligaments
Dermatomyositis and polymyositis	Subcutaneous tissue
Systemic sclerosis (lcSScl)	Subcutaneous tissue
Mixed connective tissue disease	Subcutaneous tissue
Paget disease of bone	Blood vessels
Ankylosing spondylitis	Ligaments
Fibrodysplasia ossificans progressiva	Subcutaneous tissues and muscle
Milwaukee shoulder syndrome	Tendons and ligaments
Albright hereditary osteodystrophy	Muscle

(lcSScl = limited cutaneous systemic sclerosis)

Acute inflammatory arthritis

Deposition of BCP occurs commonly in OA, both alone and in combination with CPP crystals, in which case it is referred to as mixed crystal deposition disease. An acute crystal-induced arthritis can occur, identical to pure acute CPP crystal arthritis.

Milwaukee shoulder syndrome

This is a rare syndrome, in which extensive deposition of BCP crystals in large joints is associated with progressive joint destruction. It is more common in women than in men. The onset is gradual, with joint pain, sometimes precipitated by injury or overuse. The disease progresses over a few months to cause severe pain and disability, associated with joint destruction. X-rays show joint space narrowing, osteophytes and calcification. Aspiration yields large volumes of relatively non-inflammatory fluid containing abundant BCP aggregates and often cartilage fragments. The differential diagnosis is end-stage osteonecrosis, chronic sepsis or neuropathic joint. There is no acute phase response and synovial fluid cultures are negative.

Treatment is with analgesics, intra-articular glucocorticoid injection, local physical treatments and physiotherapy. The clinical outcome is poor, however, and most patients require joint replacement. The cause is incompletely understood, but it has been speculated that deposition of BCP crystals activates collagenase and other proteases in articular cells, which are responsible for the tissue damage.

Autoimmune connective tissue disease

Deposition of BCP may occur in the subcutaneous tissues and muscle of patients with systemic sclerosis and other autoimmune connective tissue diseases. Usually, the deposits are asymptomatic, but they may be associated with pain and local ulceration. The mechanism by which this occurs is unclear and there is no specific treatment.

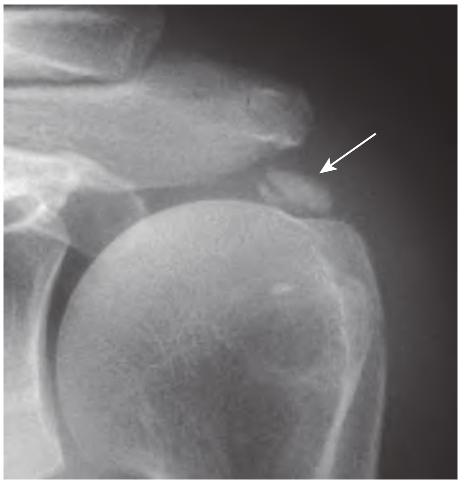

Fig. 25.28 Shoulder X-ray showing supraspinatus tendon calcification (arrow).

i 25.47 The spectrum of symptoms in fibromyalgia

Common symptoms

- Widespread pain
- Hypersensitivity to touch (allodynia)
- Generalised stiffness
- Fatigue
- Broken, non-restorative sleep
- Poor concentration (brain fog)

Other symptoms

- Non-throbbing bifrontal headache (tension headache)
- Chronic facial pain
- Colicky abdominal pain, bloating, variable bowel habit (irritable bowel syndrome)
- Restless legs
- Bladder fullness, nocturnal frequency (irritable bladder)
- Painful periods
- Depression

Fibromyalgia

Fibromyalgia (FM) is characterised by generalised pain, local tenderness to pressure on physical examination, inability to concentrate (brain fog), fatigue, and broken or non-restorative poor sleep (Box 25.47). It may be associated with tension headache, chronic facial pain, irritable bowel syndrome and genitourinary symptoms. Women are affected more commonly than men with a female-to-male ratio of 10:1. It can occur at any age including adolescence. The prevalence in the UK and United States is estimated at 2%–3%. Risk factors include life events that cause (unresolved) psychosocial distress relating to previous abuse, marital disharmony, alcoholism or illness in the family, poor sleep health, previous injury or assault and low income. FM arises in a variety of races and cultures. It may coexist with other inflammatory rheumatic diseases, including axSpA and SLE.

Pathophysiology

The cause of FM is poorly understood, but two abnormalities that may be interrelated and have been consistently reported in affected patients are disturbed, non-restorative sleep and pain sensitisation, probably caused by abnormal central pain processing.

Clinical features

The presenting feature is widespread pain, and focal tender points on examination in multiple areas on the trunk, arms and legs. The pain responds poorly to analgesics and NSAIDs. Fatigue, most prominent in the morning, is another major problem and disability is often marked. Although people can usually undertake self-care (such as eating, washing and dressing), they may be unable to perform tasks such as shopping or housework. They may experience major performance difficulties at work and may have to stop working because of their symptoms.

Examination is unremarkable, apart from the presence of hyperalgesia on moderate digital pressure (enough just to whiten the nail of the examiner) over multiple sites on the trunk, back, shoulder girdle and back.

Investigations and management

Fibromyalgia is a clinical diagnosis based on history and the finding of tender spots on examination. Blood tests and imaging are not recommended except to investigate other causes of pain if these are suspected clinically.

The aims of management are to educate the patient about the condition, address unresolved psychological issues, achieve pain control and improve sleep. Wherever possible, education should include the spouse, family or carer. It is important to tell the patient that the cause of FM is not fully understood, but that the widespread pain does not reflect inflammation, tissue damage or a serious underlying disease like cancer. The model of a self-perpetuating cycle of poor sleep and pain (Fig. 25.29) is a useful framework for problem-based management. Understanding the diagnosis can often help the patient come to terms with the symptoms. Extensive investigations may reinforce beliefs in occult serious pathology and should be avoided.

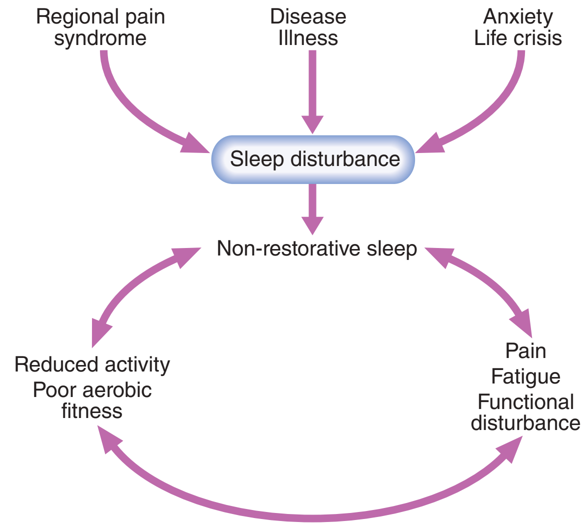

Fig. 25.29 Possible causative mechanisms in fibromyalgia.

Low-dose amitriptyline (10–75 mg at night), with or without fluoxetine, may help by encouraging delta sleep and reducing spinal cord wind-up. Many people with FM, however, are intolerant of even small doses of amitriptyline. There is limited evidence for the use of tramadol, serotonin–noradrenaline (norepinephrine) re-uptake inhibitors (SNRIs) such as duloxetine, and the anticonvulsants pregabalin and gabapentin. A graded increase in aerobic exercise can improve well-being and sleep quality. The use of self-help strategies and a cognitive behavioural approach with relaxation techniques should be encouraged. Sublimated anxiety relating to distressing life events should be specifically explored with appropriate counselling. There are patient organisations that provide additional information and support. Although treatment may improve quality of life and ability to cope, most people remain symptomatic for many years.

Bone and joint infections

Septic arthritis

Septic arthritis is the most rapid and destructive joint disease. The incidence is 2–10 per 100 000 in the general population and 30–70 per 100 000 in those with pre-existing joint disease or joint replacement. Septic arthritis is associated with significant morbidity and still has a mortality of about 10% despite advances in antimicrobial therapy. The most important risk factor for mortality is increasing age, but prevalence increases with socioeconomic deprivation.

Pathogenesis

Septic arthritis usually occurs because of haematogenous spread from infections of the skin or upper respiratory tract; infection from direct puncture wounds or secondary to joint aspiration is uncommon. Risk factors include increasing age, pre-existing joint disease (principally RA), diabetes mellitus, advanced renal disease, immunosuppression (by drugs or disease) and intravenous drug misuse. In RA, the skin is a frequent portal of entry because of maceration of skin between the toes due to joint deformity and difficulties with foot hygiene caused by hand deformity. Box 25.48 describes the particular considerations in old age.

25.48 Joint and bone infection in old age

- **Vertebral infection**: more common. Recognition may be delayed, as symptoms may be attributed to compression fractures caused by osteoporosis.
- **Peripheral vascular disease**: leads to more frequent involvement of the bones of the feet, and diabetic foot ulcers are also commonly complicated by osteomyelitis.
- **Prosthetic joint infections**: now more common because of the increased frequency of prosthetic joint insertion in older people.
- **Gram-negative bacilli**: more frequent pathogens than in younger people.
- **Cephalosporins:** contraindicated due to the high risk of *Clostridioides difficile*.
- **Septic arthritis:** mortality is high in older patients.

Clinical features

The usual presentation is with acute or subacute monoarthritis and fever. The joint is usually swollen, hot and red, with pain at rest and on movement. Although any joint can be affected, lower limb joints, such as the knee and hip, are most commonly targeted. Patients with pre-existing arthritis may present with multiple joint involvement.

The most common organism in adults is *Staphylococcus aureus*, particularly in patients with RA and diabetes, but infections with β-haemolytic streptococci and gram-negative bacilli are also frequent. Tuberculosis should always be considered where local population infection prevalence is high. Gonococcal infection can present with migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of an oligo- or monoarthritis. Painful pustular skin lesions may also be present. Gram-negative bacilli or group B, C and G streptococci are important causes among older adults and intravenous drug users. Less commonly, septic arthritis may be caused by group A streptococci, pneumococci, meningococci and *Haemophilus influenzae*. Arthritis may be a feature of Lyme disease caused by members of the *Borrelia* species of microorganisms. It is generally a late manifestation, which usually affects large joints. Brucellosis presents with an acute febrile illness, followed in some cases by the development of localised infection, which can result in arthritis, bursitis, osteomyelitis, sacroiliitis and paravertebral or psoas abscesses.

Investigations

The pivotal investigation is joint aspiration, but blood cultures should also be taken. The synovial fluid is usually turbid or blood-stained but may appear normal. If the joint is not readily accessible, aspiration should be performed under imaging guidance or in theatre. Prosthetic joints should only be aspirated in theatre to minimise the risk of introducing infection.

Synovial fluid should be sent for Gram stain and culture; cultures are positive in around 90% of cases, but the Gram stain is positive in only 50%. In contrast, synovial fluid culture is positive in only 30% of gonococcal infections, making it important to obtain concurrent cultures from the genital tract (positive in 70%–90% of cases).

There is leucocytosis with raised CRP in most patients, but these features may be absent in older or immunocompromised patients, or early in the disease course. Serial measurements of CRP are useful in following the response to treatment.

Management

The principles of management are summarised in Box 25.49. The patient should be admitted to hospital for pain relief and administration of parenteral antibiotics. Flucloxacillin (2 g IV 4 times daily) is antibiotic of first choice pending the results of cultures, since it will cover most staphylococcal and streptococcal infections. If there is reason to suspect methicillin-resistant *Staphylococcus aureus* (such as a known carrier), vancomycin should be used instead while awaiting cultures. If a gram-negative infection is suspected, initial antibiotic treatment should cover gram-negative bacilli as well as staphylococci and streptococci. Cephalosporins are a reasonable choice in this situation but carry a high risk of *Clostridioides difficile* infection in those aged over 65; gentamicin is a good alternative.

25.49 Emergency management of suspected septic arthritis

Admit patient to hospital

Perform urgent investigations

- Aspirate joint (use imaging guidance as needed). Send synovial fluid for Gram stain and culture
- Send blood for culture, routine biochemistry and haematology, including erythrocyte sedimentation rate and C-reactive protein
- Consider sending other samples (sputum, urine, wound swab) for culture, depending on patient history, to determine the primary source of infection
- Consider sending serum sample (and later a paired sample) for *Brucella* serology (see p. 356)

Commence intravenous antibiotic*

- Flucloxacillin (2 g four times daily) to cover *Staph. aureus*
- If penicillin-allergic:
  Clindamycin (450–600 mg four times daily in younger patients)
  Intravenous vancomycin (1 g twice daily if age > 65 years)
- If there is a high risk of gram-negative infection, in the immunocompromised and in IV drug users, add a 3rd generation cephalosporin
- When treating empirically before culture results are available, always seek local microbiology advice

Relieve pain

- Oral and/or intravenous analgesics or NSAID (caution in older patients) and ice packs

Aspirate joint

- Perform serial needle aspiration to dryness (1–3 times daily or as required)
- Consider arthroscopic drainage if needle aspiration is difficult
- Consider synovial biopsy at arthroscopy for tissue for PCR analysis for TB

Arrange physiotherapy

- Early regular passive movement, progressing to active movements once pain controlled and effusion not re-accumulating

*Antibiotic choice should take local epidemiology and patient risk factors into account and be supported by local guidelines where available.

Whatever antimicrobial regimen is chosen; changes may be required depending on the organism that is isolated. Microbiology advice should always be sought in complicated situations, such as when treating intravenous drug users, patients in intensive care and those who might be colonised by resistant organisms. It is traditional to continue intravenous antibiotics for 2 weeks and to follow this with oral treatment for another 4 weeks, but there is no evidence to support the optimal duration of treatment. Joint aspiration should be performed using a large-bore needle once or twice daily. If this is not possible, arthroscopic or open surgical drainage may be needed. Regular passive movement should be undertaken from the outset and active movements encouraged once the condition has stabilised. Infected prosthetic joints require management by the orthopaedic team, but prolonged antibiotic treatment on its own is often ineffective and removal of the prosthesis may be required for eradication of the infection.

Viral arthritis

The usual presentation is with acute polyarthritis following a febrile illness, which may be accompanied by a rash. Most cases of viral arthritis are self-limiting and settle down within 4–6 weeks. Human parvovirus arthropathy (mainly B19) is the most common in Europe; adults may not have the characteristic ‘slapped cheek’ facial rash seen in children. The diagnosis can be confirmed by a rise in specific IgM. Polyarthritis may also occur rarely with hepatitis B and C, rubella (including rubella vaccination) and HIV infection. A variety of mosquito-borne viruses may cause epidemics of acute polyarthritis, including Ross River (Australia, Pacific), Chikungunya and O’nyong-nyong (Asia, Africa) and Mayaro viruses (South America). A wide variety of articular symptoms have been associated with HIV, mainly in the later stages of infection (Box 25.50). Management is symptomatic, with NSAIDs and analgesics.

i 25.50 Musculoskeletal manifestations of HIV

Condition	Comment
Non-specific arthralgia and mechanical low back pain	Most common
Reactive arthritis Psoriatic arthritis Idiopathic inflammatory arthritis	Especially in men who have sex with men. Idiopathic arthritis is usually of lower limb joints and may be of SpA aetiology
Osteonecrosis Myositis or vasculitis Osteoporosis Sjögren-like disease	May be either related to HIV, to its treatment or intercurrent disease

Osteomyelitis

In osteomyelitis, the primary infection sites are bone and bone marrow. Any part of a bone may be involved, but there is preferential targeting of the juxta-epiphyseal regions of long bones adjacent to joints. The risk of osteomyelitis increases with age; the incidence is about 9 cases per 100 000 person-years in those under 18, rising to 41 cases in those aged 60–69 and 88 cases in those above the age of 80.

Pathogenesis

Haematogenous spread is the most common cause in children. In adults, contiguous spread of infection from adjacent soft tissues is more common, usually in patients with infected skin ulcers (pressure sores, neuropathic or ischaemic ulcers) or following surgery. Diabetes is a particularly important risk factor, accounting for about 30% of cases in recent series. Other risk factors include immunosuppressive therapy, HIV infection and sickle-cell disorder, which particularly increases the risk of *Salmonella* infection. The organisms most frequently implicated are *Staph. aureus* and β-haemolytic streptococci. Tuberculosis also needs to be considered as a cause in high prevalence areas. Osteomyelitis secondary to pyogenic organisms often results in a florid inflammatory response, with greatly increased intraosseous pressure. If untreated, the condition may cause localised areas of osteonecrosis, leading to the development of a fragment of necrotic bone that is called a sequestrum. Eventually perforation of the cortex by pus stimulates local new bone formation (involucrum) in the periosteum, often leading to the development of sinuses that discharge through the skin.

Clinical features

The presentation is usually with localised bone pain and tenderness, often accompanied by malaise, night sweats and pyrexia. The adjacent joint may be painful to move and may develop a sterile effusion or secondary septic arthritis. Where osteomyelitis is due to contiguous spread, there will be an overlying skin ulcer or wound, which often has necrotic tissue, purulent discharge and an offensive smell. In diabetic foot osteomyelitis, there may be no pain due to coexistent peripheral neuropathy.

Investigations

Patients suspected of having osteomyelitis should have an MRI, which is more sensitive than X-ray for detecting early changes. Where possible, cultures should be obtained by open or imaging-guided biopsy of the lesion. If tuberculosis is suspected, PCR-based analysis of synovial fluid or biopsy material should be considered. Evidence of osteopenia, localised osteolysis and osteonecrosis may be seen on X-ray. Blood cultures should be taken, which may also reveal the causative organism. Routine blood testing typically shows evidence of an acute phase response with neutrophilia and raised ESR and CRP.

Management

Early recognition is critical as once osteomyelitis becomes established and chronic, it may prove very hard to eradicate with antibiotics alone. Ideally, antibiotics should not be started until the microbiological cause has been established. The principles of management are as described for septic arthritis with the use of intravenous antibiotics. An exception is in localised osteomyelitis of the toes and fingers, which can often be treated successfully with a prolonged course of oral antibiotics. Resection of the infected bone and subsequent reconstruction may be required. Complications of chronic osteomyelitis include secondary amyloidosis and skin malignancy at the margin of a discharging sinus (Marjolin ulcer).

Discitis

Discitis is an unusual condition in which there is infection of the intervertebral disc, often extending into the epidural space or paravertebral soft tissues. *Staph. aureus* is the most common pathogen. Risk factors include diabetes mellitus, immunodeficiency or immunosuppressive therapy, and intravenous drug use. The presentation is with back pain accompanied by fever, and an acute phase response with high ESR and CRP and neutrophilia. If the diagnosis is suspected, an MRI should be performed and blood cultures taken. If blood cultures are negative, open or imaging-guided biopsy of the lesion should be performed to try to identify the organism responsible. Management is with supportive care and parenteral antibiotics followed by oral antibiotics, as described for osteomyelitis.

Tuberculosis

Tuberculosis (TB) of the musculoskeletal system is now rare in Europe and the United States but remains common in sub-Saharan Africa and South Asia. It has been estimated to occur in about 1%–3% of patients with TB overall. In about 50% of cases, the spine is affected (Pott disease). Tuberculous osteomyelitis can also occur. Osteoarticular TB is thought to occur as the result of haematogenous spread from the site of primary infection, but a reactive arthritis (Poncet disease) can also occur in TB in the absence of direct infection. Peripheral arthritis tends to affect weight-bearing joints such as the hip, knee and ankle, and presents with pain, swelling and restriction of movement on examination. The initial presentation of spinal TB is with back pain, progressing to cause deformity and spinal cord compression if untreated. Systemic symptoms such as fever and weight loss may or may not be present. Radiological changes develop slowly and are relatively non-specific, consisting of periarticular osteoporosis, bone erosions and joint space narrowing. In the spine, X-rays may show evidence of bone destruction and disc narrowing but appearances may be normal in early disease. Imaging with MRI is more sensitive than X-rays at detecting the features of osteoarticular TB and is the imaging investigation of first choice, although the appearances are non-specific (Fig. 25.30). The gold standard for diagnosis is synovial or tissue biopsy, which yields positive results in about 80% of cases in showing the characteristic histological features of TB. Culture of synovial fluid is positive in between 20% and 40% of cases, but examination of synovial fluid or synovial tissue by PCR can yield the diagnosis more rapidly, with positive results in more than 95% of culture-positive cases and 50%–60% of culture-negative cases. The key to treatment is to initiate appropriate antituberculous therapy. According to World Health Organization (WHO) guidelines, quadruple therapy with isoniazid, rifampicin, pyrazinamide and ethambutol should be given as first-line therapy for 2 months and followed by 4 months of isoniazid and rifampicin. Treatment may be required for extended periods of 12–18 months in some cases depending on the extent of disease and clinical response. Alternative agents may be required in patients with resistant organisms, as discussed in Chapter 17. In some cases, surgical débridement may be required for extensive peripheral joint disease and surgical decompression and stabilisation for patients with severe spinal disease.

Rheumatoid arthritis

Rheumatoid arthritis (RA) is a common form of inflammatory arthritis, occurring throughout the world and in all ethnic groups. The prevalence of RA is approximately 0.8%–1.0% in Europe and South Asia, with a

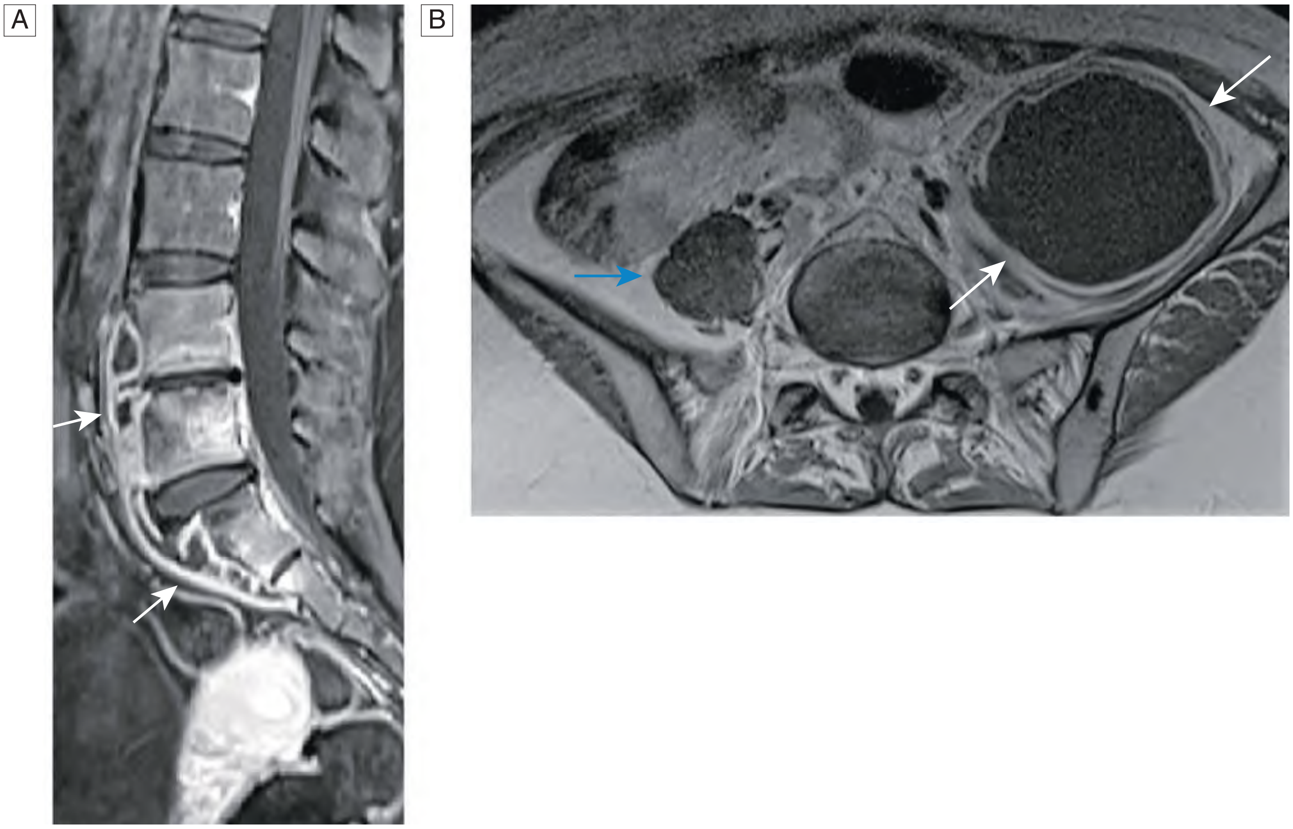

Fig. 25.30 **Tuberculosis of the spine.** A Sagittal post-contrast T1 MRI scan demonstrating enhancing L4 and L5 vertebral bodies (white arrows) in keeping with TB osteomyelitis with associated prevertebral abscess (arrows). B On the left side this is contiguous with a psoas abscess (white arrow). Note the normal right psoas muscle (blue arrow).

female-to-male ratio of 3:1. The prevalence is low in South-east Asia (0.4%) and the highest prevalence in the world is in Pima Indians (5%). It is a chronic disease characterised by a clinical course of exacerbations and remissions.

Pathophysiology

Both genetic and environmental components contribute to the occurrence of RA. The importance of genetic factors is demonstrated by higher concordance of RA in monozygotic (12%–15%) compared with dizygotic twins (3%) and an increased frequency of disease in first-degree relatives of patients. Genome-wide association studies have detected numerous loci that are associated with the risk of developing RA. The strongest association is with variants in the HLA region and is determined by variations in three amino acids in the HLA-DRβ1 molecule (positions 11, 71 and 74) and single variants in HLA-B (at position 9) and HLA-DPβ1 (at position 9). The non-HLA loci generally lie within or close to genes involved in regulating the immune response. It is believed that RA occurs when an environmental stimulus, such as infection or changes in the microbiome, trigger autoimmunity in a genetically susceptible host by modifying host proteins, through processes like citrullination, so that they become immunogenic (Fig. 25.31). However, no single specific pathogen has been identified as a cause. An important environmental risk factor is cigarette smoking, which is also associated with more severe disease and reduced responsiveness to treatment. Remission may occur during pregnancy and sometimes RA first presents post-partum. This is likely to be due to suppression of the immune response during pregnancy, but hormonal changes may also play a role.

The disease is characterised by infiltration of synovium with lymphocytes, plasma cells, dendritic cells and macrophages. There is evidence that CD4$^+$ T and B cells play important roles in the pathogenesis of RA by interacting with other cells in the synovium, as illustrated in Figure 25.31. Lymphoid follicles form within the synovium in which T- and B-cell interactions occur, causing activation of T cells to produce cytokines and activation of B cells to produce autoantibodies, including RF and ACPA. Synovial macrophages are activated by TNF-α and interferon-gamma (IFN-γ), produced by T cells. The macrophages produce several pro-inflammatory cytokines, including TNF-α, IL-1 and IL-6, which act on synovial fibroblasts to produce further cytokines, setting up a positive feedback loop. The synovial fibroblasts proliferate, causing synovial hypertrophy and producing matrix metalloproteinases and the proteinase ADAMTS-5, which degrade soft tissues and cartilage. Prostaglandins and nitric oxide produced within inflamed synovium cause vasodilatation, resulting in swelling and pain. Systemic release of IL-6 triggers production of acute phase proteins by the liver. At the joint margin, the inflamed synovium (pannus) directly invades bone and cartilage to cause joint erosions. A key pathogenic factor in bone erosions and periarticular osteoporosis is osteoclast activation, stimulated by the production of M-CSF by synovial cells and RANKL by activated T cells (see Fig. 25.31). New blood-vessel formation (angiogenesis) occurs, causing the inflamed synovium to become highly vascular. Within these blood vessels, pro-inflammatory cytokines activate endothelial cells, which support the recruitment of yet more leucocytes to perpetuate the inflammatory process.

Later, fibrous or bony ankylosis may occur. Muscles adjacent to inflamed joints atrophy and may be infiltrated with lymphocytes. This leads to progressive biomechanical joint dysfunction, which may further amplify joint destruction.

Rheumatoid nodules occur in patients who are RF- or ACPA-positive and primarily affect extensor tendons. They consist of a central area of fibrinoid material surrounded by a palisade of proliferating mononuclear cells. Granulomatous lesions may occur in the pleura, lung, pericardium and sclera.

Clinical features

The typical presentation is with pain and stiffness affecting the small joints of the hands, feet and wrists in a symmetrical fashion. Large joint involvement, systemic symptoms and extra-articular features may also occur. Clinical criteria for the diagnosis of RA are shown in Box 25.51.

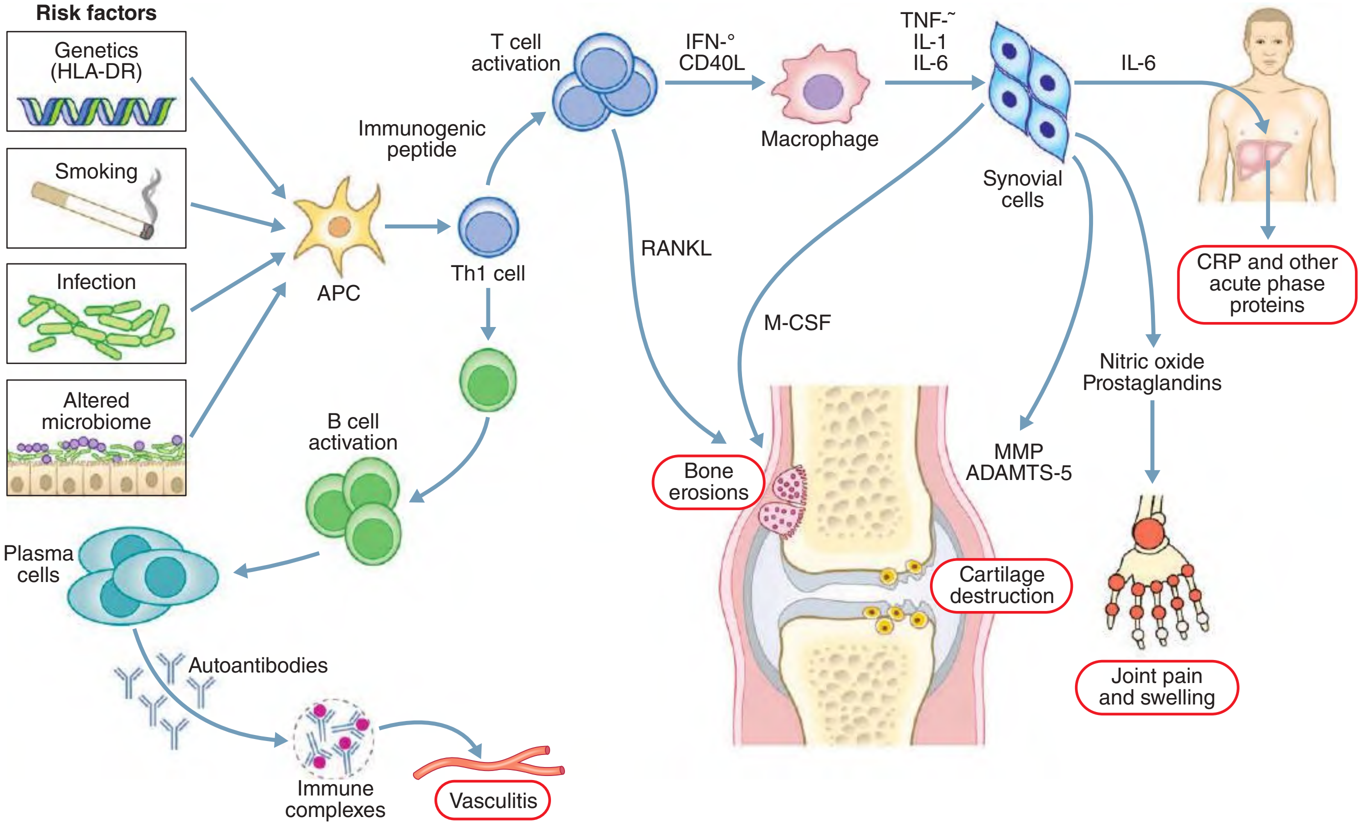

Fig. 25.31 **Pathophysiology of rheumatoid arthritis.** It is thought that trigger factors like infection, smoking or a disturbance of the microbiome cause dysregulation of the immune response in genetically susceptible individuals. This causes activation of T cells, which release cytokines that activate macrophages and synovial cells leading to joint swelling pain and inflammation, bone erosions, tissue damage and production of acute phase proteins by the liver. Activation of B cells occurs, leading to production of autoantibodies. (ADAMTS-5 = aggrecanase; APC = antigen-presenting cell; CD40L = CD40 ligand; CRP = C-reactive protein; HLA = human leucocyte antigen; IFN = interferon; IL = interleukin; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; RANKL = receptor activator of nuclear factor kappa B ligand; TNF = tumour necrosis factor)

Sometimes RA has an acute onset, with severe early morning stiffness accompanied by florid synovitis and pitting oedema, but a gradual onset is more typical. Occasionally the presentation is with proximal muscle stiffness mimicking polymyalgia rheumatica. The onset can be palindromic, with relapsing and remitting episodes of pain, stiffness and swelling that last for only a few hours or days and then disappear (palindromic rheumatism). Some of these individuals go on to develop classical RA, but in others the symptoms regress spontaneously.

Examination most often reveals swelling and tenderness of the affected joints, but others present with little in the way of physical signs apart from tenderness of the affected joints. Erythema is unusual, and its presence suggests coexistent infection. Characteristic deformities may develop with long-standing uncontrolled disease, although these have become less common over recent years with more aggressive management. They include ulnar deviation of the fingers, 'swan neck' deformity, the boutonnière or 'button hole' deformity and a Z deformity of the thumb (Fig. 25.32). Dorsal subluxation of the ulna at the distal radio-ulnar joint may occur and contribute to rupture of the fourth and fifth extensor tendons. Triggering of fingers may occur because of nodules in the flexor tendon sheaths. Subluxation of the MTP joints of the feet may result in 'cock-up' toe deformities, causing pain on weight-bearing on the exposed MTP heads and the development of secondary adventitious bursae and callosities. In the hindfoot, a valgus deformity of the calcaneus may be observed as the result of damage to the posterior tibial tendon, and the ankle and subtalar joints. This is often associated with loss of the longitudinal arch (flat foot) due to rupture of the tibialis posterior tendon. Popliteal (Baker) cysts may occur in patients with knee synovitis, in which synovial fluid communicates with the cyst, but is prevented from returning to the joint by a valve-like mechanism, but this is not specific to RA. Rupture may be induced by knee flexion, leading to calf pain and swelling that may mimic a deep venous thrombosis (DVT).

25.51 Criteria for diagnosis of rheumatoid arthritis*

Criterion	Score
Joints affected	
1 large joint	0
2–10 large joints	1
1–3 small joints	2
4–10 small joints	3
> 10 joints (at least 1 small joint)	5
Serology	
Negative RF and ACPA	0
Low positive RF or ACPA	2
High positive RF or ACPA	3
Duration of symptoms	
< 6 weeks	0
> 6 weeks	1
Acute phase reactants	
Normal CRP and ESR	0
Abnormal CRP or ESR	1
Patients with a score ≥ 6 are considered to have definite RA.	

*European League Against Rheumatism/American College of Rheumatology 2010 criteria. (ACPA = anti-citrullinated peptide antibody; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; RF = rheumatoid factor)

Systemic features

Anorexia, weight loss and fatigue may occur throughout the disease course. Osteoporosis is a common complication and muscle-wasting may occur as the result of systemic inflammation and reduced activity. Extra-articular features are most common in patients with long-standing seropositive erosive disease, but may occasionally occur at presentation,

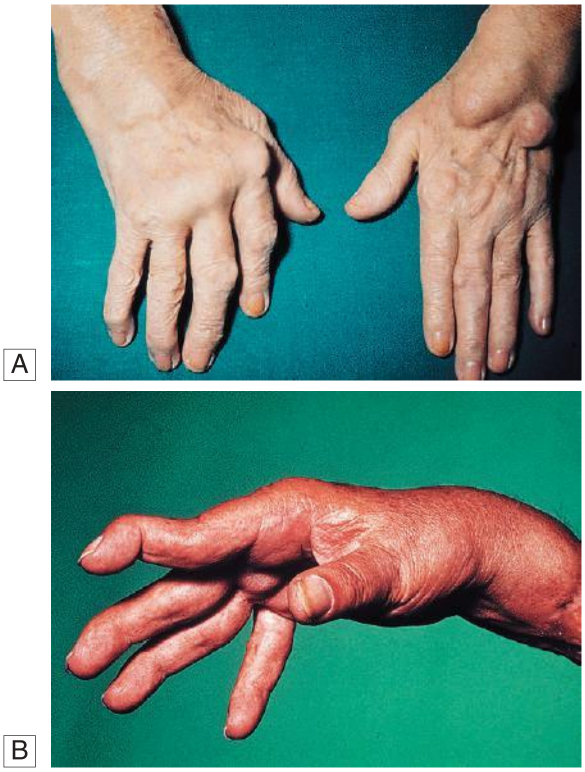

Fig. 25.32 The hand in rheumatoid arthritis. A Ulnar deviation of the fingers with wasting of the small muscles of the hands and synovial swelling at the wrists, the extensor tendon sheaths, the metacarpophalangeal and proximal interphalangeal joints. B 'Swan neck' deformity of the fingers.

especially in men. Most are due to serositis, granuloma and nodule formation or vasculitis (Box 25.52).

Nodules

Rheumatoid nodules occur almost exclusively in RF or ACPA-positive patients, usually in extensor tendons (Fig. 25.33). They are frequently asymptomatic, but some may be complicated by ulceration and secondary infection. Nodules are more common in smokers.

Vasculitis

This is uncommon but may occur in seropositive patients. The presentation is with systemic symptoms, such as fatigue and fever and nail-fold infarcts. Rarely, cutaneous ulceration, skin necrosis and mesenteric, renal or coronary artery occlusion may occur.

Ocular involvement

The most common symptom is dry eyes (keratoconjunctivitis sicca) due to secondary Sjögren syndrome. Scleritis and peripheral ulcerative keratitis are uncommon but are more serious and potentially sight-threatening complications that usually present with pain and redness. Clinical features and management are discussed in more detail in Chapter 28.

Serositis

Serositis is usually asymptomatic but may present with pleural or pericardial pain and breathlessness. Pericardial effusion and constrictive pericarditis may rarely occur.

Cardiac involvement

Heart block, cardiomyopathy, coronary artery occlusion and aortic regurgitation have all been reported but are rare. The risk of cardiovascular disease is increased due to a combination of conventional risk factors, such as high cholesterol, smoking, hypertension, reduced physical activity, NSAIDs, glucocorticoids and the effects of inflammatory cytokines on vascular endothelium.

25.52 Extra-articular manifestations of rheumatoid disease

Systemic

- Fever
- Weight loss
- Fatigue
- Susceptibility to infection

Musculoskeletal

- Muscle-wasting
- Tenosynovitis
- Bursitis
- Osteoporosis

Haematological

- Anaemia
- Thrombocytosis
- Eosinophilia

Lymphatic

- Felty syndrome (Box 25.53)
- Splenomegaly

Nodules

- Sinuses
- Fistulae

Ocular

- Episcleritis
- Scleritis
- Scleromalacia
- Keratoconjunctivitis sicca

Vasculitis

- Digital arteritis
- Ulcers
- Pyoderma gangrenosum
- Mononeuritis multiplex
- Visceral arteritis

Cardiac

- Pericarditis
- Myocarditis
- Endocarditis
- Conduction defects
- Coronary vasculitis
- Granulomatous aortitis

Pulmonary

- Nodules
- Pleural effusions
- Pulmonary fibrosis
- Obliterative bronchiolitis
- Caplan syndrome
- Bronchiectasis
- Pneumothorax

Neurological

- Cervical cord compression
- Compression neuropathies
- Peripheral neuropathy
- Mononeuritis multiplex

Amyloidosis

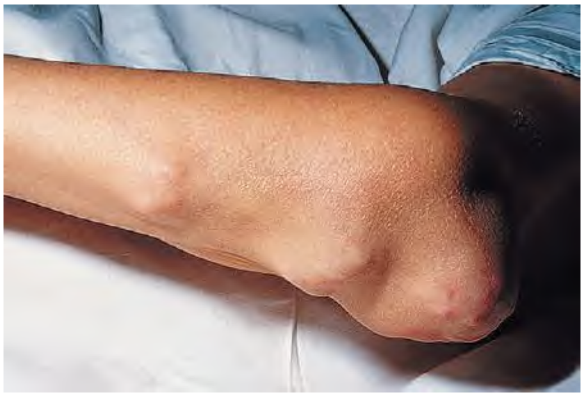

Fig. 25.33 Rheumatoid nodules and olecranon bursitis. Nodules were palpable within, as well as outside, the bursa.

Pulmonary involvement

Pulmonary fibrosis may occur but is often asymptomatic. There is some evidence that the risk of pulmonary fibrosis is increased by anti-TNF-α therapy, although it is uncertain whether this is causal or a marker of more severe disease in patients who require anti-TNF-α treatment.

Peripheral neuropathy

Entrapment neuropathies may result from compression by hypertrophied synovium or by joint subluxation. Median nerve compression is the most common, and bilateral carpal tunnel syndrome can occur as a presenting feature of RA. Other syndromes include ulnar nerve compression at the elbow or wrist, compression of the lateral popliteal nerve at the head of the fibula, and tarsal tunnel syndrome (entrapment of the posterior tibial nerve in the flexor retinaculum), which causes burning, tingling and numbness in the distal sole and toes. Diffuse symmetrical peripheral neuropathy and mononeuritis multiplex may occur in patients with rheumatoid vasculitis.

Spinal cord compression

This rare complication is caused by compression of the spinal cord from subluxation of the cervical spine at the atlanto-axial joint or at a subaxial level (Fig. 25.34). Atlanto-axial subluxation is due to erosion of the transverse ligament posterior to the odontoid peg. It can lead to cord compression or sudden death following minor trauma or manipulation. It should be suspected in any RA patient who describes new onset of occipital headache, particularly if symptoms of paraesthesia or electric shock are present in the arms. The onset is often insidious, with subtle loss of function that may initially be attributed to active disease. Reflexes and power can be difficult to assess in patients with extensive joint disease and therefore sensory or upper motor signs are most important. Patients with evidence of spinal cord compression require urgent neurosurgical referral for stabilisation and fixation.

Other complications

Amyloidosis is a rare complication of long-standing disease that usually presents with nephrotic syndrome. Microcytic anaemia can occur due to iron deficiency resulting from NSAID-induced gastrointestinal blood loss, whereas normochromic, normocytic anaemia with thrombocytosis occurs in patients with active disease. Felty syndrome is a rare complication of seropositive RA in which splenomegaly occurs in combination with neutropenia and thrombocytopenia (Box 25.53). Localised or generalised lymphadenopathy can occur in patients with active disease, but persistent lymphadenopathy may indicate the development of lymphoma, the risk of which is increased in patients with long-standing RA.

Investigations

The diagnosis of RA is essentially clinical, but investigations are useful in confirming the diagnosis and assessing disease activity (Box 25.54). The ESR and CRP are usually raised, but normal results do not exclude the diagnosis, especially if only a few joints are involved. Tests for ACPA are positive in about 70% of cases and are highly specific for RA, occurring in many patients before clinical onset of the disease. Similarly, RF is also positive in about 70% of cases, most of whom also test positive for ACPA. RF is less specific than ACPA, however, and positive tests can occur in other diseases (see Box 25.7).

Ultrasound examination and MRI are not routinely required but are of value in patients with symptoms suggestive of RA where there is clinical uncertainty about the presence of synovitis. Plain X-rays of the hands, wrist and feet are usually normal in early RA, but periarticular osteoporosis and marginal joint erosions may be observed with more advanced disease. The main indication for an X-ray is in the assessment of patients with established disease to determine whether significant structural

25.53 Felty syndrome

Risk factors

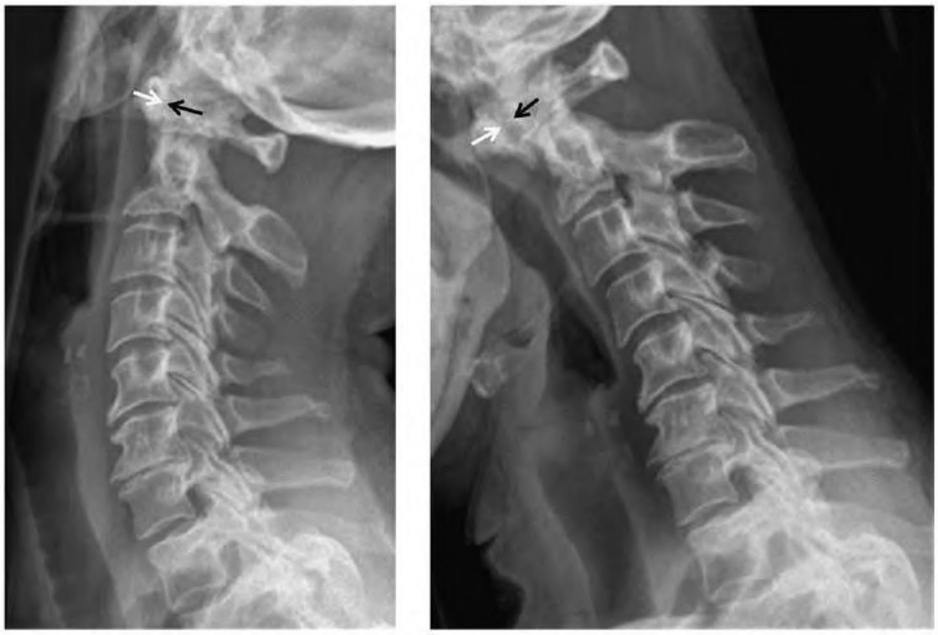
- Age of onset 50–70 years
- Female > male
- European > African ancestry
- Long-standing rheumatoid arthritis
- Deforming, but inactive disease
- Seropositive for rheumatoid factor

Common clinical features

- Splenomegaly
- Lymphadenopathy
- Weight loss
- Skin pigmentation
- Keratoconjunctivitis sicca
- Vasculitis, leg ulcers
- Recurrent infections
- Nodules

Laboratory findings

- Normochromic, normocytic anaemia
- Neutropenia
- Abnormal liver function
- Thrombocytopenia
- Impaired T- and B-cell immunity



EXTENSION FLEXION

Fig. 25.34 **Subluxation of the cervical spine.** Patient with RA with widening of the space between the anterior arch of the atlas (white arrow) and the odontoid peg of the axis (black arrow) to 10 mm on the flexion view (normal on the extension view).

25.54 Investigations and monitoring of rheumatoid arthritis

To establish diagnosis

- Clinical criteria
- Erythrocyte sedimentation rate and C-reactive protein
- Ultrasound or magnetic resonance imaging
- Rheumatoid factor and anti-citrullinated peptide antibodies

To monitor disease activity and drug efficacy

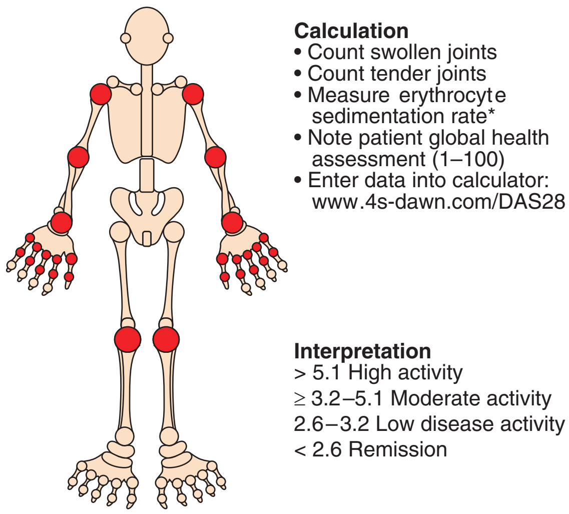
- Pain (visual analogue scale)
- Early morning stiffness (minutes)
- Joint tenderness
- Joint swelling
- DAS28 (Fig. 25.35)
- Erythrocyte sedimentation rate and C-reactive protein

To monitor disease damage

- X-rays
- Functional assessment

To monitor drug safety

- Urinalysis
- Full blood count
- Chest X-ray
- Urea and creatinine
- Liver function tests



Calculation
• Count swollen joints
• Count tender joints
• Measure erythrocyte sedimentation rate*
• Note patient global health assessment (1–100)
• Enter data into calculator: www.4s-dawn.com/DAS28
Interpretation
> 5.1 High activity
≥ 3.2–5.1 Moderate activity
2.6–3.2 Low disease activity
< 2.6 Remission

Fig. 25.35 Calculation of the Disease Activity Score 28 (DAS28). *Erythrocyte sedimentation rate or C-reactive protein can be used for the calculation.

damage has occurred. Patients who are suspected of having atlanto-axial disease should have lateral X-rays taken in flexion and extension, and an MRI. In those with suspected Baker cyst, ultrasound may be required to establish the diagnosis.

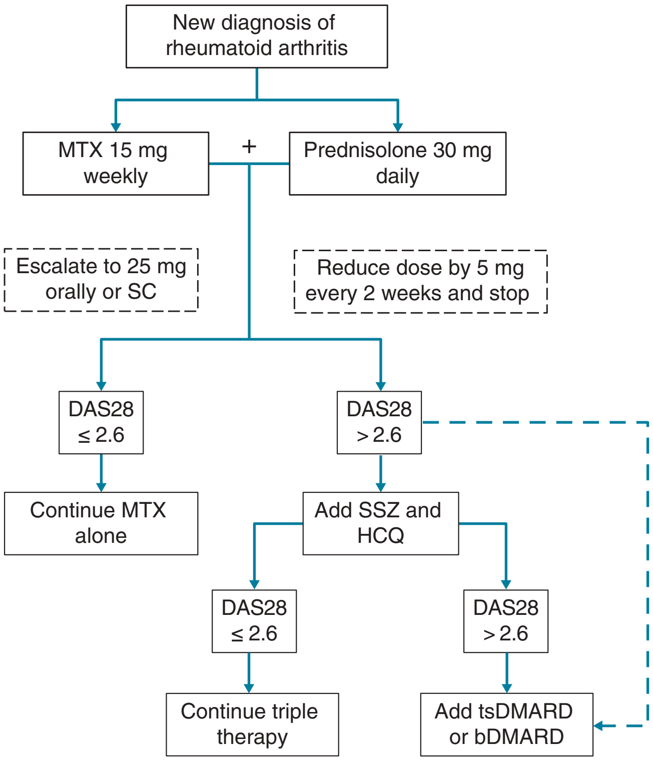
The Disease Activity Score in 28 joints (DAS28) is widely used to assess disease activity, response to treatment and need for biologic therapy. It involves counting the number of swollen and tender joints in the upper limbs and knees and combining this with the ESR or CRP and the patient's assessment of the activity of their arthritis on a visual analogue scale, where 0 indicates no symptoms and 100 the worst symptoms possible. Data are entered into a calculator to generate a numerical score. The higher the value, the more active the disease (Fig. 25.35).

Management

The treatment goal is to suppress inflammation, control symptoms, prevent joint damage and maintain function. This involves a combination of pharmacological and non-pharmacological therapies. When RA occurs in women of child-bearing age, additional considerations need to be taken into account, and these are summarised in Box 25.55.

25.55 Rheumatoid arthritis in pregnancy

- **Immunological changes in pregnancy**: many patients with rheumatoid arthritis go into remission during pregnancy.
- **Conception**: methotrexate should be discontinued for ≥ 3 months and leflunomide discontinued for ≥ 24 months before trying to conceive.
- **Paracetamol**: the oral analgesic of choice during pregnancy.
- **Oral non-steroidal anti-inflammatory drugs and selective cyclo-oxygenase 2 (COX-2) inhibitors**: can be used from implantation to 20 weeks' gestation.
- **Glucocorticoids**: may be used to control disease flares; the main maternal risks are hypertension, glucose intolerance and infection.
- **csDMARDs that may be used**: sulfasalazine, azathioprine and hydroxychloroquine if required to control inflammation.
- **csDMARDs that must be avoided**: methotrexate, leflunomide, cyclophosphamide and mycophenolate.
- **Biologic** therapy experience is limited but anti-TNF-α therapy appears to be safe during pregnancy. The main risk is immunosuppression in the neonate, except for certolizumab, which does not cross the placenta in appreciable amounts.
- **Breastfeeding**: methotrexate, leflunomide and cyclophosphamide are contraindicated.



New diagnosis of rheumatoid arthritis
MTX 15 mg weekly
+
Prednisolone 30 mg daily
Escalate to 25 mg orally or SC
Reduce dose by 5 mg every 2 weeks and stop
DAS28 ≤ 2.6
DAS28 > 2.6
Continue MTX alone
Add SSZ and HCQ
DAS28 ≤ 2.6
DAS28 > 2.6
Continue triple therapy
Add tsDMARD or bDMARD

Fig. 25.36 Algorithm for the management of rheumatoid arthritis. (bDMARD = biological DMARD; DAS28 = Disease Activity Score 28; DMARD = disease-modifying antirheumatic drug; HCQ = hydroxychloroquine; MTX = methotrexate; SC = subcutaneous; SSZ = sulfasalazine; tsDMARD = targeted synthetic DMARD)

Pharmacological therapy

Prompt initiation of csDMARD therapy is indicated in all patients as this improves outcome. A variety of therapeutic regimens exist based on a treat-to-target approach with the aim of achieving remission or low disease activity. A typical algorithm is shown in Figure 25.36. For example: on diagnosis, prednisolone can be started in a dose of 30 mg daily gradually reducing in 5 mg increments every 2 weeks until therapy is withdrawn after about 12 weeks. At the same time, oral or subcutaneous methotrexate (MTX) should be started at an initial dose of 15 mg weekly, along with folic acid 5 mg weekly 24 hours after MTX, and escalated up to a maximum of 25 mg weekly, depending on the response. If the patient fails to respond adequately or dose-limiting toxicity occurs, then additional csDMARDs can be commenced with MTX. A common combination is triple therapy, in which MTX, SSZ and HCQ are combined. Alternatively, a tsDMARD or bDMARD can be initiated in patients who still have moderate disease activity despite MTX treatment (see Fig. 25.36). Leflunomide 10–20 mg daily can be used as an alternative to MTX. The first-line bDMARD in RA is anti-TNF-α therapy because of cost, but several other options are available both in terms of tsDMARDs (see Box 25.34) and other bDMARDs (see Box 25.35). A reduction in biologic dose can be considered in patients who have been stable for 12 months or more on therapy, since it is possible to reduce the dose in up to 50% of patients without loss of therapeutic effect. The efficacy and durability of response to biologics is enhanced by co-treatment with MTX which is thought to inhibit the production of anti-drug antibodies.

Disease flares can occur from time to time even in patients who are established on DMARD and biologic therapy. Transient flares can be dealt with by local joint or intramuscular (IM) steroid injection or a short course of oral prednisolone, but if a sustained flare occurs, a change in DMARD should be considered.

Non-pharmacological therapy

Physiotherapy, occupational therapy and psychology support are all important for RA patients. Liaison with social services may be appropriate and may enhance the holistic support of patients whose lives are changed by the chronic disease. Patient-run charitable organisations can offer a wealth of education and support to RA patients and their families.

Surgery

Synovectomy can be helpful in joints that have failed to respond adequately to systemic therapy and intra-articular injections. Joint arthroplasty may be required where secondary OA evolves, but the need for this has diminished as the result of more aggressive medical management. Other surgical procedures that can be helpful are metatarsal osteotomies, ulnar head excision, wrist synovectomy (to prevent overlying extensor tendon rupture) and upper cervical spine fusion where there is progressive atlanto-axial subluxation. Joint fusion (wrist or triple hindfoot) can reduce pain where there is evidence of joint damage (see Box 25.28).

Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the term accepted by the international community for several forms of arthritis (Box 25.56) based on the International League of Associations for Rheumatology 2001 criteria. This includes juvenile forms of psoriatic arthritis (JPsA), rheumatoid arthritis (JRA) and more undifferentiated forms of inflammatory arthritis. Most patients with JIA have a phenotype that is distinct from adult inflammatory arthritis and includes a strong association with uveitis. JIA affects about 1:1000 children and young people up to 16 years of age – similar to the prevalence of diabetes (1:700). The annual incidence is approximately 1 per 10 000 children and young people.

Whereas restricted joint movement is usually caused by joint damage in adults, in children it indicates inflammatory activity. Arthritis in children affects limb growth and can negatively impact on attainment of final height and weight. In young children, effective disease control can repair joint damage before puberty.

Oligoarthritis is the most common form of JIA, accounting for about 60% of cases. It is more common in females and tends to affect large joints in an asymmetrical pattern. There is an association with uveitis and many patients are ANA-positive. Polyarticular JIA is heterogeneous: some patients are RF and/or ACPA-positive, while others are negative for autoantibodies.

Systemic juvenile idiopathic arthritis (sJIA, formerly known as Still disease) is characterised by fever, rash, arthritis, hepatosplenomegaly and serositis in association with anaemia and a raised ESR and CRP. Autoantibody tests are negative. This form of JIA can be associated with haemophagocytic lymphohistiocytosis (HLH) where there is life-threatening activation of immune cells. It is discussed in more detail in Chapter 24.

Many cases of enthesitis-related arthritis (ERA) are likely to be self-limiting forms of axSpA. This can progress over time into a more obviously defined axSpA.

Investigations

The ESR and CRP do not correlate well with the extent or severity of inflammation and may be normal. A very high ESR may indicate the presence of inflammatory bowel disease or (very rarely) leukaemia. Low haemoglobin is likely to be due to anaemia of chronic disease rather than iron deficiency. A positive ANA occurs in 40%–75% of cases of JIA and indicates an increased risk of eye disease. Ultrasound is the radiological investigation of choice to confirm synovitis or tenosynovitis. The false-negative rate is higher in foot and ankle disease than in other joints. Arthroscopy should be avoided unless a biopsy is required. Synovial fluid aspiration is essential if there is suspicion of infection.

Management

The key approach is to gain early rapid control of inflammation, minimise the adverse effects of treatment and support the general physical and mental health of the patient, and family, which requires full multidisciplinary team input. Standard therapy is MTX (subcutaneous MTX is typically used in young children). Alternative treatments include LEF, SSZ and HCQ. AZA and ciclosporin can be used to treat JIA with uveitis. MMF and tacrolimus are considered to have a specific role in treating uveitis alone. Where csDMARDs fail, biologics (see Box 25.35), including anti-TNF-α, abatacept and tocilizumab, are effective, though precise indications vary in different parts of the world according to local protocols and guidelines. Anakinra and canakinumab can be used to treat sJIA.

Prognosis

Suboptimal outcomes are associated with delayed diagnosis and referral to the specialist multidisciplinary team, inadequate disease control, presentation with uveitis, sJIA in males and poor engagement with services. Psychological support of affected children and their families is associated

i 25.56 The main clinical features of juvenile idiopathic arthritis

Subtype	Frequency	Clinical features	Immunology
Systemic juvenile idiopathic arthritis	5%	Fever, rash, arthralgia, hepatosplenomegaly	Autoantibody-negative
Oligoarthritis (≤ 4 joints)	60%	Large-joint arthritis, uveitis	ANA-positive
Polyarthritis (≥ 5 joints)	20%	Polyarthritis; may be extended form of oligoarthritis	ANA-positive
Enthesis-related	5%	Sacroiliitis, enthesopathy	HLA-B27-positive
RF-positive	5%	Polyarthritis, similar to RA	RF-positive, ACPA-positive
Psoriatic arthritis	5%	Same as adult disease	Autoantibody-negative

(ACPA = anti-citrullinated peptide antibody; ANA = antinuclear antibody; HLA = human leucocyte antigen; RA = rheumatoid arthritis; RF = rheumatoid factor)

25.57 Juvenile idiopathic arthritis in adolescence

- **Uveitis**: may be clinically silent and persists into adulthood. All (not just those who are ANA-positive) need ophthalmic screening for eye involvement.
- **Persistence into adulthood** occurs in 50% of cases, especially in systemic disease. Specific supportive management through transition from adolescence to adulthood should be planned.
- **Reduced peak bone mass**: common in polyarthritis and systemic juvenile idiopathic arthritis, but there are few data on fracture risk and the evidence base for treatment is poor.
- **Therapy**: methotrexate is standard treatment, used after NSAIDs alone are insufficient. Anti-TNF therapy is effective in all forms of juvenile idiopathic arthritis, but long-term safety remains unclear.

25.58 Features common to all spondyloarthritides

- Asymmetrical inflammatory oligoarthritis (lower > upper limb)
- History of inflammatory back pain
- Sacroiliitis
- Osteitis (bone marrow oedema on MRI)
- Enthesitis (Achilles tendinitis, plantar fasciitis)
- Dactylitis
- Family history of axSpA common
- HLA-B27 association
- Psoriasis (of skin and/or nails)
- Uveitis
- Sterile urethritis and/or prostatitis
- Inflammatory bowel disease
- Aortic root lesions* (aortic incompetence, conduction defects)

*Not recognised in psoriatic disease.
(HLA = human leucocyte antigen; MRI = magnetic resonance imaging)

with improved outcome. Oligo-JIA often resolves at puberty. Polyarticular disease and sJIA remain active into adulthood in about 50% of cases. Common issues around the transition of adolescent patients into adulthood are shown in Box 25.57.

Spondyloarthritides

The spondyloarthritides comprise a group of related inflammatory diseases that show overlap in their clinical features and have a shared immunogenetic association with HLA-B27 (Box 25.58). The spectrum of spondyloarthritis (SpA) includes:

- axial spondyloarthritis (axSpA) comprising:
  - non-radiographic SpA (nr-axSpA)
  - radiographic axSpA (ankylosing spondylitis [AS])
- reactive SpA
- psoriatic arthritis
- enteropathic SpA (arthritis associated with inflammatory bowel disease).

In axSpA the axial skeleton is predominantly affected. In contrast to RA, there are frequent and notable non-synovial musculoskeletal lesions – mainly inflammatory in nature – of ligaments, tendons, periosteum and other bone lesions in SpA. A hallmark lesion of SpA is enthesitis, which is inflammation at the site of a ligament or tendon insertion into bone. Dactylitis, inflammation of a whole finger or toe, may also occur (see Fig. 25.42).

It has been estimated that about 1% of the adult population in the United States may have an SpA (about 2.7 million). There is a striking association with HLA-B27, particularly for AS > 95%, which affects men more commonly than women in a ratio of about 3:1. In Europe, more than 90% of those affected are HLA-B27-positive (HLA-B27 population prevalence in those of European origin is about 9%). The overall prevalence of AS is below 0.5% in most populations. Additionally, SpAs are thought to arise as the result of an aberrant host response to infection and abnormal mucosal immunity primarily mediated through increased production of IL-23, which in turn causes activation of Th17 lymphocytes that produce IL-17, TNF-α and other inflammatory cytokines. In some situations, a triggering organism can be identified, as in reactive arthritis following bacterial dysentery or chlamydial urethritis, but in others the environmental trigger remains obscure. Familial clustering not only is common to the specific condition occurring in the proband but also may extend to other diseases in the SpA group.

25.59 Assessment of SpondyloArthritis International Society (ASAS) criteria for axial spondyloarthritis

In patients with > 3 months' back pain and age at onset < 45 years, either A or B is present:

A: Sacroiliitis on imaging* plus ≥ 1 SpA feature	B: HLA-B27 plus ≥ 2 SpA features

SpA features are:

- Inflammatory back pain
- Arthritis
- Enthesitis (heel)
- Uveitis
- Dactylitis
- Psoriasis
- Crohn disease/colitis
- Good response to NSAIDs
- SpA family history
- HLA-B27
- Elevated CRP

*'Sacroiliitis on imaging' here is defined as *either* active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA, *or* definite radiographic sacroiliitis according to the modified New York criteria.
(CRP = C-reactive protein; HLA = human leucocyte antigen; MRI = magnetic resonance imaging; NSAID = non-steroidal anti-inflammatory drug)

Axial spondyloarthritis

Axial spondyloarthritis (axSpA) is the diagnostic term that includes patients with non-radiographic axial SpA (nr-axSpA) and ankylosing spondylitis (AS, also termed radiographic axSpA). The diagnostic criteria for axSpA are shown in Box 25.59. Inflammatory changes in the axial skeleton (such as sacroiliitis, see Fig. 25.38) are characteristic of axSpA and are best visualised by MRI. Radiographic alterations, such as new bone formation with syndesmophytes and ankylosis, develop later in the course of the disease and, by definition, are not present in patients with nr-axSpA. A diagnosis of AS (radiographic axSpA), which requires evidence of these radiographic changes on X-ray, can often only be made many years after a patient's symptoms started. It is important to recognise that not all patients with nr-axSpA will go on to develop AS.

Pathophysiology

Axial SpA arises from an interaction between environmental pathogens and the host immune system in genetically susceptible individuals (Fig. 25.37). There is increasing evidence that axSpA is due to an abnormal host response to the intestinal microbiota with involvement of Th17 cells, which have a key role in mucosal immunity. This leads to production of various cytokines, including IL-23, IL-17 and TNF-α, which play key roles in the pathogenesis of enthesitis, other inflammatory lesions, local bone erosions and systemic osteoporosis. The mechanisms by which osteosclerosis and syndesmophytes occur in axSpA are not well understood. The T-cell cytokine IL-22 has been identified as a potential mediator, but various coupling factors are released during bone resorption which promote bone formation (see Fig. 25.2) and they may also play a role in the skeletal effects of axSpA pathophysiology (see Fig. 25.37).

There is a strong association between axSpA and carriage of the major histocompatibility complex (MHC) class I molecule HLA-B27. This is particularly striking in patients defined as having AS, more than 95% of whom are positive for HLA-B27. Other susceptibility genes also implicated in susceptibility to AS include ERAP-1 (an endoplasmic reticulum protein with a role facilitating intracellular antigen processing and binding with its presenting MHC molecule HLA-B27), the IL-23 receptor and downstream signalling molecules involved in directing Th17 cell responses, such as STAT3 (see Fig. 4.3). The

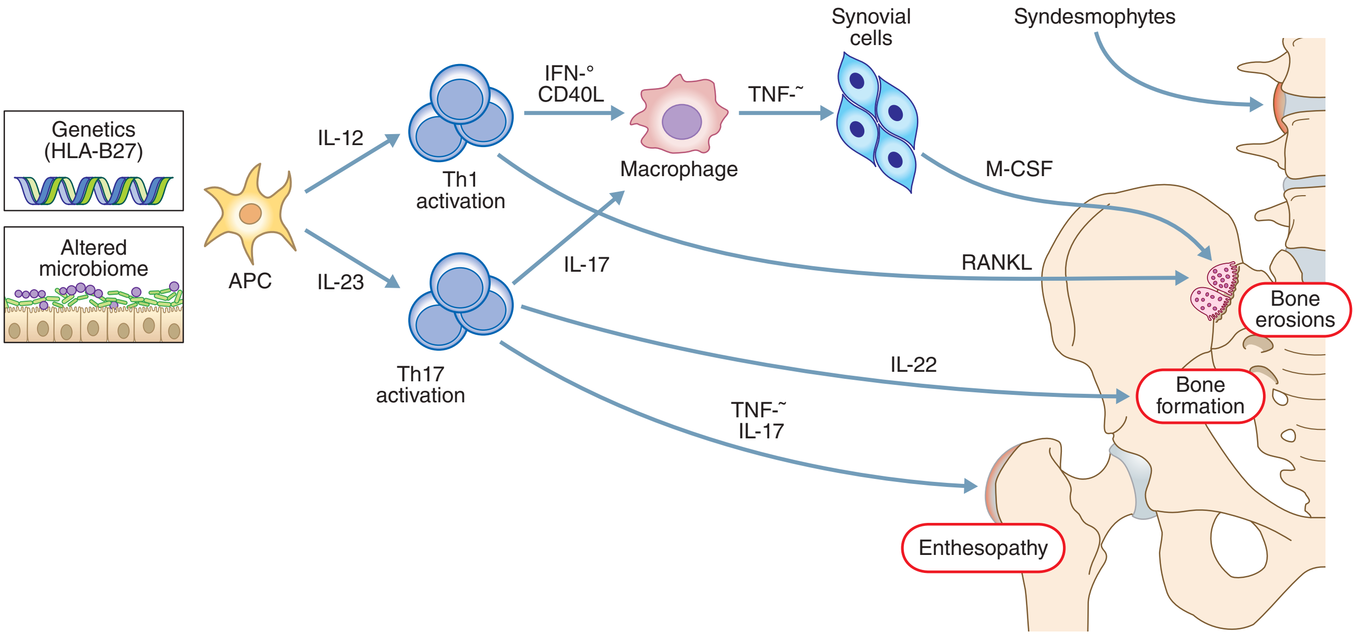


Fig. 25.37 Pathophysiology of axial spondyloarthritis. In genetically susceptible individuals, it is thought that bacterial components penetrate the mucosal barrier to activate antigen-presenting cells (APCs) in the intestinal submucosa. These cells produce increased amounts of interleukin (IL)-23, which activate Th17 cells resulting in production of IL-17, tumour necrosis factor (TNF)-α and other inflammatory mediators. IL-17 has a pivotal role in driving inflammation, causing sacroiliitis and enthesitis. Possible mediators of new bone formation in axSpA include IL-22 produced by T cells or coupling factors released during the process of osteoclastic bone resorption. (CD40L = CD40 ligand; IFN-γ = interferon gamma; M-CSF = macrophage colony-stimulating factor; RANKL = receptor activator of nuclear factor kappa B ligand)

HLA-B27 molecule itself is implicated through its antigen-presenting function or because of its propensity to form homodimers that activate leucocytes. HLA-B27 molecules may also misfold, causing increased endoplasmic reticulum stress. This could lead to inflammatory cytokine release by macrophages and dendritic cells, thus triggering inflammatory disease.

Clinical features

The cardinal feature of axSpA is inflammatory back pain and early morning stiffness, with low back pain radiating to the buttocks or posterior thighs if the sacroiliac joints are involved. Symptoms are exacerbated by inactivity and relieved by movement. Musculoskeletal symptoms may be prominent at entheses, may be episodic and, if persistent, can present as widespread pain and be mistaken for fibromyalgia. Fatigue is common. A history of psoriasis (current, previous or in a first-degree relative) and inflammatory bowel symptoms (current or previous) are important clues. Physical signs include a reduced range of lumbar spine movements in all directions, pain on sacroiliac stressing and a high enthesitis index. Entheses that are typically affected include Achilles insertion, plantar fascia origin, patellar ligament entheses, gluteus medius insertion at the greater trochanter and tendon attachments at humeral epicondyles. Acute anterior uveitis is the most common extra-articular feature, which occasionally precedes joint disease. The extent of extra-articular features is shown in Box 25.60.

A number of validated clinical questionnaires, such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath Ankylosing Spondylitis Functional Index (BASFI) and Ankylosing Spondylitis Disease Activity Score (ASDAS-CRP), can be used to assess disease activity and functional status.

Spinal fusion can develop as AS progresses, but it does so over many years, varies in its extent and in most cases does not cause a gross flexion deformity. However, a few patients develop marked kyphosis of the dorsal and cervical spine that may interfere with forward vision. This may prove incapacitating, especially when associated with fixed flexion contractures of hips or knees. Osteoporosis is a common complication, particularly of the spine, leading to an increased risk of vertebral fracture.

i **25.60 Extra-articular features of axial spondyloarthritis**

- Fatigue, anaemia
- Anterior uveitis (25%)
- Prostatitis (80% of men) and sterile urethritis
- Inflammatory bowel disease (in up to 50%)
- Osteoporosis
- Osteoproliferation and osteosclerosis
- Cardiovascular disease (aortic valve disease 20%)
- Amyloidosis (rare)
- Atypical upper lobe pulmonary fibrosis (very rare)

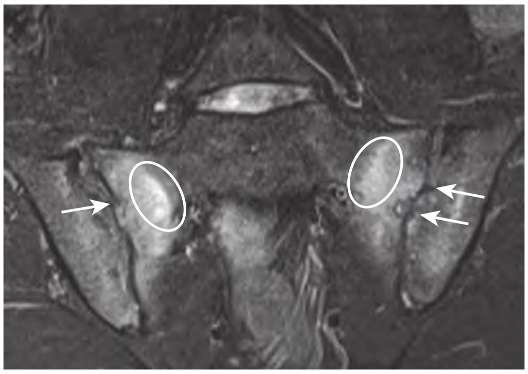

Fig. 25.38 Magnetic resonance imaging appearances in sacroiliitis. Coronal MRI short T1 inversion recovery (STIR) sequence showing bilateral sacroiliitis in axial spondyloarthritis. Bone marrow oedema (circles) is present around both sacroiliac joints, which show irregularities due to erosions (arrows).

Investigations

The diagnosis of axSpA is aided by ultrasound or MRI of entheses, or by MRI of the sacroiliac joints and spine (Fig. 25.38). Other findings may include raised ESR and CRP (although these can be normal), anaemia and positive HLA-B27. Faecal calprotectin is a useful screening test for associated inflammatory bowel disease.

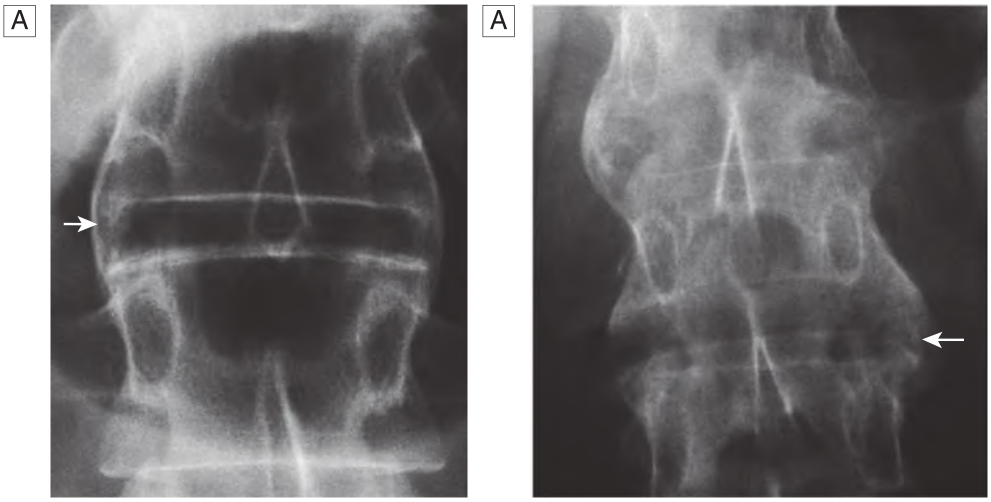

Fig. 25.39 Radiographic changes in A axial spondyloarthritis (axSpA; given radiographic changes so termed ankylosing spondylitis [AS]) and in B psoriatic spondylitis. **A** Fine symmetrical marginal syndesmophytes typical of AS (arrow). **B** Coarse, asymmetrical non-marginal syndesmophytes more typical of psoriatic spondylitis (arrow).

By definition, abnormalities are not seen in X-rays in nr-axSpA. In AS, X-rays of the sacroiliac joint show irregularity and loss of cortical margins, widening of the joint space and subsequently sclerosis, joint space narrowing and fusion. Lateral thoracolumbar spine X-rays may show anterior 'squaring' of vertebrae due to erosion and sclerosis of the anterior corners and periostitis of the waist. Bridging syndesmophytes may also be seen. These are areas of calcification that follow the outermost fibres of the annulus (Fig. 25.39). In advanced disease, ossification of the anterior longitudinal ligament and facet joint fusion may also be visible. The combination of these features may result in the typical 'bamboo' spine (Fig. 25.40). Erosive changes may be seen in the symphysis pubis, ischial tuberosities and peripheral joints. Osteoporosis is common and vertebral fractures may occur. Atlanto-axial dislocation can arise as a late feature. MRI is more sensitive for detection of early sacroiliitis than X-rays (see Fig. 25.38) and can also detect inflammatory changes in the lumbar spine. DXA scanning or vertebral quantitative CT can be performed as part of a fragility fracture risk assessment.

Management

Patient education, NSAID use (optimally, once daily or slow release taken at bedtime) and physical therapy are key interventions at the outset. For severe and/or persistent peripheral joint involvement, a trial of SSZ or MTX should be considered. These medications have no impact on spinal symptoms or axial skeletal disease progression.

In patients with axial skeletal disease who fail to respond to, or who cannot tolerate, NSAIDs, and those with peripheral SpA who fail SSZ therapy, progression to biologic therapy with either TNF-α, an IL-17 inhibitor or a JAKi should be considered. In general, following current trends, one of the two bDMARDs is chosen before a JAKi. Anti-TNF-α and anti-IL-17 are effective for both the axial and peripheral lesions of both nr-axSpA and AS and reduce (radiographically determined) disease progression. Anti-TNF-α is favoured if SpA is accompanied by either uveitis or inflammatory bowel disease (though etanercept should be avoided) and anti-IL-17 therapy favoured if SpA is associated with psoriasis. If treatment with one bDMARD fails, then a switch to the other bDMARD or a JAKi is recommended.

Local glucocorticoid injections can be useful for persistent plantar fasciitis, other enthesopathies and peripheral arthritis. Oral glucocorticoids may be required for acute uveitis, but do not help spinal disease. Severe hip, knee or shoulder arthritis with secondary OA may require arthroplasty. In AS, spinal osteotomy, to correct stoop and make eyeline posture 'more normal', can make a significant difference to patients with severely ankylosed kyphotic spines.

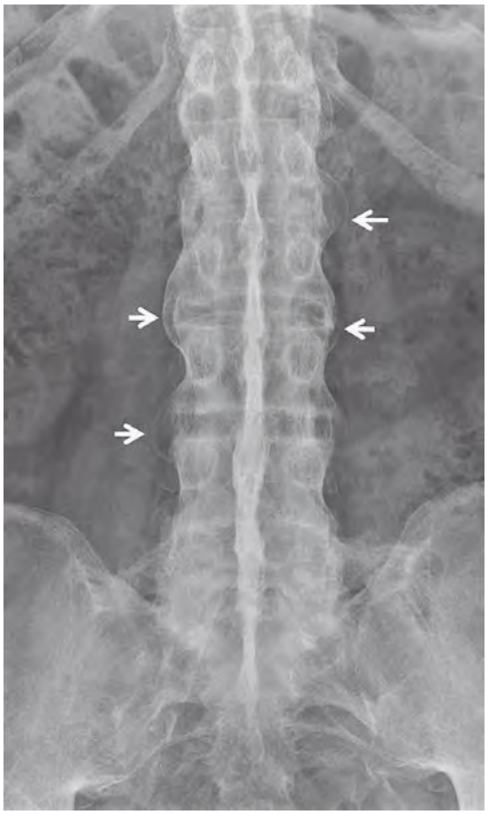

Fig. 25.40 'Bamboo' spine of advanced ankylosing spondylitis. Note the symmetrical marginal syndesmophytes (arrows), sacroiliac joint fusion and generalised osteopenia.

Prognosis

The markers of prognosis in patients diagnosed with nr-axSpA are not fully understood. AxSpA can remain mild and/or episodic in many patients for many years, but persistently high inflammatory markers and functional incapacity are indicators of a poor outcome. Nonetheless, over 75% of patients are able to remain in employment and enjoy a good quality of life. Even if severe ankylosis develops, functional limitation may not be marked if the spine fuses in an erect posture.

Reactive arthritis

Reactive (spondylo)arthritis (ReA) is a 'reaction' to a number of bacterial triggers with clinical features in keeping with all SpA conditions. The known triggers are *Chlamydia*, *Campylobacter*, *Salmonella*, *Shigella* and *Yersinia*. Notably, non-SpA-related reactive arthritis can occur following infection with many viruses, *Mycoplasma*, *Borrelia*, streptococci and mycobacteria, including *M. leprae*, which causes leprosy (Hansen disease); however, the 'reaction' in these instances consists typically of myoarthralgias, is not associated with HLA-B27 and is generally not chronic. Arthritis associated with rheumatic fever is also an example of a reactive arthritis that is not associated with HLA-B27.

Sexually acquired reactive arthritis (SARA) is predominantly a disease of young men, with a male preponderance of 15:1. This may reflect a difficulty in diagnosing the condition in young women, in whom *Chlamydia* infection is often asymptomatic and hard to detect in practical terms. Between 1% and 2% of patients with non-specific urethritis seen at genitourinary medicine clinics have SARA. The syndrome of chlamydial urethritis, conjunctivitis and reactive arthritis was formerly known as Reiter disease.

With enteric triggering infections (enteropathic ReA), HLA-B27 may predict the arthritic reaction and its severity, though the condition occurs in HLA-B27-negative people. The incidence of specific triggering infections causing ReA around the world varies, depending on the epidemiology of the infection and prevalence of HLA-B27 in the local population.

Clinical features

The onset is typically acute, with an inflammatory enthesitis, oligoarthritis, sacroiliitis and/or spinal inflammation. Lower limb joints and entheses are predominantly affected. In all types of ReA, there may be considerable systemic disturbance, with fever and weight loss. Achilles insertional enthesitis/tendinitis or plantar fasciitis may also be present. The first attack of arthritis is usually self-limiting, but recurrent or chronic arthritis can develop and about 10% of patients will still have active disease 20 years after the initial presentation. Low back pain and stiffness due to enthesitis and osteitis are common and 15%–20% of patients develop sacroiliitis. Many extra-articular features in ReA involve the skin, especially in SARA:

- circinate balanitis, which starts as vesicles on the coronal margin of the prepuce and glans penis, later rupturing to form superficial erosions with minimal surrounding erythema, some coalescing to give a circular pattern
- keratoderma blennorrhagica, which begins as discrete waxy, yellow–brown vesico-papules with desquamating margins, occasionally coalescing to form large crusty plaques on the palms and soles of the feet
- pustular psoriasis
- nail dystrophy with subungual hyperkeratosis
- mouth ulcers
- conjunctivitis
- uveitis, which is rare with the first attack, but arises in 30% of patients with recurring or chronic arthritis.

Other complications in ReA are very rare but include aortic incompetence, conduction defects, pleuro-pericarditis, peripheral neuropathy, seizures and meningoencephalitis.

Investigations

The diagnosis is usually made clinically, but joint aspiration may be required to exclude crystal arthritis and articular infection. ESR and CRP are raised. High vaginal swabs may reveal *Chlamydia* on culture. Except for post-*Salmonella* arthritis, stool cultures are usually negative by the time the arthritis presents, but serology may help confirm previous dysentery. RF, ACPA and ANA are negative.

In chronic or recurrent disease, X-rays show periarticular osteoporosis; proliferative erosions, notably at entheses; periostitis, especially of metatarsals, phalanges and pelvis; and large, 'fluffy' calcaneal spurs. In contrast to AS, radiographic sacroiliitis is often asymmetrical and sometimes unilateral, and syndesmophytes are predominantly coarse and asymmetrical, often extending beyond the contours of the annulus ('non-marginal') (see Fig. 25.39). Radiographic changes in the peripheral joints and spine are identical to those seen in psoriasis.

Management

Acute ReA should be treated with rest, NSAIDs and analgesics. Intra-articular or systemic glucocorticoids may be required in patients with severe monoarticular synovitis or polyarticular disease, respectively. There is no convincing evidence for the use of antibiotics unless a triggering infection is identified. If chlamydial urethritis is diagnosed, it should be treated empirically with a short course of doxycycline or a single dose of azithromycin. Treatment with csDMARDs (usually SSZ or MTX) should be considered for patients with persistent marked symptoms, recurrent arthritis or severe keratoderma blennorrhagica. Anterior uveitis is a medical emergency requiring topical, subconjunctival or systemic glucocorticoids. For csDMARD-recalcitrant cases, anti-TNF-α therapy should be considered.

Psoriatic arthritis

Based on data from the UK and Denmark, the estimated population prevalence of psoriatic arthritis (PsA) from registry and coding data is approximately 0.2%. It is likely the true prevalence is considerably higher, but this has not been extensively studied. The prevalence of PsA in psoriasis patients varies widely between different studies but has been estimated to be about 20%. Early PsA may present as axSpA. The onset is usually between 25 and 40 years of age, but juvenile forms exist. Occasionally, PsA and psoriasis develop synchronously, but the onset of musculoskeletal and skin disease is frequently separated by many years. Classification of PsA requires key assessments of family history and screening for enthesitis (Box 25.61).

Pathophysiology

Genetic factors have an important role in PsA and family studies have suggested that heritability is about 30%. Variants in the *HLA-B* and *HLA-C* genes are the strongest genetic risk factors, but multiple other variants also play a part. Carriage of the HLA-B27 allele in those with PsA of European descent is about 20% as compared with the background rate of 9%. Many of these variants overlap with those implicated in psoriasis, where there are (currently known) about 80 susceptibility loci. These lie within or close to genes in the IL-12, IL-23 and nuclear factor kappa B (NFκB) signalling pathways. It is thought that lifestyle and environmental factors such as alterations in the microbiome, infections, obesity and mechanical loading trigger disease in genetically susceptible individuals, leading

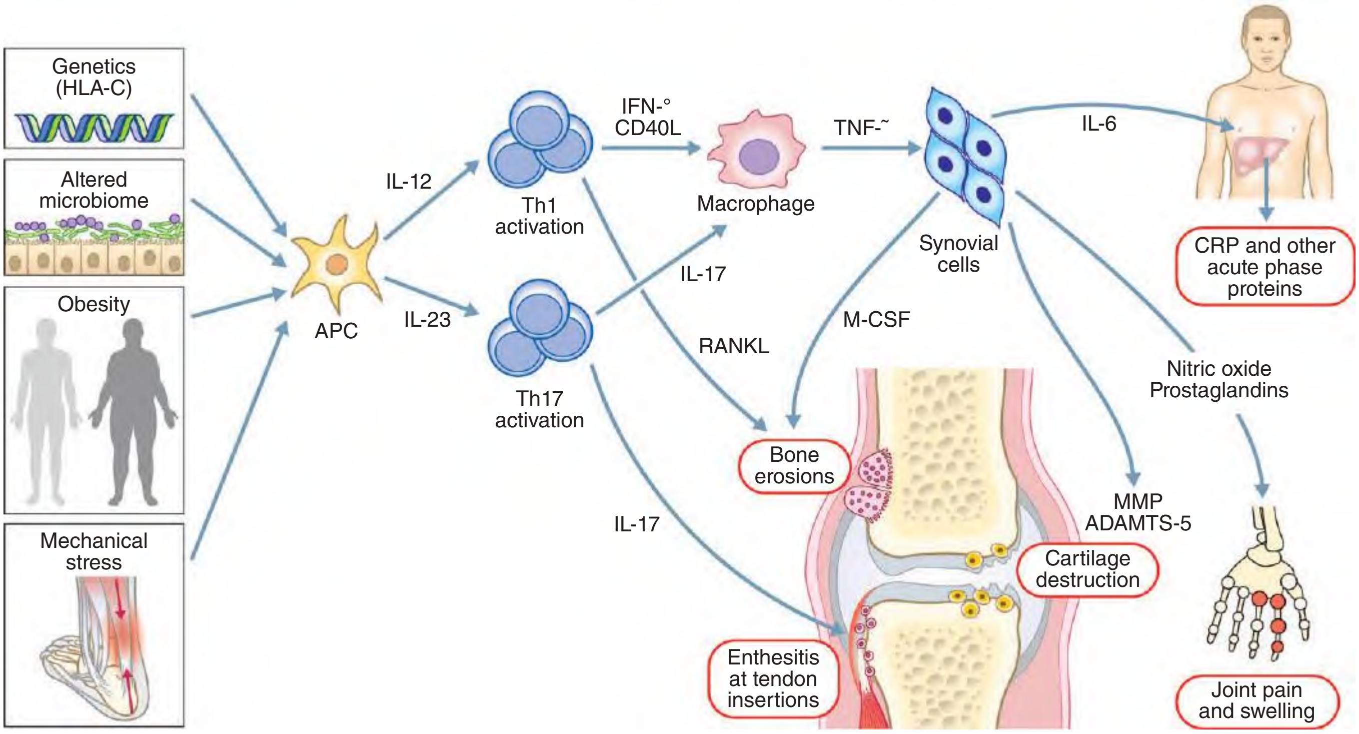
25.61 The Classification Criteria for Psoriatic Arthritis (CASPAR)

Inflammatory articular disease (joint, spine or enthesis) with ≥ 3 points from the following (1 point each unless stated):

- Current psoriasis (scores 2 points)
- History of psoriasis in first- or second-degree relative
- Psoriatic nail dystrophy
- Negative IgM rheumatoid factor[1]
- Current dactylitis
- History of dactylitis
- Juxta-articular new bone[2]

[1] Established by any method except latex.

[2] Ill-defined ossification near joint margins (excluding osteophytes) on X-rays of hands or feet.



Genetics (HLA-C)
Altered microbiome
Obesity
Mechanical stress
APC
IL-12
IL-23
Th1 activation
Th17 activation
IFN-°
CD40L
Macrophage
TNF-˜
Synovial cells
IL-6
CRP and other acute phase proteins
IL-17
RANKL
M-CSF
Bone erosions
IL-17
Nitric oxide
Prostaglandins
MMP
ADAMTS-5
Cartilage destruction
Enthesitis at tendon insertions
Joint pain and swelling

Fig. 25.41 Pathogenesis of psoriatic arthritis. As in the case of axSpA, the IL-23/IL-17 axis is thought to play a key role in PsA. Some of the cytokines and cellular interactions important in psoriatic arthritis are also shown. (ADAMTS-5 = aggrecanase; APC = antigen-presenting cell; CD40L = CD40 ligand; IFN = interferon; IL = interleukin; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; RANKL = receptor activator of nuclear factor kappa B ligand; TNF = tumour necrosis factor)

to immune activation involving dendritic cells and T cells (Fig. 25.41). $CD8^+$ T cells (which recognise antigen presented in the context of HLA class I) are more abundant than $CD4^+$ T cells within the joint, which is in keeping with the genetic association between PsA and HLA-C and -B variants. There is increasing evidence that the IL-23/IL-17 pathway plays a pivotal role in PsA. It is thought that the triggering stimulus causes over-production of IL-23 by dendritic cells, which in turn promotes differentiation and activation of Th17 cells that produce the pro-inflammatory cytokine IL-17. This and Th1 cytokines like IFN-γ and TNF-α act on macrophages and tissue-resident stromal cells at entheses, in bone and within the joint to produce additional pro-inflammatory cytokines and other mediators, which contribute to inflammation and tissue damage, as shown in Figure 25.41.

Clinical features

The presentation is with pain and stiffness affecting joints, tendons, spine and entheses. Joints are typically not swollen; however, several patterns of joint involvement are recognised (see below), including an oligoarticular form. These patterns are not mutually exclusive. Marked variation in disease patterns exists, including a disease course of intermittent exacerbation and remission. Destructive arthritis and disability are uncommon, except in the case of arthritis mutilans.

Asymmetrical inflammatory mono-/oligoarthritis
